ABSTRACT

In this work, decomposition behaviors of cellulose, xylan (representative hemicellulose subtype), and lignin have been compared using thermogravimetric analysis (TGA) and differential thermogravimetry (DTG). The TGA data were also used to perform kinetic analysis using non-isothermal isoconversional methodology (Friedman’s method). The values of average activation energy of decomposition of cellulose, xylan, and lignin were calculated as 137.80 kJ/mol, 202.74 kJ/mol, and 151.55 kJ/mol respectively. The pre-exponential factor was calculated via Kissinger’s equation. The thermodynamic significance of kinetic analysis has also been extended here. This study can help in understanding the heterogeneity in the pyrolysis behavior of the whole biomass by elucidating the decomposition properties of the individual components.

1. Introduction

Biomass is being extensively studied worldwide for bio-fuel generation via pyrolysis. Study of decomposition behavior and the associated kinetics is essential for process optimization and scale-up. However, biomass decomposition is challenging to generalize because of its heterogeneous nature. Different biomass types comprise varying ratios of three key components: cellulose, hemicellulose, and lignin. Cellulose is a linear chain polysaccharide of repeating D-glucose (a six-carbon ring, also known as pyranose) units linked to each other by acetyl bonds (-O-, β (1→4) glycoside linkage). Hemicelluloses are heteropolysaccharides of different monomers such as glucose, galactose, mannose, xylose, arabinose, and glucuronic acid. These monomers are present in the form of polysaccharides such as xylan, gluconoxylan, arabinoxylan, glucomannan, and xylglucan (Dhyani and Bhaskar, 2019, 2018a). Lignin is a high molecular weight polymer, which may constitute as much as 20-35% of the organic matrix of wood and other vascular plants (Wang et al., 2017). It is a three-dimensional highly branched polymer, made up of phenylpropane units attached by alkyl-aryl ether bonds. Hemicelluloses and lignin cover the cellulose microfibrils (Hergert, 1971; Kawamoto, 2017; Patwardhan et al., 2011).

The heterogeneity in the biomass properties arises because of different decomposition temperature regimes and varying decomposition rates of each component (Dhyani et al., 2017; Yang et al., 2007). Although much work has already been done in understanding the chemical nature of the biomass components, relatively less work has been performed on decomposition kinetics of the individual biomass components (Miller and Bellan, 1997; Yeo et al., 2017).

In this work, the decomposition of biomass components was studied using thermogravimetric analysis (TGA). The activation energy ($E_a$) of decomposition of biomass components was estimated using Friedman’s method. The values of average activation energy of decomposition of cellulose, xylan, and lignin were calculated as 137.80 kJ/mol, 202.74 kJ/mol, and 151.55 kJ/mol respectively. The pre-exponential factor was calculated via Kissinger’s equation. The reaction models were predicted using the combined kinetic method. The values of activation energy were also used for calculating the thermodynamic parameters, enthalpy entropy, and Gibbs free energy (Awasthi et al., 2019).

This study can help in shedding light on the complex behavior of biomass pyrolysis and understanding the convolution of the contribution of the individual components on the whole biomass.

2. Materials and methods

2.1. Feedstock

Cellulose, xylan from beechwood (representative polysaccharide for hemicellulose), and Kraft lignin were obtained from Sigma-Aldrich. The proximate analysis of the individual biomass components on a moisture-free basis is given in Table 1.
Several reaction models for the solid-state have been developed and tested. These models have either been developed based on the assumption of the reaction mechanism by empirical fitting with little physical meaning. A survey of different reaction models for solid-state kinetics is provided by Dhyani and Bhaskar (2018).

2.2. Thermogravimetric analysis

The thermogravimetric analysis (TGA) was performed in a DTG-60 unit (Shimadzu, Japan). The weight-loss profiles obtained from TGA runs were used for proximate and kinetic analysis. Moisture, ash, and volatile matter were obtained via the ASTM standards, E871 (drying for 30 min at 105 ± 1°C in), E1755 (oxidation at 575 ± 25°C), and E872 (rapid de-volatilization at 950°C). The fixed carbon content was calculated by difference:

\[
\% \text{Fixed Carbon} = 100 - (\% \text{Moisture} + \% \text{Volatile Matter} + \% \text{Ash})
\]  

(1)

2.3. Kinetic analysis

The rate of progression in terms of ‘conversion’ with Arrhenius expansion can be stated as:

\[
\frac{d\alpha}{dt}_i = A_i e^{-\frac{E_i}{RT_i}} f(\alpha)
\]  

(2)

\[
\alpha = \frac{m_{\text{initial}} - m_t}{m_{\text{initial}} - m_{\text{final}}}
\]  

(3)

where, \(m_{\text{initial}}, m_{\text{final}}\) and \(m_t\) are initial weight, final weight, and weight at any time ‘\(t\)’ during the thermal decomposition.

\[
\frac{d\alpha}{dt}_i
\]

in equation (2) is the instantaneous time derivative of \(\alpha\) obtained from equation (3).

The kinetic analysis of individual biomass components, cellulose, xylan, and lignin was performed using the non-isothermal isovolcanosynthesis method. These methods can be considered superior to conventional model-fitting methods as they yield the value of activation energy without assuming any reaction model in advance (Dhyani and Bhaskar, 2018b).

Friedman’s method, which is a differential isovolcanosynthesis method, was used for the calculation of activation energy (Friedman, 1964). The working equation for Friedman’s method can be given as,

\[
\ln \left( \frac{d\alpha}{dt}_i \right)_j = \ln[f(\alpha)A_i] - \frac{E_i}{RT_i}
\]  

(4)

In the above equation, \(i\) denotes different temperature programs at which the non-isothermal TGA runs are being conducted, \(\ln (d\alpha/dt)_j\) denotes the set of \(d\alpha/dt\) values at a fixed value of conversion at different heating rates and similarly, \(T_m\) is the temperature at which ‘\(i\)’ conversion has taken place at different heating rates. For a fixed value of conversion, the term \(\ln [f(\alpha)_i A_i]\) is constant. Thus, for each value of \(\alpha\) the plot of \(\ln (d\alpha/dt)_j\) vs. \((1/T_m)\) should give a straight line with slope equal to \((-E_i/R)\).

The non-isothermal TGA data from six different heating rates (5, 10, 15, 20, 30, and 40°C/min) was used for the calculation of slope in equation (4).

\[
A_i = \beta E_a \exp \left( \frac{E_a}{RT_m} \right)
\]  

(5)

where \(\beta\) is the heating rate and \(T_m\) is the temperature at the maximum conversion rate.

Reaction models describe the quantitative relationship between conversion rate and extent of conversion. They are a mathematical translation of the reaction progression mechanism.

2.4. Thermodynamic analysis

Thermodynamic parameters, enthalpy (\(\Delta H\)), Gibbs free energy (\(\Delta G\)), and entropy (\(\Delta S\)) were calculated using equations (8) to (10).

\[
\Delta H = E - RT\alpha
\]  

(8)

\[
\Delta G = E + R.T_m\ln(K_B.T_m^\alpha)
\]  

(9)

\[
\Delta S = \frac{\Delta H - \Delta G}{T_m}
\]  

(10)

In equation (9) \(h\) is the Planck constant \((6.62607004 \times 10^{-34} \text{ m}^2 \text{ kg/ s})\) and \(K_B\) is the Boltzmann constant \((1.38064852 \times 10^{-23} \text{ m}^2 \text{ kg/ K})\).

3. Results and discussion

3.1. Thermogravimetric analysis

The thermal decomposition profiles of cellulose, xylan, and lignin at heating rates of 5, 10, 15, 20, 30, and 40°C/min are shown in Figure 1. A lateral shift in the TGA and DTG profiles can be observed with increasing heating rates, which can be attributed to the discrepancy in heat flow rate inside the biomass particles with variation in the heating program. It can be observed that the decomposition of cellulose is mainly confined in the temperature range of 300 to 350°C (Figure 1(a) & (b)), xylan decomposed predominantly between 250 to 300°C (Figure 1(c) & (d)), and lignin demonstrated a broad range of decomposition extending from 200 to 700°C (Figure 1(e) & (f)). Although for each heating program, the percent residual solid showed some variation, the mean residual solid at 700°C for cellulose, xylan, and lignin were 11%, 29%, and 35% respectively.

The values of conversion obtained from the heating program of 10°C/ min normalized between 0 to 1 (\(\alpha_{\text{cellulose}} = 0\) and \(\alpha_{\text{xylan}} = 1\)) are shown in Figure 2(a). It can be observed that cellulose decomposition reached the conversion value of 0.9 at 375°C, while xylan and lignin reached the same conversion values at 465°C and 530°C respectively. The peak value of the rate of conversion for cellulose was significantly higher than the xylan and lignin (Figure 2(b)). If the interaction between the biomass components is ignored the DTG profile of any whole biomass can be constructed by knowing the composition of biomass components. To illustrate this, a DTG profile of pseudo biomass comprising of an equal percentage of cellulose, xylan, and lignin is also shown in Figure 2(b).

3.2. Results of the kinetic analysis

The comparison of activation energy (\(E_a\)) calculated using Friedman’s equation for the three component was made between the conversion (\(\alpha\)) values of 0.2 to 0.8 (Figure 3(a)). It was observed that cellulose demonstrated a decreasing \(E_a\) vs. \(\alpha\) dependency (\((E_a)_{\text{average}} = 137.80 \text{ kJ/ mol}\), indicating an irreversible-endothermic decomposition. Decomposition of xylan (\((E_a)_{\text{xylan}} = 202.74 \text{ kJ/ mol}\) showed a trend close to cellulose decomposition till \(\alpha = 0.65\), followed by a sudden increase in \(E_a\). An increasing \(E_a\) vs. \(\alpha\) dependency (\((E_a)_{\text{average}} = 151.55 \text{ kJ/ mol}\) throughout the decomposition range was observed for lignin, which is an indication of parallel and competing reactions.

The values of \((E_a)\) obtained from Kissinger’s equation follow a trend similar to \(E_a\). The \((E_a)\) vs. \(\alpha\) plot obtained at the heating rate of 10°C/
The $f(\alpha)$ vs. $\alpha$ profile obtained by substituting the values of $E_\alpha$ and $A_\alpha$ in TGA data is shown in Figure 3(c), while the results of non-linear curve fitting (equation 7) on the experimental data are shown in Figure 4. The values of the parameters $c$, $n$, and $m$ for cellulose, xylan, and lignin are mentioned in Table 2.

**Table 2.** Results of fitting of experimental data to $f(\alpha) = c (\alpha)^n (1 - \alpha)^m$

| Component | $c$ | $n$ | $m$ | Adj. R-Square |
|-----------|-----|-----|-----|---------------|
| Value     | Std. error | Value | Std. error | Value | Std. error |
| Cellulose | 48.370 | 13.679 | 9.234 | 0.156 | 17.364 | 0.284 | 0.999 |
| Xylan     | $9.021 \times 10^7$ | $1.296 \times 10^8$ | 10.590 | 0.835 | 17.601 | 1.361 | 0.994 |
| Lignin    | $9.513 \times 10^4$ | $3.201 \times 10^5$ | -6.181 | 1.666 | -2.899 | 3.588 | 0.990 |

min is shown in Figure 3(b). It can be observed that $\ln(A_\alpha)$ values increase rapidly as the conversion increases. This can be attributed to an increase in the collisions in the reaction system at higher conversion values, which is dependent on temperature in the present study. Although $\ln(A_\alpha)$ is an indirect measure of reactivity of the system, a quantification of the reactivity can only be made by evaluation of changes in the entropy of the system against conversion.
3.1. Results of thermodynamic analysis

A comparison of $\Delta H_\alpha$, $\Delta G_\alpha$, and $\Delta S_\alpha$ vs. $\alpha$ for each biomass component at the heating rate of 10°C/min has been shown in Figure 5. The $\Delta H_\alpha$ (Figure 5(a)) profiles for all the biomass components is highest near $\alpha = 0.8$, indicating that the decomposition process is more endothermic near the completion of the reaction. The $\Delta G_\alpha$ vs. $\alpha$ (Figure 5(b)) curves don’t show any considerable variation with conversion, which indicates that the available energy of the reactants stays almost constant during the pyrolysis reaction (Kaur et al., 2018). $\Delta G_\alpha$ values are highest for lignin, followed by cellulose and xylan. The variations in entropy of the system comply with the changes in enthalpy confirming that the reaction systems are most reactive near the completion (Figure 5(c)).

4. Conclusions

Biomass is composed of three principal components, cellulose, hemicellulose, and lignin. The overall decomposition properties of the biomass are results of convolution of decomposition profiles of individual components. In this work, the decomposition behavior of cellulose, xylan, and lignin was studied using TGA/DTG. The TGA results were also used for calculation of kinetic parameters and thermodynamic properties. Most of the cellulose decomposition took place from 300 to 350°C with 137.80 kJ/mol. Xylan decomposition showed a peak between 250 and 300°C with an 202.74 kJ/mol. The decomposition of lignin took place over a broad temperature range from 200 to 700°C with an 151.55 kJ/mol. All the components showed an increase in endothermicity with reaction progression.
