Nonlinear Fokker-Planck equations endowed with curl drift forces are investigated. The conditions under which these evolution equations admit stationary solutions, which are $q$-exponentials of an appropriate potential function, are determined. It is proved that when these stationary solutions exist, the nonlinear Fokker-Planck equations satisfy an $H$-theorem in terms of a free-energy like quantity involving the $S_q$ entropy. A particular two dimensional model admitting analytical, time-dependent, $q$-Gaussian solutions is discussed in detail. This model describes a system of particles with short-range interactions, performing overdamped motion under drag effects due to a rotating resisting medium. It is related to models that have been recently applied to the study of type-II superconductors. The relevance of the present developments to the study of complex systems in physics, astronomy, and biology, is discussed.

I. INTRODUCTION

The nonlinear Fokker-Planck equation \cite{1} constitutes a powerful tool for the study of diverse phenomena in complex systems \cite{2–8}, with applications including (among many others) type-II superconductors \cite{9}, granular media \cite{10}, and self-gravitating systems \cite{11, 12}. It governs the behavior of a time-dependent density $F(x, t)$, where $x \in \mathbb{R}^N$ designates a location in an $N$-dimensional configuration space. The evolution of $F$ is determined by two terms: a nonlinear diffusion \cite{13, 14} term and a linear drift term (more general equations with nonlinear drift terms have also been proposed, but we are not going to consider them in the present work). In several of the above mentioned applications, the density $F$ is a real physical density (as opposed to a statistical ensemble probability density) describing the evolving distribution of a set of interacting particles executing overdamped motion, in the relevant configuration space \cite{8, 15}. In these kind of scenarios, the nonlinear diffusion term constitutes an effective description of the interaction between the particles, while the drift term describes the effects of other external forces acting upon them. The nonlinear Fokker-Planck equations recently addressed in the literature exhibit several interesting and physically relevant properties. They obey an $H$-theorem in terms of a free-energy-like quantity \cite{16}. In some important cases, the nonlinear Fokker-Planck equations admit exact analytical solutions of the $q$-Gaussian form, that can be interpreted as maximum entropy ($q$-maxent) densities obtainable from the optimization under appropriate constraints, of the nonadditive power-law entropic functionals, $S_q$ \cite{17, 18}. Indeed, there is a deep connection between the nonlinear Fokker-Planck dynamics and the generalized thermostatistics based on the $S_q$ entropies. Although this connection was first pointed out more than twenty years ago \cite{19}, its full physical implications are being systematically explored only in recent years (see, for instance, \cite{2, 15, 20–22} and references therein). A remarkable example of this trend is given by experimental work on granular media published in 2015 \cite{10} that verifies, within a 2% error and for a wide experimental range, a scale relation predicted in 1996 on the basis of the theoretical analysis of $q$-Gaussian solutions of the nonlinear Fokker-Planck equation \cite{23}. The particular case of the nonlinear Fokker-Planck equation with vanishing drift corresponds to the porous media equation.

Virtually all the literature on the nonlinear Fokker-Planck equation and its applications deals with Fokker-Planck equations in which the drift forces $K$ can be derived from a
potential function $V(x)$, leading to stationary densities which are $q$-exponentials of the potential $V$. In the present contribution, we consider more general scenarios where the drift force $K$ has, besides a component given by minus the gradient of a potential $V$, a term $\tilde{K}$ that does not come from a potential. In two or three space dimensions, this situation corresponds to having forces exhibiting a non vanishing rotational or curl, which are usually referred to as curl forces [24]. The incorporation of curl forces enriches the dynamical features of the nonlinear Fokker-Planck equations, enabling it to describe a wider set of phenomena. Curl forces, although not dynamically fundamental [25], are nevertheless relevant as useful effective descriptions of diverse physical problems, as for example the nonconservative force fields generated by optical tweezers [26]. Dynamical systems with curl forces have interesting properties that are not yet fully understood and are the subject of current research [25, 27]. In the present work, we investigate the behavior of nonlinear Fokker-Planck equations under the presence of curl forces. We determine the conditions under which these evolution equations admit stationary solutions of the $q$-maxent form and satisfy an $H$-theorem. We also discuss in detail a two dimensional example admitting analytical time-dependent solutions, that describes a set of interacting particles undergoing overdamped motion, under the drag effect arising from a uniformly rotating medium.

II. THE NONLINEAR FOKKER-PLANCK EQUATION

In the present work, we shall consider nonlinear Fokker-Planck equations (NLFP) of the form

$$\frac{\partial F}{\partial t} = D \nabla^2 [F^{2-q}] - \nabla \cdot [FK], \quad (1)$$

where $F(x, t)$ is a time-dependent density, $D$ is a diffusion constant, $K(x)$ is a drift force, and $q$ is a real parameter characterizing the (power-law) nonlinearity appearing in the diffusion term. The density $F$ is a dimensionless quantity of the form $F = \rho(x, t)/\rho_0$, where $\rho$ has dimensions of inverse volume and $\rho_0$ is a constant with the same dimensions as $\rho$. Therefore, the dimensional density $\rho(x, t)$ obeys the evolution equation $\partial[\rho/\rho_0]/\partial t = D\nabla^2[(\rho/\rho_0)^{2-q}] - \nabla \cdot [(\rho/\rho_0)K]$. As already mentioned, in the most frequently studied case of Eq.(1), the drift force $K$ is assumed to arise from a potential function $V(x)$,

$$K = -\nabla V. \quad (2)$$
The stationary solutions of the NLFP then satisfy
\[
\nabla \left[ D \nabla \left( F^{2-q} \right) + F \nabla V \right] = 0.
\] (3)

Let us consider the \( q \)-statistical ansatz \[18\]
\[
F_q = A \exp_q[-\beta V(x)] \\
= A \left[ 1 - (1-q)\beta V(x) \right]^{\frac{1}{1-q}},
\] (4)

where \( A \) and \( \beta \) are constants to be determined, and the function \( \exp_q(z) = [1 + (1-q)z]^{\frac{1}{1-q}} \), usually referred to as the \( q \)-exponential function, vanishes whenever \( 1 + (1-q)z \leq 0 \). One finds that the ansatz given by Eq.(4) complies with the equation
\[
D \nabla \left( F^{2-q} \right) + F \nabla V = 0,
\] (5)

if
\[
(2-q)\beta D = A^{q-1}.
\] (6)

It therefore satisfies also equation (3) and constitutes a stationary solution of the NLFP equation. In summary, the \( q \)-exponential ansatz \[11\] is a stationary solution of the NLFP equation, if the drift force \( K \) is derived from a potential and \( A \) and \( \beta \) satisfy the relation \[15\].

We shall assume that the stationary distribution \( F_q \) has a finite norm, that is, \( \int F_q d^N x = I < \infty \). The specific conditions required for \( F_q \) to have a finite norm (such as the allowed range of \( q \)-values) cannot be stated in general, because they depend on the particular form of the potential function \( V(x) \). Since in many applications the solution of the NLFP equation is interpreted as a physical density (as opposed to a probability density) we assume finite norm, but not necessarily normalization to unity. The stationary density \( F_q \) can be regarded as a \( q \)-maxent distribution, because it maximizes the nonextensive \( q \)-entropic functional \( S_q \) under the constraints corresponding to the norm and the mean value of the potential \( V \) \[18, 19\].

In the limit \( q \to 1 \), the standard linear Fokker-Planck equation,
\[
\frac{\partial F}{\partial t} = D \nabla^2 F - \nabla \cdot [F K],
\] (7)
is recovered. In this limit, the \( q \)-maxent stationary density \[4\] reduces to the exponential, Boltzmann-Gibbs-like density,
\[
F_{BG} = \frac{1}{Z} \exp[-\frac{1}{D} V(x)],
\] (8)
with the condition \([6] \) becoming \( \beta D = 1 \), independent of the normalization constant \( A \).

The density \( F_{BG} \) is normalized to one provided that \( Z = \int \exp[\frac{-1}{\beta}V(x)]dx \). The density \( F_{BG} \) optimizes the Boltzmann-Gibbs entropy \( S_{BG} = -\int F \ln F dx \), under the constraints of normalization and the mean value \( \langle V \rangle \) of the potential \( V \).

Note that a dynamical system with a phase space flux of the form \([2] \) (that is, of a gradient form) evolves always \textit{down-hill} on the potential energy landscape, so as to minimize the potential energy function \( V(x) \). The components \( \{K_i, \ i = 1, \ldots, N\} \) of such a field satisfy

\[
\frac{\partial K_i}{\partial x_j} = \frac{\partial K_j}{\partial x_i} = \frac{\partial^2 V}{\partial x_i \partial x_j},
\]

which in two or three dimensions leads to \( K \neq -\nabla V \iff \nabla \times K \neq 0 \).

III. NONLINEAR FOKKER-PLANCK EQUATION WITH CURL DRIFT FORCES: STATIONARY SOLUTIONS

Now we consider NLFP equations endowed with drift forces having two terms, one exhibiting the gradient form and the other one not arising from the gradient of a potential. That is, we consider drift fields of the form

\[
K = G + \tilde{K},
\]

where the force \( G \) is equal to minus the gradient of some potential function \( V(x) \), while the component \( \tilde{K} \) does not come from a potential (that is, \( \partial \tilde{K}_i/\partial x_j \neq \partial \tilde{K}_j/\partial x_i \)). Our aim is to determine under which conditions a density proportional to the \( q \)-exponential of the potential \( V \) still provides a stationary solution of the NLFP equation, preserving thus the link between this equation and the generalized nonextensive thermostatistics. Substituting the above drift force \( K \) and \( q \)-exponential density \( F_q \) \([3] \) into the stationary NLFP equation \([3] \), one obtains

\[
D \nabla^2 [F_q^{2-q}] + \nabla \cdot [F_q (\nabla V)] - \nabla [F_q \tilde{K}] = 0.
\]

It can be verified that, if \( A \) and \( \beta \) satisfy \([6] \), the sum of the first two terms in the above equation vanish, since \( F_q \) is a stationary solution of the NLFP equation \([3] \), when the drift field \( K \) consists solely of the gradient field \( G \). In order for \( F_q \) to comply also with the full NLFP equation \([11] \), including the drift contribution associated with the non-gradient field \( \tilde{K} \), it is then necessary that

\[
\nabla [F_q \tilde{K}] = 0.
\]
If the above relation is satisfied, the density $F_q$ constitutes a stationary solution of the full NLFP equation, corresponding to the complete drift force $\mathbf{K} = - (\nabla V) + \tilde{\mathbf{K}}$. To have the $q$-maxent stationary solution, one therefore requires

$$\nabla \left( \tilde{\mathbf{K}} \mathbf{A} [1 - (1 - q) \beta V]^{\frac{1}{1 - q}} \right) = 0,$$

which in turn leads to the following relation between the non-gradient drift component $\tilde{\mathbf{K}}$ and the potential function $V(x)$

$$[1 - (1 - q) \beta V] (\nabla \cdot \tilde{\mathbf{K}}) - \beta (\tilde{\mathbf{K}} \cdot \nabla V) = 0.$$  \hspace{1cm} (14)

This is a consistency relation that the potential function $V$, the non-gradient force field $\tilde{\mathbf{K}}$, the Lagrange multiplier $\beta$, and the entropic parameter $q$ have to satisfy, in order that the nonlinear Fokker-Planck equation admits the $q$-maxent stationary solution (4). The general $\beta$-dependent equation (14) constitutes a rather complicated relation between the non-gradient field $\tilde{\mathbf{K}}$ and the potential function $V$, which is difficult to characterize. Moreover, this relation depends explicitly on the value of $\beta$. This means that for given forms of $\tilde{\mathbf{K}}(x)$ and $V(x)$, one may have stationary solutions of the $q$-maxent form (4), only for particular values of $\beta$.

It follows from the relation (14) that, in order for the NLFP equation to admit the $\beta$-parameterized family of stationary solutions (4), with a continuous allowed range of $\beta$-values, two conditions have to be fulfilled. On the one hand, the non-gradient component of the drift, $\tilde{\mathbf{K}}$, has to be a divergenceless vector field,

$$\nabla \cdot \tilde{\mathbf{K}} = 0.$$  \hspace{1cm} (15)

On the other hand, $\tilde{\mathbf{K}}$ has to be everywhere orthogonal to the gradient of the potential,

$$\tilde{\mathbf{K}} \cdot (\nabla V) = 0.$$  \hspace{1cm} (16)

Notice that conditions (15) and (16) are not only sufficient, but also necessary conditions for the ansatz (4) to be a stationary solution of the NLFP equation (1), for a continuous range of $\beta$-values. Indeed, if (4) solves (1) for such a set of $\beta$-values, the left hand side of (14), which is an inhomogeneous linear function of $\beta$, has to vanish for an interval of values of $\beta$. This clearly implies that both the independent term, and the coefficient of the $\beta$-linear term, have to vanish individually, leading in turn to conditions (15) and (16). It
is interesting that these conditions do not explicitly depend on the value of the $q$-parameter, constituting a $q$-invariant structure. The stationary solution guaranteed by these conditions is a physical solution when it is normalizable (otherwise, it is not physical, although still formally a solution of the NLFP equation). The normalizability of the stationary solution depends on the particular shape of the potential $V$ and on the value of $q$ and, as already mentioned, can only be studied in a case by case way.

In two or three space dimensions, the decomposition $K = G + \tilde{K}$, with $G = -\nabla V$ and $\nabla \cdot \tilde{K} = 0$, resembles the decomposition of a vector field into a curlless (irrotational) component and a solenoidal (divergenceless) component arising from the celebrated Helmholtz theorem \[28\]. We are not, however, imposing the boundary conditions on the fields $K$, $G$, and $\tilde{K}$, that are usually considered in connection with the Helmholtz decomposition. Furthermore, we require the point to point orthogonality of the irrotational and the divergenceless components of $K$, which is not a condition usually considered in connection with the Helmholtz decomposition.

It is interesting that the Helmholtz-like decomposition (10), with orthogonal irrotational and divergenceless parts, $G \cdot \tilde{K} = 0$, arises naturally in some circumstances. For instance, the most general rotationally invariant vector field in two dimensions has precisely this form. Indeed, such vector fields are of the form

\[
G = -g(r)e_r, \\
\tilde{K} = l(r)e_\theta,
\]

where $g(r)$ and $l(r)$ are functions of the radial coordinate $r = (x^2 + y^2)^{1/2}$ and $e_r$ and $e_\theta$ respectively denote the radial and tangential unit vectors. It is clear that the field $G$ in (17) is of the form $-\nabla V(r)$ with $V(r) = \int^r g(r')dr'$, and that the field $\tilde{K}$ satisfies $\nabla \cdot \tilde{K} = 0$ and $G \cdot \tilde{K} = 0$.

Summing up, we have thus determined that the NLFP equation (11) having a non-potential drift force of the form (10) admits, for a continuous range of values of the parameter $\beta$, the family of $q$-maxent stationary solutions (4) if and only if the relations (15) and (16) are satisfied.
IV. \textit{H}-THEOREM

We are now going to explore the possibility of formulating an \textit{H}-theorem for the nonlinear Fokker-Planck equations, endowed with a drift term involving a non-vanishing-curl force $\tilde{K}$, not derivable from the potential function $V$. Let us first consider the time derivative of the power law entropic functional $S_{q^*}$, with $q^* = 2 - q$. This is a reasonable choice, because $q^*$ is precisely the exponent that appears inside the Laplacian term in the NLFP equation \cite{11}. The duality $q \to 2 - q$ appears frequently in the $q$-generalized thermostatistical formalism \cite{18}. We have,

\[
\frac{dS_{q^*}}{dt} = \frac{q^*}{1 - q^*} \int F^{q^*-1} \frac{\partial F}{\partial t} d^N x - \int F^{2q^*-3} |\nabla F|^2 d^N x \\
+ q \int F^{q^*-1} (\nabla F) \cdot (\nabla V) d^N x + \int F^{q^*} \left( \nabla \cdot \tilde{K} \right) d^N x . \tag{18}
\]

It is clear that the first term in the above expression is definite positive. However, the second term does not have a definite sign. Consequently, the time derivative of $S_{q^*}$ does not have a definite sign and the entropic form $S_{q^*}$ does not itself verify an \textit{H}-theorem. The last two terms in the expression for $\frac{dS_{q^*}}{dt}$, describing the contribution of the drift term to the change in the entropy, suggest that a linear combination of $S_{q^*}$ and of the mean value of the potential function $V$ may comply with an \textit{H}-theorem. The time derivative of $\langle V \rangle = \int F V d^N x$ is

\[
\frac{d\langle V \rangle}{dt} = \int V \frac{\partial F}{\partial t} d^N x \\
= -q^* D \int F^{q^*-1} (\nabla F) \cdot (\nabla V) d^N x - \int F |\nabla V|^2 d^N x + \int F (\nabla V) \cdot \tilde{K} d^N x . \tag{19}
\]

Combining now equations (18) and (19) one obtains, after some algebra,

\[
\frac{d}{dt} (DS_{q^*} - \langle V \rangle) = \int F \left| q^* D F^{q^*-2} (\nabla F) + \nabla V \right|^2 d^N x \\
+ \int F^{q^*} \left( \nabla \cdot \tilde{K} \right) d^N x + \int F (\nabla V) \cdot \tilde{K} d^N x . \tag{20}
\]

If the curl component $\tilde{K}$ of the drift force complies with the requirements given by equations (15) and (16), which are necessary and sufficient for the nonlinear Fokker-Planck equation to have the family of $q$-maxent stationary solutions \cite{11}, it follows from (20) that the nonlinear Fokker-Planck equations satisfies the \textit{H}-theorem,

\[
\frac{d}{dt} (DS_{q^*} - \langle V \rangle) = \int F \left| q^* D F^{q^*-2} (\nabla F) + \nabla V \right|^2 d^N x \\
= \left\langle \left| q^* D F^{q^*-2} (\nabla F) + \nabla V \right|^2 \right\rangle \geq 0 . \tag{21}
\]
It is worth stressing that the conditions (15) and (16) for having stationary $q$-maxent solutions are essentially the same as those for having an $H$-theorem.

There is an interesting consequence of the $H$-theorem, in relation with the uniqueness of the decomposition (10) of the total drift force $K$ into a gradient component $G = -\nabla V$ and an (orthogonal) divergenceless component $\tilde{K}$. Let us assume that that total drift force can be decomposed in this fashion in two different ways, $K = -\nabla V_1 + \tilde{K}_1 = -\nabla V_2 + \tilde{K}_2$. If the nonlinear Fokker-Planck equation admits a stationary solution (of finite norm) $F_{st}$, it follows from the $H$-theorem (21) that

$$\nabla V_1 = \nabla V_2 = -q^* D F_{st}^{q^* - 2} (\nabla F_{st}) ,$$

which, in turn, implies also that $\tilde{K}_1 = \tilde{K}_2$. Consequently, if the nonlinear Fokker-Planck equation admits a stationary solution, the decomposition of the total drift force into the sum of a gradient term and a divergenceless term is unique.

V. QUADRATIC POTENTIAL AND LINEAR DRIFT

We now consider in detail the case of a quadratic potential $V$ and a linear drift $\tilde{K}$. We shall see that in this case the conditions (15) and (16) are required even for having a stationary solution of the $q$-exponential form (4) for one, single value of the parameter $\beta$. We assume and potential and a drift field respectively of the forms,

$$V(x) = \sum_{ij}(a_{ij}x_ix_j) + \sum_i(b_ix_i) ,$$

$$\tilde{K}(x) = \sum_j(c_{ij}x_j) + d_i ,$$

with the $a_{ij}$, $c_{ij}$, $b_i$ and $d_i$ constant coefficients. We can assume $a_{ij} = a_{ji}$, although the $c_{ij}$ are not necessarily symmetric. Equation (14) leads to a set of constraints on these coefficients, thus defining $V(x)$ and $\tilde{K}(x)$. If we substitute equations (23) and (24) in Eq.(14), we obtain

$$\left\{ 1 - (1 - q)\beta \left[ \sum_{ij}(a_{ij}x_ix_j) + \sum_i(b_ix_i) \right] \right\} \left( \sum_k c_{kk} \right)$$

$$- \beta \sum_k \left[ \sum_i(c_{ki}x_i) + d_k \right] \left[ \sum_j((a_{kj} + a_{jk})x_j) + b_k \right] = 0 .$$

(25)
Equation (25) is a second degree polynomial in the $x_i$’s that is equal to zero. Since this equality should hold for any value of $x$, the coefficients of the different powers of the $x_i$ should each be equal to zero. Therefore, by separately equating to zero the independent zero-th, first and second order terms in the left-hand side of Eq.(25), one obtains

$$\sum_k (c_{kk} - \beta d_k b_k) = 0,$$  \hspace{1cm} (26a)

$$\sum_k [(1-q)c_{kk}b_i + c_{ki}b_k + (a_{ki} + a_{ik})d_k] = 0, \quad \forall i,$$ \hspace{1cm} (26b)

$$\sum_k [(1-q)c_{kk}(a_{ij} + a_{ji}) + c_{ki}(a_{kj} + a_{jk}) + c_{kj}(a_{ki} + a_{ik})] = 0, \quad \forall i,j.$$ \hspace{1cm} (26c)

With symmetric $a_{ij}$, we shall now assume

$$\det |a_{ij}| \neq 0.$$ \hspace{1cm} (27)

This assumption is also necessary if $V(x)$ should represent a confining potential, leading to a normalizable stationary state of the nonlinear Fokker-Planck equation.

If we introduce an appropriate shift in the $x_i$ coordinates, it is possible to work using a potential $V(x)$ (Eq.(23)) with no linear terms. We thus define

$$\overline{x}_i = x_i - r_i,$$ \hspace{1cm} (28)

so that the $r_i$ are constants that can be derived from constraints, as we will show. We can then express Eq.(28) in terms of the $\overline{x}_i$ as

$$V(x) = \sum_{ij} a_{ij} [\overline{x}_i \overline{x}_j + (\overline{x}_i r_j + \overline{x}_j r_i) + r_i r_j] + \sum_i b_i (\overline{x}_i + r_i).$$ \hspace{1cm} (29)

The linear terms in Eq.(29) are now

$$\sum_i \left\{ \left[ \sum_j (a_{ij} r_j + a_{ji} r_j) \right] + b_i \right\} \overline{x}_i,$$ \hspace{1cm} (30)

and they will vanish if the $r_j$’s satisfy,

$$b_i + \sum_j (a_{ij} + a_{ji}) r_j = 0, \quad \text{or}$$

$$b_i + 2 \sum_j a_{ij} r_j = 0, \quad i = 1, \ldots, N.$$ \hspace{1cm} (31)
The $N$ equations (31) can be solved for the $r_j$’s because the condition in Eq.(27) holds. The constant term $(\sum_i b_i r_i) + \left(\sum_{ij} a_{ij} r_i r_j\right)$ in the potential $V$ can be ignored and eliminated: since the potential enters the NLFP equation only through its gradient, this constant term has no physical significance. Therefore, in terms of the shifted coordinates $\overline{x}_i$, we have

\begin{align}
V(\overline{x}) &= \sum_{ij} a_{ij} \overline{x}_i \overline{x}_j, \quad (32a) \\
\tilde{K}_i(\overline{x}) &= \sum_j (c_{ij} \overline{x}_j) + \overline{d}_i, \quad (32b)
\end{align}

where $\overline{d}_i = \sum_j (c_{ij} r_j) + d_i$. We thus see that, after an appropriate shift in the phase space variables, the problem reduces to that of a homogeneous, quadratic potential.

If the associated nonlinear Fokker-Planck equation admits a $q$-maxent stationary solution, even for one single value of $\beta$, it follows from Eq.(26a) that we must have

$$\sum_j c_{jj} = 0 \implies \nabla \cdot \tilde{K} = 0,$$

(33)

from which it follows that the condition $\tilde{K} \cdot \nabla V = 0$ also follows. In other words, for a quadratic potential $V$ and a linear drift $\tilde{K}$, if one has a $q$-maxent stationary solution even for one single value of $\beta$, it is possible after a coordinates shift to recast the system in terms of a drift field complying with conditions (15) and (16).

VI. TWO DIMENSIONAL SYSTEM WITH EXACT TIME-DEPENDENT $q$-GAUSSIAN SOLUTIONS.

We now consider, as an example of a time-dependent solution of a nonlinear Fokker-Planck equation with a $\tilde{K}$ not arising from a potential, that admits a $q$-maxent stationary solution, a bi-dimensional system submitted to the following quadratic potential and nongradient linear drift term. For simplicity of notation, we will name the phase space state variables as $x \equiv \overline{x}_1$ and $y \equiv \overline{x}_2$, so that the potential and drift term can be expressed as

\begin{align}
V(\overline{x}) &= a(x^2 + y^2), \quad (34) \\
\tilde{K}(\overline{x}) &= (-by, +bx). \quad (35)
\end{align}
It can be verified that (34) and (35) satisfy conditions given by equations (15) and (16). The NLFP equation then has the form

\[
\frac{\partial F}{\partial t} = D \nabla^2 [F^{2-q}] + \frac{\partial [(2ax + by)F]}{\partial x} + \frac{\partial [(2ay - bx)F]}{\partial y}.
\]  

We propose the ansatz

\[
F(x, y, t) = \eta(t) \left[1 - (1 - q)(\alpha(t)x^2 + \delta(t)xy + \gamma(t)y^2)\right]^\frac{1}{1-q},
\]

where \(\eta(t), \alpha(t), \delta(t)\) and \(\gamma(t)\) are time-dependent parameters. This ansatz has a time-dependent Tsallis \(q\) maximum entropy (\(q\)-maxent) form, with the time dependence represented in the parameters \(\eta, \alpha, \delta\) and \(\gamma\). We then define

\[
\varphi = 1 - (1 - q)(\alpha x^2 + \delta xy + \gamma y^2),
\]

calculate the terms of the nonlinear Fokker-Planck equation (1) and obtain the following expressions

\[
\frac{\partial F}{\partial t} = \dot{\eta}\varphi^{\frac{1}{1-q}} - \eta(\dot{\alpha}x^2 + \dot{\delta}xy + \dot{\gamma}y^2)\varphi^{\frac{2}{1-q}},
\]

\[
\frac{\partial^2 F^{2-q}}{\partial x^2} = (2 - q)\eta^{2-q} \left(-2\alpha\varphi^{\frac{1}{1-q}} + (2\alpha x + \delta y)^2\varphi^{\frac{2}{1-q}}\right),
\]

\[
\frac{\partial^2 F^{2-q}}{\partial y^2} = (2 - q)\eta^{2-q} \left(-2\gamma\varphi^{\frac{1}{1-q}} + (2\gamma y + \delta x)^2\varphi^{\frac{2}{1-q}}\right),
\]

\[
\frac{\partial [(2ax + by)F]}{\partial x} = \eta \left[2a\varphi^{\frac{1}{1-q}} - (2ax + by)(2\alpha x + \delta y)\varphi^{\frac{2}{1-q}}\right],
\]

\[
\frac{\partial [(2ay - bx)F]}{\partial y} = \eta \left[2a\varphi^{\frac{1}{1-q}} - (2ay - bx)(2\gamma y + \delta x)\varphi^{\frac{2}{1-q}}\right].
\]

Next we substitute the right-hand side of the above equations (39) into the NLFP equation (36) and, with some algebra, obtain the following set of ordinary differential equations for the time evolution of the parameters \(\eta, \alpha, \delta\) and \(\gamma\)

\[
\frac{d\eta}{dt} = 4\eta a - 2(2 - q)D\eta^{2-q}(\alpha + \gamma),
\]

\[
\frac{d\alpha}{dt} = -(2 - q)D\eta^{1-q} \left(4\alpha^2 + \delta^2\right) + 4a\alpha - b\delta,
\]

\[
\frac{d\gamma}{dt} = -(2 - q)D\eta^{1-q} \left(4\gamma^2 + \delta^2\right) + 4a\gamma + b\delta,
\]

\[
\frac{d\delta}{dt} = -4(2 - q)D\eta^{1-q}\delta(\alpha + \gamma) + 4a\delta + 2b(\alpha - \gamma).
\]
Therefore the q-maxent ansatz (37) will be a solution of the NLFP equation (36), provided that the functions \( \eta(t) \), \( \alpha(t) \), \( \delta(t) \) and \( \gamma(t) \) satisfy the set of four coupled ordinary differential equations (40).

When we interpret the function \( F_q(x_1, \ldots, x_N, t) \) (4) as a probability density in phase space, or as a physical density of particles or other entities, we should require that the norm \( I \) of \( F_q \) is finite, so that

\[
I = \int F_q \, dx_1 dx_2 \cdots dx_N \leq \infty .
\] (41)

For the density function (37) to have a finite norm, in that expression, we should have

\[
\alpha x^2 + \delta xy + \gamma y^2 = \text{const.} > 0,
\]
determining the isodensity curves which should correspond to ellipses. Therefore the quadratic form \( \alpha x^2 + \delta xy + \gamma y^2 \) has to be definite positive. Consequently, the discriminant

\[
\varsigma = \alpha \gamma - \frac{\delta^2}{4}
\] (42)

has to be positive. It follows from (40) that the time derivative of the discriminant

\[
\frac{d\varsigma}{dt} = [\delta^2 - 4\alpha \gamma][(2 - q)D\eta^{1-q}(\alpha + \gamma) - 2a]
= 4\varsigma[2a - (2 - q)D\eta^{1-q}(\alpha + \gamma)].
\] (43)

We see that the value of the discriminant is not constant in time. However, equation (43) implies that the positive character of \( \varsigma \) is preserved under the time evolution of the system.

For the proposed q-statistical ansatz (37), we find after some algebra that, for \( q < 1 \), the norm (equation 41) is

\[
I = \frac{\pi \eta}{(2 - q)\sqrt{\alpha \gamma - \frac{\delta^2}{4}}}. \tag{44}
\]

After some more calculation, it is also possible to verify using the equations of motion (40) that

\[
\frac{dI}{dt} = \frac{\partial I}{\partial \eta} \frac{d\eta}{dt} + \frac{\partial I}{\partial \alpha} \frac{d\alpha}{dt} + \frac{\partial I}{\partial \gamma} \frac{d\gamma}{dt} + \frac{\partial I}{\partial \delta} \frac{d\delta}{dt} = 0 , \tag{45}
\]

so that \( I \) is a conserved quantity during the time evolution of the system, as is to be expected.

A density \( F(x, t) \) governed by the partial differential equation (36) can be interpreted as describing the distribution of a set of particles interacting via short range interactions, performing overdamped motion under the drag effects due to a uniformly rotating medium, and confined by an external harmonic potential. To see this, let us consider the equation of motion of one individual test particle of this system

\[
m \ddot{r} = -\nabla W_{\text{int}} - \nabla W_{\text{ext}} - \Gamma (\dot{r} - \dot{r}_R), \tag{46}
\]
where $m$ is the mass of the test particle, $W_{\text{int}}$ is the potential function associated with the forces acting on the test particle due to the other particles of the system, $W_{\text{ext}}$ is the external confining potential, and $\Gamma$ is a drag coefficient describing the drag forces due to a resisting medium that rotates uniformly with an angular velocity $\Omega$. Notice that the equation of motion \((46)\) is expressed with respect to an inertial reference frame (with cartesian coordinates \((x, y)\)) and not with respect to the rotating frame where the resisting medium is at rest. With respect to the inertial frame, the local velocity $\dot{\mathbf{r}}_R$ of the medium has components $(-\Omega y, +\Omega x)$.

Since the interactions between the particles are short-range, we assume that the potential function $W_{\text{int}}$ is a function of the local density $F$, that is $W_{\text{int}} = D(F)$. In the regime of overdamped motion, equation \((46)\) becomes

$$\dot{\mathbf{r}} = -\frac{1}{\Gamma} \nabla W_{\text{int}} - \frac{1}{\Gamma} \nabla W_{\text{ext}} + \dot{\mathbf{r}}_R, \quad (47)$$

implying that the velocity $\dot{\mathbf{r}}$ of a particle in the system, at a given time, is completely determined by its location $\mathbf{r}$. It can then be verified, after some calculations, that the continuity equation in configuration space, $\partial F/\partial t = -\nabla (\dot{\mathbf{r}} F)$, describing the evolution of the space density $F$ of a set of articles moving according to the equation of motion \((47)\), is precisely the NLFP equation \((36)\), after the identifications $D = 0$, $b = \Omega$.

An illustrative example of the time evolution of the $q$-Gaussian solution \((37)\) is provided in Figures 1-4. In these Figures, the parameters $\alpha$, $\gamma$, $\delta$, and $\eta$, determining the evolving size and shape of the two-dimensional $q$-Gaussian \((37)\), are depicted as a function of time. The different curves shown in each Figure correspond to the NLFP equation \((36)\), with $q = 0.5$, $D = 0.5$, $a = 1$, $b = 4$, and different initial conditions. The curves were therefore obtained from the numerical integration of the set of coupled ordinary differential equations \((40)\). All solutions exhibited correspond to evolving densities normalized to unity (that is, $I = 1$). See equation \((44)\). The initial conditions are $\alpha_0 = 1$, $\delta_0 = 0$, with different initial values of the parameter $\gamma$, as indicated in the Figures. The initial value of $\eta$ is calculated from the initial values of the other three parameters, using the normalization condition $I = 1$.

It can be appreciated from Figures 1-4 that the different initial densities considered (all having the same norm $I = 1$) relax to the same final stationary distribution (characterized by the same value of the norm). This stationary distribution is rotationally symmetric.
FIG. 1. Evolution of the parameter $\alpha$ appearing in the time-dependent solution (37) of the NLFP equation (36), for $q = 0.5$. The units employed are defined in terms of the constants $D$ and $b$ appearing in the NLFP equation. The parameter $\alpha$ has dimensions of inverse squared length and is measured in units of $\frac{b}{sD}$. The time $t$ is measured in units of $\frac{4}{b}$.

FIG. 2. Evolution of the parameter $\gamma$ appearing in the time-dependent solution (37) of the NLFP equation, for $q = 0.5$. The parameter $\gamma$ has dimensions of inverse squared length. The units employed are the same as in Figure 1.

Consequently, the initial asymmetry of the density tends to decrease as the evolution takes place (the two axis of the isodensity curves tend to become equal to each other). The oscillatory behavior of the parameter $\delta$, which takes alternating signs as time advances,
FIG. 3. Evolution of the parameter $\delta$ appearing in the time-dependent solution (37) of the NLFP equation, for $q = 0.5$. The parameter $\delta$ has dimensions of inverse squared length. The units employed are the same as in Figure 1.

FIG. 4. Evolution of the parameter $\eta$ appearing in the time-dependent solution (37) of the NLFP equation, for $q = 0.5$. The parameter $\eta$ is dimensionless. The time $t$ is measured in the same units as in Figure 1.

indicates that the asymmetric density rotates as the evolution proceeds. Note that at the times when $\delta = 0$ the axis of the isodensity curves are parallel to the coordinate axis. This happens at approximately regular time intervals, indicating that the elliptical isodensity curves rotate at an approximately constant mean angular velocity. The oscillatory behavior associated with the rotation affects the other variables (besides $\delta$) as well, which also exhibit
oscillations whose amplitudes tend to decrease as the density function $F$ relaxes towards the stationary one.

VII. CONCLUSIONS

We investigated the main properties of multi-dimensional NLFP equations involving curl drift forces. We considered drift force fields comprising both an irrotational term $G$ derived from a potential function $V(x)$ and a curl, non-gradient term $\mathbf{K}$. We determined the requirements that the two parts $G$ and $\mathbf{K}$ of the drift field have to satisfy, in order for the corresponding NLFP equation to admit a stationary solution of the $q$-maxent form (that is, a $q$-exponential of the potential function $V(x)$ associated with the gradient component of the drift force). We found that this kind of stationary solution exists for a continuous range of values of the parameter $\beta$ if and only if, the curl part $\mathbf{K}$ is divergenceless and the curl part is orthogonal to the gradient part $G$. We also proved that NLFP equations admitting a stationary solution also verify an $H$-theorem, in terms of an appropriate linear combination of the $S_q$ entropic functional and the mean value of the potential $V$. Finally, we studied exact analytical time-dependent solutions of a two dimensional NLFP equation, describing a system of interacting particles in an overdamped motion regime, under the drag effects originating on a uniformly rotating medium. The connection between rotation and NLFP equations with curl forces, combined with the connection between $q$-thermostatistics and self-gravitating systems, indicates that those evolution equations may have applications in geophysical and astrophysical problems. Previous successful physical applications of NLFP equations also suggest that experimental implementations involving rotating granular materials may also be worth exploring.

Another potential field of application of the NLFP dynamics, investigated in the present work, is the space-time behavior of some biological systems [29]. Diffusion processes are useful to model the spread of biological populations [30, 31]. Nonlinear diffusion equations have been proposed, as effective descriptions of the interaction between the members of a diffusing biological population [32–34]. On the other hand, drift terms can be used to describe other effects on the motion of the individuals. In this biological context, since the “forces” are not fundamental but rather the effective result of a set of complex circumstances, it is to be expected that non-gradient forces can be relevant. NLFP equations with non-
gradient drift fields may also be useful in connection with the generalized Boltzmann machine approach (based on a \( q \)-generalization of simulated annealing \cite{35}) to neural network models of memory \cite{36}, when considering asymmetric neural interactions. Any further developments along these or related lines will be very welcome.
