Abstract

We propose a novel approach to the statistical analysis of stochastic simulation models and, especially, agent-based models (ABMs). Our main goal is to provide fully automated, model-independent and tool-supported techniques and algorithms to inspect simulations and perform counterfactual analysis. Our approach: (i) is easy-to-use by the modeller, (ii) improves reproducibility of results, (iii) optimizes running time given the modeller’s machine, (iv) automatically chooses the number of required simulations and simulation steps to reach user-specified statistical confidence, and (v) automates a variety of statistical tests. In particular, our techniques are designed to distinguish the transient dynamics of the model from its steady-state behaviour (if any), estimate properties in both “phases”, and provide indications on the (non-)ergodic nature of the simulated processes – which, in turn, allows one to gauge the reliability of a steady-state analysis. Estimates are equipped with statistical guarantees, allowing for robust comparisons across computational experiments. To demonstrate the effectiveness of our approach, we apply it to two models from the literature: a large-scale macro-financial ABM and a small scale prediction market model. Compared to prior analyses of these models, we obtain new insights and we are able to identify and fix some erroneous conclusions.

1. Introduction

In this article we present a model-independent and fully automated approach to the statistical analysis of stochastic simulation models and, especially, agent-based models (ABMs). In particular, our work allows one to distinguish the transient dynamics of the model from its steady-state behaviour (if any), to estimate properties of the model in both “phases”, to check whether the ergodicity assumption is reasonable, and to equip the results with statistical guarantees, allowing for robust comparison of model behaviours’ across computational experiments.

Though these tasks would improve the robustness and reliability of counterfactual analyses, especially coming from the comparison of simulated policies, we believe they are still challenging and sometimes overlooked.\textsuperscript{1} In the

\textsuperscript{1} We focus on models that are stochastic (in the sense that they entail random draws over the simulation) and that need to be initialized. As a consequence, for every configuration of parameters and initialization, we observe a certain degree of stochasticity leading the system to exhibit properties that are either stable or unstable over the unfolding of simulation time. Our work focuses on the analysis of such properties.
last two decades, the use of Agent-Based Models has spread across several fields – including ecology (Grimm and Railsback, 2013), health care (Eftken et al., 2012), sociology (Macy and Willer, 2002), geography (Brown et al., 2005), medicine (An and Wilensky, 2009), research in bioterrorism (Carley et al., 2006), and military tactics (Ilachinski, 1997). In economics, ABMs contributed to the understanding of a variety of micro and macro phenomena (Tsetsfatsion and Judd, 2006). They provided an alternative environment for policy-testing in the aftermath of the last financial crisis, when more traditional approaches (e.g., dynamic stochastic general equilibrium models and computable general equilibrium models) failed (Fagiolo and Roventini, 2012, 2017). Moreover, they were recently used for macroeconomic forecasting with promising results (Delli Gatti and Grazzini, 2020; Poledna et al., 2020).

The key advantage of ABMs lies in the flexibility they allow when modelling realistic micro-level behaviours (e.g., bounded rationality, routines, stochastic decision processes) and interactions of the agents (e.g., imitation, network effects, spatial influence). These features - heterogeneity and interactions - give rise to aggregate dynamics that are qualitatively different, and cannot be deduced a priori, from those characterizing single agents. Indeed, ABMs often show the emergence of statistical equilibria (e.g., Delli Gatti et al., 2005, 2018; Dosi and Roventini, 2019), i.e., states of macroscopic equilibrium characterized by stable statistical distributions of variables describing aggregate phenomena accompanied by possibly unstable and evolving microscopic behaviours (Feller, 1957).

Depending on the applications, one might be interested in studying if - and how - the system reaches a statistical equilibrium, whether the equilibrium is unique, what properties the system displays therein, and whether they change for different parameter values and initial conditions (Windrum et al., 2007; Grazzini, 2012; Fagiolo et al., 2019). For example, the macro ABM literature has traditionally focused on characterizing long-run behaviours of macroeconomic aggregates under different policy regimes, washing away dependencies from initial conditions and transient dynamics (Fagiolo and Roventini, 2017); contrarily, history-friendly models rooted in evolutionary economics have often focused on microeconomic transients, interpreted as industrial paths of development (Malerba et al., 1999).

As closed-form solutions of the distributional dynamics of ABMs are rarely available, the analysis must rely on numerical simulations. However, we believe that little attention has been devoted to simulation protocols. While decisions about (i) how many steps to run, (ii) how many steps to use as warmup (or transient) period, and (iii) how many runs to perform under each parameter configuration deeply influence the reliability of the analysis, they are often poorly justified. For example, statements like “the results have been averaged over n simulations” or “we run a Monte Carlo exercise of size n”, without a proper justification for the choice of n, are rather ubiquitous (see, e.g., Beygelzimer et al., 2012; Kets et al., 2014; Caiani et al., 2016; Lamperti et al., 2018, 2019; Dosi et al., 2019; Fagiolo et al., 2020). While irrelevant for “thought experiments”, these aspects deserve attention when different policies are compared in counterfactual simulation experiments, or multiple parameter configurations are explored to discriminate among emerging behaviours. Secchi and Seri (2017) conducted a study on 55 ABMs published between 2010 and 2013 in high-quality management and organizational science journals. Their study showed that - in most cases - simulation exercises did not offer acceptable statistical quality, casting doubt on the results and their implications. The main cause of low statistical accuracy turned out being an insufficient number (n) of simulations performed. Similarly, a poor handling of transient behaviours can distort results and the interpretation of steady-state behaviours (see, e.g., Galán and Izquierdo, 2005). Furthermore, ergodicity tests are necessary to establish whether performing a steady-state analysis makes sense at all.

In our opinion, these problems are partially due to the fact that the simulation-based analysis of ABMs (i.e., the inspection of simulations of models) is sometimes handcrafted, i.e., there is not one set of well-engineered procedures.

---

The authors analyse the power of F-tests in simulations on different model configurations.
and tests widely accepted by the whole community and available as robust software artifacts, resulting in a time-consuming and error-prone process (see also Lee et al., 2015). Notable exceptions are the R packages RNetLogo (Thiele et al., 2012), calibrar (Carrella, 2021) and freelunch (Carrella, 2021) that offer a number of statistical analysis techniques for ABMs complementary to the ones considered in this paper. The simulation, operations research, and computer science communities have substantially advanced the engineering of such tasks, developing automatic techniques equipped with statistical guarantees (see, e.g., Law and Kelton, 2015). While cross-disciplines fertilisation existed already in the previous century (see, e.g., Kwiatkowski et al., 1992), and it has further recently increased (Dahlke et al., 2020), these developments are often overlooked by the so-called ACE (agent-based computational economics) community. In Section 2, we use the model by Grazzini (2012) to illustrate an example concerning the identification of transient dynamics.

This paper introduces a novel, automated and efficient approach to the inspection of stochastic ABMs over simulation time and across alternative configurations of parameters. We distinguish between: (i) transient analysis, which focuses on estimating properties of the model at specific points in time equipping them with a reliable measure of uncertainty; and (ii) steady-state analysis, which focuses on the long-run behaviour of the model and must be invariant to the transient dynamics. Further, we include in our steady-state analysis a methodology for ergodicity diagnostics, which provides indications on whether the model behaves ergodically, and thus on the reliability of the steady-state analysis itself. By leveraging statistical model checking (Agha and Palmskog, 2018; Legay et al., 2019), a successful simulation-based verification approach from computer science, and MultiVeStA (Sebastio and Vandin, 2013; Gilmore et al., 2017), a statistical model checking tool-box that can be integrated with existing simulators to perform automated and distributed statistical analysis, we aim to deliver a set of techniques and algorithms which: (i) is easy-to-use by the modeller, (ii) improves reproducibility of the results, (iii) distributes simulations across the cores of a machine or across computer networks, (iv) automatically chooses a sufficient number of simulations and simulation steps to reach a user-specified statistical confidence, and (v) automatically runs a variety of statistical tests that are often overlooked by practitioners. While previous versions of MultiVeStA have been successfully applied in a wide range of domains including, e.g., highly-configurable systems (ter Beek et al., 2020, 2015; Vandin et al., 2018), public transportation systems, (Gilmore et al., 2014; Ciancia et al., 2016), security risk modeling (ter Beek et al., 2021), biological systems (Gilmore et al., 2017), business process modeling (Corradini et al., 2021), collective adaptive systems (Galpin et al., 2018), robotic scenarios with planning capabilities (Belzner et al., 2016, 2014), and crowd steering scenarios (Pianini et al., 2014), it has never been employed for the analysis of the transient and steady-state properties of ABMs.  

Our work contributes to two strands of the ACE literature. First, it complements many recent proposals for the validation of simulated models (see the surveys in Fagiolo et al., 2019; Lux and Zwinkels, 2018). The method proposed by Guerini and Moneta (2017) for macro ABMs requires the model to be in a steady state and to remove the transient period from the analysis; calibration approaches based on simulated moments (Winker et al., 2007; Franke and Westerhoff, 2012; Grazzini and Richiardi, 2015), as well as recent Bayesian techniques (see, e.g., Grazzini et al., 2017), apply to ergodic models. Further, our transient analysis can be employed to evaluate probabilities of observing certain patterns, which would support the use of validation metrics recently proposed in the literature (see, e.g., Barde, 2017).

---

3 MultiVeStA originally supported Java and C++, simulators. We extended it in terms of support for further environments like R and Python, and for statistical tests (and their power) to compare different model parameterizations, and ex-novo design and development of steady-state analysis. Furthermore, by applying it to two known ABM models, we also contribute to increasing the accessibility of ABMs and to the replicability of their results. MultiVeStA is maintained by one of the authors. More information is provided in Appendix E.

4 In non-ergodic settings, a possible calibration procedure might rely upon techniques like those in, e.g., Seri et al. (2021).
Second, we contribute to the analysis of the complexities of ABM output (Lee et al., 2015; Mandes and Winker, 2017; Kukacka and Kristoufek, 2020) by providing fast and practical tools to inspect models with statistical guarantees (Secchi and Seri, 2017), and by complementing the proposals in Seri and Secchi (2017) to determine the adequate number of simulation runs. Finally, we offer an automated environment to carry out tests across some of the experiments are typical in the macro ABM literature (see, e.g., Dosi et al., 2015; Lee et al., 2015).

We proceed as follows. Section 2 introduces the framework of analysis; Sections 3 and 4 introduce our algorithms and methods, respectively. Next, we showcase the proposed approach on two established ABMs from the literature. Section 5 replicates and enriches the transient analysis from Caiani et al. (2016) on a large-scale benchmark stock-flow consistent macro ABM. We optimize the number of simulations to reach a given (user-defined) level of statistical precision for each time point of interest and use such information to establish, in a statistically sound manner, differences across model configurations. We show that our approach facilitates the interpretation of counterfactual experiments. In particular, we focus on a behavioural and a policy experiment, which highlight that business cycles are sensitive to changes in risk aversion (yet just in the short run), while relatively small income tax variations tend to produce significant and enduring effects on aggregate dynamics. Section 6 performs a steady-state analysis of the prediction market model of Kets et al. (2014). This model has been chosen because of its analytical tractability, which provides an effective ground truth against which we test our techniques. We show that an erroneous identification of the transient period led to misleading qualitative and quantitative results in the original simulation-based analysis by Kets et al. (2014). Indeed, we first show that the agents’ relative wealths and the relationships between market price and other model parameters were incorrectly characterized and, second, we provide a numerical solution matching the analytical results of Bottazzi and Giachini (2019b). Finally, Section 7 applies our methodology for ergodicity analysis to (non-ergodic) variants of this prediction market model, showing how it can be used to further increase the reliability of a steady-state analysis, while Section 8 concludes the paper. The paper contains an appendix where: Appendix A discusses the potential multiple hypothesis problem related to our techniques; Appendix B presents further details on the transient analysis performed on the considered macro ABM; Appendix C and Appendix D provide further details on the market ABM model and on the steady-state analysis performed on it, respectively; Appendix E provides details on statistical model checking and on the tool-support for our techniques, while Appendix F demonstrates the run-time gains offered by offered parallelization capabilities.

2. Analysis of simulation output

The analysis of ABMs typically employs stochastic simulations, relying on Monte Carlo methods, e.g., to derive reliable estimates of the true model characteristics (Richiardi et al., 2006; Lee et al., 2015; Fagiolo et al., 2019). Without loss of generality, one can represent an ABM as a mapping $\mathit{map} : I \rightarrow O$ from a set of input parameters $I$ into an output set $O$. Usually, $I$ is a multidimensional space spanned by the support of each parameter, while $O$ is typically larger and more complex, as it comprises time-series realizations of a very large number of micro- and macro-level variables. In most cases we can think of the output of an ABM as a discrete-time stochastic process $(Y_t)_{t \geq 0}$ describing the longitudinal evolution of a vector of variables of interest (e.g., the wealth of an agent, the GDP

---

5 All materials and instructions for replicating the experiments presented in this paper are available at https://github.com/andrea-vandin/MultiVeStA/wiki. Furthermore, MultiVeStA is freely available from the website together with information on how to integrate new simulators.

6 The model has been analytically studied in Bottazzi and Giachini (2019b), proving asymptotic results about agents’ wealth and market price.
Simulations

Transient analysis

Steady-state analysis by Replication and Deletion (RD)

Figure 1: Transient and steady-state analysis using $n$ simulations of $m$ steps each

of a country, etc.). For simplicity, here we focus on the case in which $(Y_t)_{t>0}$ contains only one time series of interest $(Y_t)_{t>0}$. However, our framework straightforwardly covers the concurrent analysis of multiple time series.

Figure 1(a) depicts $n$ independent simulations of $Y_t$ (one per row) each comprising $t = 1, \ldots, m$ steps (one per column). The outcome of a simulation $i$ is therefore a sequence $\{y_{i,1}, \ldots, y_{i,m}\}$ denoting a realization of length $m$. Clearly, the observations within the same row $i$ are not independent, while those in the same column $t$ are independent and identically distributed (IID). Here we focus on two typical classes of properties:

- **Transient properties** concerning $E[Y_t]$; what is the expected value of a property of a model at a given time $t$ (or within a time range, or at the occurrence of a specific event)?

- **Steady-state properties** concerning $E[Y]=\lim_{t \to \infty} E[Y_t]$; what is the expected value of a property of a model at steady state (i.e., when the system has reached a statistical equilibrium)?

An example of transient property is given in Section 5: *what is the expected unemployment rate in each of the first 400 quarters of a macro ABM?* In this example, a transient analysis is particularly important because the model has been designed to study fluctuations in the quarters following a given initial condition. In contrast, an example of steady-state property is given in Sections 6 and 7: *given a market with repeated sessions, what is the expected wealth of each agent at steady state?* In this example, a steady-state analysis is particularly important because the model has been designed to study problems of market selection and informative efficiency. Obviously, a steady-state analysis is meaningful only “around” a statistical equilibrium. This requires that $\lim_{t \to \infty} E[Y_t]$ exists and is finite. We first present two complementary techniques for steady-state analysis that rely on such assumption, and then (in Section 4) we combine them into a methodology for ergodicity diagnostics; that is, a methodology for assessing whether the assumption is reasonable or clearly violated.

Figures 1(b) and (c) depict how to compute statistical estimates for $E[Y_t]$ and $E[Y]$, respectively. Such estimates can and should be accompanied by appropriate measures of uncertainty, e.g., computing “$\alpha$-$\delta$ confidence intervals” (CI) around them. Given two user-specified parameters $\alpha \in (0, 1)$ and $\delta \in \mathbb{R}^+$, we will show how to guarantee with statistical confidence $(1 - \alpha) \cdot 100\%$ that the actual expected value belongs to the interval of width $\delta$ centred at its

---

5By *independent simulations* we mean runs obtained from different random seeds that have been used for each replication, with the simulator status reset to an initial configuration at the beginning of each replication.

8What we mean by steady state for a stochastic simulation model consists in reaching a statistical equilibrium, that is - to repeat - a state of macroscopic equilibrium maintained by a large number of transitions in opposite directions (Feller, 1957).

9We leave to future work extensions of our framework that would allow us to detect the number and nature of the statistical equilibria of a simulation model.
estimate, and how to optimize the number of runs needed to obtain such guarantee. These steps, which are sometimes overlooked in the ABM community, can make the statistical analysis of ABMs sounder and more informative for policy analysis. We now provide more details on our proposals for transient and steady-state analyses.

**Transient analysis.** Procedures for transient analysis are well-established and relatively simple. As shown in Figure 1(b), for a given time point \( t \) (a column) we obtain an unbiased estimator for \( E[Y_t] \) by computing the vertical mean \( \bar{Y}_t \) of the observations at \( t \) (across the rows). Since these observations are IID, we can use standard statistical techniques based on the law of large numbers to build CIs as follows (see Chapter 9 of Law and Kelton, 2015):

\[
\bar{Y}_t \pm t_{n-1,1-\delta/2} \cdot \sqrt{\frac{s^2}{n}},
\]

where \( n \) is the number of simulations, \( s^2 \) is the sample variance of \( Y_t \), and the multiplier \( t_{n-1,1-\delta/2} \) is obtained from the tabulation of the Student’s t distribution with \( n - 1 \) degrees of freedom (the area under the density function integrated from minus infinity to \( t_{n-1,1-\delta/2} \) is equal \( 1 - \frac{\delta}{2} \)).\(^{10}\) For any fixed confidence level \( \alpha \), the width of the CI decreases as \( n \) increases. Therefore, in an automated procedure for computing an \( \alpha \)-\( \delta \) CI, we can continue performing new simulations until the width becomes smaller than the desired \( \delta \) (the target width can also be expressed as a fraction of the mean value; \( \delta \% \) of \( \bar{Y}_t \)). Note that the CI width shrinks slowly, at the rate of the square root of \( n \). Therefore, it is important to perform the correct number of simulations to guarantee the target width without performing unnecessary computations. Our proposed techniques offer an automated procedure for doing so. Furthermore, since in many cases different times \( t \) might have different variances \( s^2 \), we account for the fact that different number of simulations might be required at each \( t \) to get CIs of homogeneous width across times. As we will see in Section 5.3, this is particularly important for counterfactual analysis.

We remark that the parameter \( \delta \) provides a sort of ‘precision’ on the performed estimations. Equation (1) shows an estimated mean (\( \bar{Y}_t \)) with its confidence interval (the right-hand-side part starting with \( \pm \)). The parameter \( \delta \) is used to impose a maximal width to all such CIs: the algorithms that we will present here are designed so to perform enough simulations (and simulation steps) to guarantee that all the computed CIs have a width of at most \( \delta \). Clearly, for a given statistical confidence \( \alpha \), the smaller is \( \delta \), the tighter will be the computed CIs, therefore the more precise will be the estimations. At the same time, smaller values of \( \delta \) require more simulations. Therefore, when choosing the value of \( \delta \) for the analysis at hand, one has to keep into account such a trade-off.

A common exercise that builds upon transient analysis is to compare estimates obtained for different model configurations (typically corresponding to different sets of input parameter values) – as to assess whether the configurations differ significantly in terms of the output variables under consideration. Given the outcomes of the transient analyses for the two configurations and a user-defined significance level \( \alpha \), our set of techniques performs a Welch’s t-test of means’ equality (Welch, 1947) for every \( t \) of interest. The proposed techniques also allow for the computation of power of such test (Chow et al., 2002) in detecting a difference of at least a given precision \( \varepsilon \) (see Section 3.1.2).\(^{11}\)

**Steady-state analysis.** Figure 1(c) depicts how a steady-state analysis can be performed similarly to a transient one by adding a pre-processing phase. We first compute the horizontal mean \( \bar{Y}_{(h)} \) within each simulation \( i \), ignoring

---

\(^{10}\)The Student’s t distribution is exact if the data are normally distributed with the same variance; it is an approximation, widely accepted by the researchers (see Law and Kelton, 2015), if they are not. In particular, it is a penultimate distribution (see, e.g., Gomes and Haan, 1999).

\(^{11}\)In Section 5.3 we show that a reasonable choice is to set \( \varepsilon = \delta \). Our techniques also support so-called Wilcoxon-Mann-Whitney test, or just \( u \)-test (Mann and Whitney, 1947). This is an alternative to Welch’s t-test with milder assumptions, for which, however, to the best of our knowledge no closed-formula exists for power estimation. This is presented in Appendix B.2.
a given number \( w \) of initial observations. Since all these means are IID, we can compute their vertical mean \( \overline{Y}(w) \) and build a CI around it as in Equation (1). Unfortunately, this approach has intricacies that hinder its automatic implementation and can lead to relevant analysis errors. Depending on the chosen number \( w \) of initial observations to discard, the estimator \( \overline{Y}(w) \) of \( E[Y] \) might carry a bias due to the transient behaviour of the system, and not give us reliable information on its steady state (see Section 6.2 for a notable example from the literature). In order to avoid this issue, we need to identify the correct \( w \) the system needs to exit its transient (or warmup) period, and discard the initial \( w \) observations from each simulation. Such procedure is known as Replication and Deletion (RD, Law and Kelton, 2015). Effectively identifying the length of the warmup period is a difficult problem. The most popular approaches in the ABM community are rooted in the Welch’s method (Welch, 1983):

1. Perform \( n \) simulations of given length \( m \) and compute averages \( \overline{Y}_t, t = 1, \ldots, m \) as in Figure 1(b);
2. Plot \( \overline{Y}_t, t = 1, \ldots, m \); \(^{12}\)
3. Choose the time \( w \) after which the plot seems to converge. If no such time exists, iterate the procedure from point (1), performing a new batch of \( n \) simulations of length \( m \), and computing averages over all simulations.

Being only semi-automated and based on a visual assessment, this procedure is time consuming, error-prone, and not backed by a strong statistical justification. It also critically depends on choosing a large enough “time horizon” \( m \) – of course progressively larger \( m \) can be tried, adding to the computational burden.

More recently, Grazzini (2012) presented an alternative approach where a single simulation of length \( m \) is performed and divided into windows of length \( w_i \) (\( m \) and \( w_i \) are arbitrarily chosen). If the distribution of the means computed within each window passes a randomness test (in particular the Runs Test by Gibbons, 1986; Wald and Wolfowitz, 1940), then the author concludes that the system is in steady state. The use of statistical tests rather than visual assessments makes the approach more reliable, fostering its use in the ABM literature (e.g., Guerini and Moneta, 2017; Lamperti et al., 2020). However, the approach is still not fully automated – and relies on the arbitrary choice of \( m \) and \( w_i \): quoting from the author “with appropriate settings the tests can detect non-stationarity” (Grazzini, 2012).

In the next section we introduce a fully automated statistical procedure for estimating the end of the warmup period.

3. Automated simulation-based analysis with statistical guarantees

Our approach to transient and steady-state analysis is fully automated, in that all parameters are computed automatically or have default values. The user specifies the properties to be studied, the \( \alpha \) and \( \delta \) parameters to be employed in the CI construction, and an optional maximum number of allowed simulations (if this number is reached before satisfying the CI constraints, the analysis terminates with the currently computed CIs). As in Section 2, we focus the description on a single variable \( Y_t \), but our treatment applies straightforwardly to the analysis of multiple model characteristics (indeed, our actually implemented techniques support multi-variable analyses).

We have to notice here that our techniques make extensive use of statistical testing and the probability of observing a supposedly significant difference under the null hypothesis may be larger than the nominal value \( \alpha \). This problem goes under the multiple hypothesis testing problem. We critically discuss such an issue in Appendix A.

3.1. Transient analysis

Section 3.1.1 describes how to estimate transient properties expressed as expected values, \( E[Y_t] \), and how to build CIs around them. After this, Section 3.1.2 describes how to statistically compare estimates from different experiments.

\(^{12}\)In Point (2) one might smooth the plot, e.g., employing moving-windows averages, where one is in effect further averaging each \( \overline{Y}_t \) with a few neighbouring steps.
Welch’s t-test. Given estimates from two transient analyses for a set of time points can be computed as in Chow et al. (2002).

3.1.2. Test for equality of means and power computation

Our proposed set of techniques allows one to concurrently estimate $E[Y_i]$ for different time points $t$ (e.g., average bankruptcies in each $t$ from 1 to 400 in Section 5). This is done by computing, at each iteration, mean, variance and CI only for the elements of $Y$ (Line 7) that correspond to time points whose current CI width is still above $\delta$. At each iteration of a block of $bl$ simulations, the time horizon $m$ is updated with the largest $t$ still to be processed.

3.1.3. Mean estimation and CI computation

Algorithm 1 illustrates autoIR, a simple automated algorithm for transient analysis that takes in input $bl$ (discussed later), a time of interest $t$, and $\alpha$ and $\delta$, and produces in output an estimate of $E[Y]$ and a corresponding CI. The algorithm determines automatically the number $n$ of simulations required to guarantee that the $(1-\alpha)\times 100\%$ CI centred at the estimate has width at most $\delta$.

Lines 2-4 set $t$ as time horizon $m$, and initialize the counter $n$ of computed simulations and the list $\mu$ to store the observations at step $t$ from each simulation (the $y_{ij}$ in Figure 1(b)). Lines 6-11 perform a block of $bl$ simulations, by default 20 (Law and Kelton, 2015), populating $\mu$. In Line 7, $y$ is a list of size $m$ containing a value $y_{ij}$ for each time point $t$ from 1 to $m$ for the current simulation $i$, but only the value for $t = m$ is used, adding it to $\mu$. After performing $bl$ simulations, autoIR computes the mean $\bar{\mu}$ and variance $s^2$ of $\mu$, used to compute the width $d$ of the current CI. If $d$ is greater than $\delta$, autoIR performs another block of $bl$ simulations, otherwise it returns the current CI. The actual implementation of autoIR used in later sections allows one to concurrently estimate $E[Y_i]$ for different time points $t$ (e.g., average bankruptcies in each $t$ from 1 to 400 in Section 5). This is done by computing, at each iteration, mean, variance and CI only for the elements of $Y$ (Line 7) that correspond to time points whose current CI width is still above $\delta$. At each iteration of a block of $bl$ simulations, the time horizon $m$ is updated with the largest $t$ still to be processed.

Algorithm 2 autoRD: Steady-state analysis by Replication and Deletion

Require: $B$, $b$, $bs$, $minVar$, $bl$, $a$, $\delta$ (default: 128, 4, 16, 1E-7, 20, 0.05, 0.1)

1: $w \leftarrow$ autoWarmup($B$, $b$, $bs$, $minVar$)
2: $m \leftarrow w \cdot 2$
3: $n \leftarrow 0$
4: $\mu \leftarrow$ empty list
5: repeat
6: for $i \in \{1, \ldots , bl\}$ do
7: \quad $y \leftarrow$ drawIndependentSimulation($m$)
8: \quad $\mu$.add($y$)
9: end for
10: $n \leftarrow n + 1$
11: until $d > \delta$
12: return $(1 - \alpha) \cdot 100\%$ CI $[\bar{\mu} - \frac{\alpha}{2}, \bar{\mu} + \frac{\alpha}{2}]$ of width at most $\delta$

For the sake of presentation, all algorithms in the paper consider $\delta$ given as absolute values. The case of $\delta$ given in percentage terms relatively to the studied means is trivially obtained by changing the comparisons $d > \delta$ in $d/|\bar{\mu}| > \delta$. 

8
number of simulations for time \( t \) in experiment \( i \). We take \( D \) as input and, for each \( t \), compute

\[
\tau_t = \frac{\bar{Y}_{jt} - \bar{Y}_{kt}}{f_{jt} + f_{kt}},
\]

where \( f_{jt} = s_{jt}^2/n_{jt}, \; i \in \{j, k\} \). Following Welch (1947), under the null hypothesis that the difference between the two means is zero, each \( \tau_t \) is asymptotically normal, and it is usually approximated by a Student’s \( t \) distribution – which can be considered a penultimate distribution – with degrees of freedom approximated as in Satterthwaite (1946):

\[
\nu_t \approx \left(\frac{f_{jt} + f_{kt}}{n_{jt} - 1} + \frac{f_{jt}^2}{n_{jt} - 1}\right).
\]

Therefore, given a statistical significance \( a_{aw} \), we use \( \tau_t \) to perform the test of no difference between the two means producing 1 if \( \tau_t \in [-t_{\nu_t, 1-a_{aw}}^2, t_{\nu_t, 1-a_{aw}}^2] \) (the null hypothesis of equal means is not rejected) and 0 otherwise. The significance \( a_{aw} \) is user-specified, and can be set to be equal to the \( \alpha \) used for the transient analysis.

\section*{Power of the test}

Following Chow et al. (2002), we estimate the power \( 1 - \beta_t \) of Welch’s \( t \)-test in detecting a difference of at least a given precision \( \epsilon \) between the two means at time \( t \). This is

\[
\beta_t = T_{\nu_t} \left( t_{\nu_t, 1-a_{aw}}^2 \left| \frac{|\epsilon|}{\sqrt{f_{jt} + f_{kt}}} \right. \right),
\]

where \( T_{\nu_t}(x|\theta) \) is the cumulative distribution function of a non-central \( t \)-distribution with \( \nu_t \) degrees of freedom and non-centrality parameter \( \theta \), evaluated at point \( x \). Calculating the power of Welch’s \( t \)-test requires specifying the minimum difference \( \epsilon \) (Chow et al., 2002). As a rule of thumb, we suggest setting \( \epsilon \geq \delta \), the parameter used in the transient analysis, which expresses a precision for the estimated mean. In Section 5, setting \( \epsilon = \delta \) leads to very good power for the considered macro ABM.

\subsection*{3.2. Steady-state analysis}

A statistically sound analysis of steady-state properties poses challenges that have been thoroughly investigated by the simulation community – at the boundary of computer science and operations research. Two main approaches have emerged (Alexopoulos and Goldsman, 2004; Whitt, 1991; Law and Kelton, 2015): those based on Replication and Deletion (RD, see Section 2), and those based on batch means (BM, Conway, 1963; Alexopoulos and Seila, 1996; Steiger et al., 2005). Unlike RD, which computes many short simulations, BM computes one long run which is evenly divided into adjacent non-overlapping subsamples labelled as batches. Intuitively, if certain statistical properties hold, each batch can be used similarly to a a simulation in RD – as depicted in Figure 2. This can be seen as a generalized version of the proposal by Grazzini (2012), which allows one to estimate the end of the warmup period rather than to check whether a given time is subsequent to such end.\footnote{More precisely, Grazzini (2012) appears to employ a non-automated version of BM. Yet the first automated version of BM was published in 1979 (Law and Carson, 1979). This is a clear signal of the potential (and often overlooked) complementaries between the simulation community and the ABM community in economics.}

There is no best approach between RD and BM (Alexopoulos and Goldsman, 2004; Whitt, 1991; Kelton and Law, 1984). They are complementary, and therefore have complementary (dis)advantages. RD, which uses many
short simulations, suffers from biases due to initial conditions. BM, which uses many short batches from one long simulation, is less affected by initialisation bias but has to adopt corrections to deal with correlations among batch means. While some automated BM-based procedures have been proposed (e.g., Steiger et al., 2005; Tafazzoli et al., 2011; Gilmore et al., 2017), to the best of our knowledge, little attention has been paid to RD. Interestingly, Lada et al. (2013) tried to combine the two approaches exploiting their respective strengths: they use BM for warmup analysis, and automate RD by discarding the estimated transient behaviour from each simulation. Following a similar approach, we extract and condense the warmup analysis capabilities inspired by BM into a simple self-standing procedure for warmup estimation (autoWarmup), and we introduce automated RD- and BM-based algorithms (autoRD and autoBM, respectively) which use autoWarmup. In all algorithms (see Figure 3) we favour simplicity and accessibility.

3.2.1. Steady-state analysis by replication and deletion

Algorithm 2 illustrates autoRD. The difficult part in automating RD is the warmup analysis. However, in our setting we can easily do this by invoking autoWarmup (Line 1; see Section 3.2.2 below). For now it is sufficient to know that \( w \) is the last step of the estimated warmup period. Once \( w \) has been determined, we have to set a substantially larger time horizon (Law and Kelton, 2015). We can do this using a (small) multiplier. In Line 2 the default multiplier for \( w \) is 2. The code of autoRD presents also a second modification with respect to that of autoIR: we replaced Line 9 of Algorithm 1 with Lines 8-9 of Algorithm 2 to discard the first \( w \) observations from \( y \), and add the mean of the remaining values of \( y \) (the horizontal mean in Figure 1(b)) to \( \mu \).

3.2.2. Warmup estimation

Algorithm 3 provides pseudo-code for our automatic warmup estimation, inspired by existing BM-based approaches for steady-state analysis (Steiger et al., 2005; Gilmore et al., 2017; Tafazzoli et al., 2011). Indeed, such algorithms include a form of warmup analysis that we extract and refine into a simple self-standing procedure. Lines 1-5 perform a simulation of \( m = B \times bs \) steps (by default, \( B = 128 \) and \( bs = 16 \)). The simulation is divided in \( B \) adjacent non-overlapping batches, each containing \( bs \) steps. After this, the array \( \mu \) stores the mean of each batch (therefore the name batch means): each entry \( \mu[i] \) stores the corresponding \( \bar{B}_i \) (see Figure 2). The algorithm then proceeds iteratively by performing statistical tests to check whether \( m \) is large enough to cover the warmup period, doubling the number of performed steps while keeping the number of batches fixed (doubling the steps \( bs \) in each batch) until all tests are passed. The key point is that if the process satisfies properties required for steady-state analysis (see the discussion on the mixing property in Section 4), then such iterative procedure will lead to approximately IID normally distributed batch means \( \mu \) for a sufficiently large value of \( bs \).

BM-based approaches perform different statistical tests on \( \mu \) to check whether \( m \) is large enough for completing the warmup period; Tafazzoli et al. (2011) use the von Neumann (1941) randomness test, while Steiger et al. (2005) use a
See Appendix D for a discussion and a comparative exercise.

among consecutive batch means (i.e., the lag-1 autocorrelation of µ) test for stationary multivariate normality on groups of 4 consecutive batches followed by a check for low correlation among the initial batches, obtaining minVar below a minimum threshold (parameter ρ). The rationale is that if the variance among the batch means is deterministic fixed point, therefore we can safely assume that the initial warmup period has terminated. Concerning normality, Line 5 uses the Anderson-Darling test implemented in the SSJ library (L’Ecuyer, 2016; L’Ecuyer et al., 2002) to check whether it is statistically plausible that µ’ has been sampled from a normal distribution specified by its mean and variance, and obtain a p-value a. The Anderson-Darling test may overweight the tails of the distribution, hence we provide the Cramer–Von Mises normality test as an alternative. See Appendix D for a discussion and a comparative exercise.

Figure 3: BM-based algorithms for estimating the initial warmup period (left), and for studying steady-state properties (right).

---

Algorithm 3 autoWarmup: Warmup estimation

 Require: B, b, bs, minVar. (default: 128, 4, 16, 1E-7)
1: //Draw the first B - bs steps
2: µ ← array(B)
3: for i ∈ [1, ... , B] do
4: µ[i] ← drawBatchAndComputeMean(bs)
5: end for
6: (a, ρ) ← goodnessOfFitTests(µ, b, minVar)
7: //Keep doubling bs and time horizon until tests pass
8: while a > a’ or ρ > ρ’ do
9: for i ∈ [1, ..., B/2] do
10: µ[i] ← (µ[2 · i] + µ[2 · i + 1])/2
11: end for
12: bs ← 2 · bs
13: for i ∈ [B/2 + 1, ..., B] do
14: µ[i] ← drawBatchAndComputeMean(bs)
15: end for
16: (a, ρ) ← goodnessOfFitTests(µ, b, minVar)
17: end while
18: return Warmup period estimated to terminated after B - bs steps

Algorithm 4 goodnessOfFitTests

 Require: µ, b, minVar
1: µ′ ← (µb1, ..., µb)
2: (µ̄, s̄) ← computeMeanAndVariance(µ′)
3: (α, ρ, δ) ← (0, 0)
4: if s̄ > minVar then
5: a ← AndersonDarlingNormalityTest(µ′, µ̄, s̄)
6: ρ ← lag1Autocorrelation(µ′, µ̄, s̄)
7: end if
8: return (a, ρ);

Algorithm 5 autoBM: Steady-state analysis by Batch Means

 Require: B, b, bs, minVar, a, δ (default: 128, 4, 16, 1E-7, 0.05, 0.1)
1: autoWarmup(B, b, bs, minVar) //Fast-forward simulation after warmup
2: µ ← array(B)
3: for i ∈ [1, ... , B] do
4: µ[i] ← drawBatchAndComputeMean(bs)
5: end for
6: (a, ρ, δ) ← goodnessOfFitTestsAndCI(µ, b, minVar, a)
7: //Keep doubling bs and time horizon until tests pass
8: while a > a’ or ρ > ρ’ or δ > δ do
9: for i ∈ [1, ..., B/2] do
10: µ[i] ← (µ[2 · i] + µ[2 · i + 1])/2
11: end for
12: bs ← 2 · bs
13: for i ∈ [B/2 + 1, ..., B] do
14: µ[i] ← drawBatchAndComputeMean(bs)
15: end for
16: (a, ρ, δ) ← goodnessOfFitTestsAndCI(µ, b, minVar, a)
17: end while
18: return (1 - a) · 100% confidence interval [µ̄ − s̄, µ̄ + s̄] of width at most δ, adjusted for keeping into account residual correlation

Algorithm 6 goodnessOfFitTestsAndCI

 Require: µ, b, minVar, a
1: µ′ ← (µb1, ..., µb)
2: (µ̄, s̄) ← computeMeanAndVariance(µ′)
3: (α, ρ, d, n) ← (0, 0, 0, B − b)
4: if s̄ > minVar then
5: a ← AndersonDarlingNormalityTest(µ′, µ̄, s̄)
6: ρ ← lag1Autocorrelation(µ′, µ̄, s̄)
7: δ ← computeCIWidth(µ̄, s̄, n, α, ρ)
8: end if
9: return (a, ρ, δ);

---

15The Anderson-Darling test may overweight the tails of the distribution, hence we provide the Cramer–Von Mises normality test as an alternative. See Appendix D for a discussion and a comparative exercise.
returns $a$ and $\rho$, which are used in Line 8 of `autoWarmup` to decide whether the tests are passed – using minimum thresholds $a^\ast$ and $\rho^\ast$ based on prior publications (Gilmore et al., 2017; Steiger et al., 2005). If any of the tests fail, then an iteration of the `while` loop in Lines 8-17 is performed to double the number of steps $m$ by doubling the current batch size $bs$. We note that the current $B$ batch means are `squeezed` in the first half of $\mu$, (Lines 9-11), and $m$ new steps are performed to create the new batch means in the second half of $\mu$ (Lines 13-15). The statistical tests are performed on the new batch means, and new iterations of the loop are performed until both statistical tests are passes. The algorithm terminates returning the final value of $m = B \times bs$ as the estimated end of the warmup period.

### 3.2.3. Steady-state analysis by batch means

Algorithm 5 illustrates our automatic BM-based procedure for steady-state analysis. Line 1 invokes `autoWarmup`, which `moves` the simulator to the end of the estimated warmup period. No other information from `autoWarmup` is used. The algorithm then proceeds similarly to `autoWarmup`, the only difference being that we add a third statistical test: we also compute the width $d$ of the CI according to the current batch means. This is obtained by invoking `goodnessOfFitTestsAndCI` from Algorithm 6 rather than `goodnessOfFitTests`. Since the tests for normality and absence of correlation already passed during `autoWarmup`, one might expect that they are no longer necessary. We note however that the tests passed for the last value of $bs$ used in `autoWarmup`, so they could potentially fail for initial small values of $bs$. When all statistical tests are passed, we return the computed $(1 - \alpha)100\%$ CI of width at most $\delta$, adjusted by the computed residual correlation among the batch means. This is done similarly to Steiger et al. (2005), using an inverse Cornish-Fisher expansion (Stuart and Ord, 1994) based on a standard normal density.

### 3.2.4. Some remarks on `autoBM` and `autoRD`

We note that both `autoBM` and `autoRD` proceed by iterations, during which new samples are drawn and new statistical tests are performed. In `autoBM`, new simulation steps are added onto the same long simulation (the number of simulations $n$ is constant, the time horizon $m$ grows). In `autoRD`, new simulations of fixed length are added ($n$ grows, $m$ is constant). In some sense, the computational burden of `autoRD` is higher, as $w$ steps from each newly performed simulation are ignored. However, the simulations performed in each iteration of `autoRD` can be trivially parallelized – so the additional computation can be efficiently handled. Rather, which approach to prefer depends on the model at hand and on the available hardware:

- The longer the initial warmup period, the more advantageous is `autoBM` relative to `autoRD`.
- The higher is the parallelism supported by the hardware, the more advantageous is `autoRD` relative to `autoBM`.

The ABM community favours the RD approach due to its simplicity, but its `trivially parallelisable` nature is not always exploited due to limited computer engineering skills. Notably, some studies have shown that the BM approach might provide more accurate results in specific cases (Whitt, 1991; Alexopoulos and Goldsman, 2004). Our tool-supported algorithms enable modellers to freely choose between the two approaches and to exploit the distributed nature of the tool-box to parallelize simulations. The next section shows how `autoRD` and `autoBM` can be combined to obtain a methodology for ergodicity diagnosis.

---

16In particular, the significance level for the normality test is set to $a^\ast = 1\%$ while the lag-1 autocorrelation threshold is set to $\rho^\ast = \sin(0.927 - \frac{q}{\sqrt{\mu}})$, where $q$ is the 99% quantile of the standard normal distribution. See Steiger et al. (2005) for more details.

17See Section 2 of Steiger et al. (2005) for the exact formula.
4. Ergodicity diagnostics using **autoRD** and **autoBM**

As discussed, not all ABMs can be studied at steady state. We hereby provide a methodology to help the modeller understand whether she should focus instead on transient analysis. As a matter of fact, consistency and unbiasedness of the estimates produced by **autoBM** and **autoRD** rely on the underlying process possessing the *strong mixing* property. \(^\text{18}\) Indeed, once normality of batch means in **autoWarmup** is well approximated and autocorrelation is low, we can be confident that future observations will not have initialization bias (Steiger et al., 2005). If at a certain point in time the batch means resemble a sample of IID observations from the same Gaussian population, then the effects of initial conditions must have disappeared. Further, the strong mixing assumption ensures that such a point in time can eventually be reached by increasing the batch size (Law and Carson, 1979; Steiger and Wilson, 2001). Figure 4 depicts a procedure that combines **autoRD** and **autoBM** to assess whether this assumption is met. We have fully implemented this procedure, allowing for its validation in Section 7 on variants of a prediction market model.

The procedure is as follows. We start performing both **autoBM** and **autoRD** for given \(\alpha\) and \(\delta\) (step 1). If any of the two fails to converge in due time (step 2), we have evidence that the process is eventually non-stationary (or fails to reach its stationary phase within the allotted computational time/resources). In such cases, performing any steady-state analysis could be misleading and should be avoided (step 3). If both **autoBM** and **autoRD** successfully terminate, we can be confident that the process possesses *ergodic properties* (Gray, 2009; Billingsley, 1995) – meaning, intuitively, that the horizontal means of its realisations (i.e., the means across simulations as in Figure 1(c)) indeed converge asymptotically to a finite number (see also Seri and Martinoli, 2021). However, there could be potentially different limits for different simulations. In these cases, a natural check for ergodicity is to compare the results of **autoBM** and **autoRD** (step 4). This is in line with previous approaches to ergodicity analysis from the literature (e.g., Grazzini, 2012), where BM-like means across one long simulation are compared with RD-like means across several simulations. The difference is that our BM and RD results are obtained using automated algorithms (**autoBM** and **autoRD**), rather than from arbitrarily parametrized experiments. Our test, performed in step 4, checks whether the difference between BM and RD estimates is larger in absolute value than the \(\delta\) used for CI implementation. If this is the case, we have evidence of non-ergodicity and therefore of violation of the strong mixing assumption (step 6). For example, this could be due to the presence of multiple stationary points in the process: **autoBM** would end up exploring only one of such stationary points, while **autoRD** would provide averaged information on the possible realizations. If the difference between BM and RD estimates is small, we have no evidence that the assumption is violated and we

---

\(^{18}\)The strong mixing property guarantees that two sufficiently distant observations in \((Y_t)_{t>0}\) are approximately independent, e.g., any correlation among them is negligible. There are various definitions of the property; we utilize the \(\phi\)-mixing definition provided in Steiger and Wilson (2001)
proceed with a second test on the horizontal means of autoRD (step 5). Indeed, under the null hypothesis that the process is strongly mixing and that the initial warmup phase has been effectively discarded, the central limit theorem for weakly correlated variables states that the horizontal means should be approximately normally distributed. In particular, we perform an Anderson-Darling normality test (with significance level 1%) on the sample of horizontal means. If the null hypothesis is not rejected we again have no evidence of violation of the strong mixing assumption, and we therefore return the values computed by either of the two algorithms (step 7).

5. Transient analysis of a large macro ABM

5.1. The macro ABM of Caiani et al. (2016)

The model has been developed to bridge the stock-flow consistent approach (SFC; Godley and Lavoie (2006)) with the macroeconomic agent based literature (see, e.g., Delli Gatti et al., 2005; Cincotti et al., 2010; Dosi et al., 2010; Dawid et al., 2019; Popoyan et al., 2020). It depicts an economy composed of households selling their labour to firms in exchange for wages, consuming, and saving into deposits at (commercial) banks. Households own shares of firms and banks in proportion to their wealth, and receive a share of profits of the firms and banks as dividends; they also pay taxes as set by the Government, which runs fiscal policy. There are two categories of firms. Consumption firms produce a homogeneous good using labour and the capital goods manufactured by the other class of firms: capital firms. Firms may apply for loans in order to finance production and investment. Retained profits enter the financial system as deposits of the banks. Banks provide credit to firms, buy bonds issued by the Government and need to satisfy mandatory capital and liquidity ratios. Finally, a Central Bank holds reserve accounts of the banks and the government account, accommodates the demand of banks for cash advances at a fixed discount rate, and possibly buys government bonds that have not been purchased by banks.

Here we focus on two key indicators of economic activity: the unemployment rate, and the bankruptcy rate of business firms. They have been chosen because of: (i) the relative large fluctuations they exhibit during the transient dynamics (see Figure 2 in Caiani et al., 2016), which we aim at reproducing and testing and (ii) their well known role as proxies of the health of an economy at macro and micro level, respectively. We sketch how these two quantities are modelled by Caiani and co-authors while leaving the additional details about the model to the original paper.

The labour market is composed of workers, firms, and the public sector. Firms in the capital good sector (indexed by \(k\)) demand workers based on their desired level of production \(y^{D}_{rt}\) and the productivity of labour \((\mu_N)\), which is assumed to be constant and exogenous:

\[
N_{kt}^{D} = \frac{y^{D}_{rt}}{\mu_N} \quad (4)
\]

Differently, the request of workers by consumption good firms (indexed by \(c\)) is given by

\[
N_{ct}^{D} = u^{D}_{ct} \kappa_{ct} \quad (5)
\]

where \(\kappa_{ct}\) is the capital stock, \(l_k\) is a constant expressing the capital-to-labour ratio and \(u_{ct}\) is the utilization capacity needed to obtain the desired production. Workers can be fired under two circumstances: workers in excess of production needs are randomly sampled from the pool of firm employees and fired, and workers can lose their job because of

\[\text{19}\text{A rather detailed overview of the macro ABM literature can be found in Fagiolo and Roventini (2017) and Dosi and Roventini (2019).}\]

\[\text{20}\text{Of course, all variables present in the original model could be analysed using the very same procedure; we selected two for illustrative purposes.}\]
an exogenous positive employee turnover (a fixed share of workers is fired in every period). Finally, a constant share of households are employed by the public sector and public servants are also subject to an exogenous turnover.

After having planned production, firms and the government interact with unemployed households on the labour market. Workers follow an adaptive heuristic to set the wage they ask for: if over the year (i.e., four periods), they have been unemployed for more than two quarters, they lower the asked wage by a stochastic amount. In the opposite case, they increase their asked wage. The share of workers that is not employed at the end of each session of interaction in the labour market represents the prevailing unemployment rate.

After production, firms sell their products and need to compensate for the inputs they received. Firms may default when they run out of liquidity to pay wages or to honour the debt service. Defaulted firms are bailed-in by households (who are the owners of firms and banks and receive dividends) and depositors, as the authors seek to maintain the number of firms constant. Hence, the bankruptcy rate emerges as the ratio between defaulted firms before the bailing-in event and the total number of firms in the economy. As the defaulted firms create non-performing loans that might trigger vicious cycles and - ultimately - a financial crisis, they offer key information on the turbulence and riskiness of the business cycle.

5.2. Transient analysis with autoIR: automatic computation of confidence intervals

The model is run in its baseline configuration considered in Section 5.1 of Caiani et al. (2016). The artificial time series show the model first experiences a sequence of expansionary and recessionary regimes, then converging, in most cases, to a relatively stable behaviour where aggregate variables (including the unemployment and the bankruptcy rates) fluctuate around particular values, and nominal aggregates grow at similar rates. Our focus is centred on the first part of this process.

As a first exercise, we reproduce (Figure 5) the behaviour of the economic indicators we selected in the first 400 steps of the simulation, as done in the original paper, and construct CIs around their mean according to Equation (1). In particular, we choose \( \alpha = 0.025 \) and set \( \delta \) at the maximal allowed width of the confidence intervals around our central estimates (i.e., \( \delta_U = 0.005 \) for the unemployment rates and \( \delta_B = 0.5 \) for the average bankruptcies) and let autoIR automatically decide the number of simulations needed to obtain the desired confidence intervals. We deem \( \delta_U = 0.005 \) and \( \delta_B = 0.5 \) to offer an adequate precision because, as shown in Figure 5, the unemployment rate goes...
We stress that our algorithms automatically determine the number of runs required to obtain the desired CI for each point in time and for whatever variable of interest. As shown in the top of Figure 6, this required at most 378 simulations for both properties.

As a concept-proof of our approach, the inspection of Figure 5 confirms that our algorithms do not modify the model and deliver the same dynamics (see Figure 2 of Caiani et al., 2016). However, Caiani et al. (2016) performed 100 simulations for all the 400 time steps, without providing information on the obtained confidence intervals.

The ability to specify the precision of the confidence intervals comes with a number of advantages. First, it is a flexible requirement that can be expressed either in absolute or relative terms (see Section 3), leaving the chance to statistically compare the expected behaviour of the model to a certain target (say, an employment rate not higher than 5% or an inflation rate of 2%) or to its mean (e.g., allowing one to compute for each period the probability to observe bankruptcy rates 10% higher than the average). Second, and more relevantly, it allows evaluating the robustness (and the uncertainty) of the dynamics simulated by the model. In particular, Figure 6 shows how the absolute width of the confidence intervals vary, for each time point and property, across the simulation span for various number of simulations. The top row shows the intermediate CI widths obtained after every iteration of the blocks of simulations performed by our approach (see the discussion in Section 3.1.1 - we use $bl = 42$). We note that the widths decrease at

---

21 We highlight that the artificial time series we generate are somehow comparable to Figure 2 of Caiani et al. (2016); however, Caiani et al. apply a bandpass filter over their series and just show the emerging trend component. Contrarily, we show the “raw” series that the model generates. We notice that the latter is the prevailing practice in the literature (see for example the models reviewed in Fagiolo and Roventini, 2017).
every iteration, and that some time points (from 100 to 200) require more simulations than the others to get the desired CI width. The two top figures also show that the unemployment rate required only a few iterations of simulations to obtain the required CI widths for all time points, while the bankruptcies required up to 9 iterations. Instead, the bottom of the figure compares the CIs obtained by our approach (in green) against those obtained using the setting of the original paper (i.e., 100 simulations for all time steps, in red). We note that, apart for the first time points which present very low variance, our CIs computed tend to be homogeneous and close to the required δ, demonstrating that the minimum number of simulations are computed for the given δ. Instead, the setting used by Caiani et al. (2016) might lead to CIs of different widths which follow the trend of the computed means. This is particularly evident for the case of bankruptcies of firms, cf. Figure 6 (bottom-right), while the same does not happen for unemployment rates (bottom-left of the figure). The figure suggests that each property and time point should be studied using its own best number of simulations, confirming that a trade-off between an insufficient and an excessively large number of simulations exists. When this is too low the across-runs variability might not be adequately washed-out and the representation of (stochastic) uncertainty could depend on the level of the relevant variable; conversely, when the number of simulations is too large, simulations are redundant and the same representation of uncertainty can be effectively offered saving computational time. Finally, in line with Secchi and Seri (2017), the right-hand panels of both figures confirm that the arbitrary choice of n = 100, which is common in the literature (see the discussion in Sections 1 and 2), is unjustified by the properties of the model itself.

5.3. Experiment comparison and statistical testing: A behavioural experiment

The second exercise we perform uses the confidence intervals (and the means, variances and number of samples computed by our algorithms) to automatize a series of tests that identify statistical differences across model configurations discussed in Section 3.1.2. Indeed, one of the most common approaches in the macro ABM literature is to focus on key parameters or mechanisms of interest and test how the dynamics of the model respond to changes. The difference across experiments is tested comparing the value of some statistic of interest (e.g., the growth rate of output) - usually averaged over the entire time span - by means of t-tests (e.g., in Dosi et al., 2015; Popoyan et al., 2020). Obviously, the ability of the test to discern across experiments and to validate the counterfactual policy intervention is affected by the choice of n, as an insufficient number of runs is likely to make model configurations (i.e., experiments) difficult to distinguish. Even further, it is not infrequent that statistical tests about differences across experiments are completely missing (see, e.g., Cincotti et al., 2010; Caiani et al., 2019), which weakens the potential of the paper and the eventual policy recommendations.

Our techniques provide an automatic series of t-tests across experiments, where the expected value of any variable of interest in any pre-determined set of experiments is tested against a baseline configuration for each step of the transient period. As discussed in Section 3.1.2, tests are run post-mortem and consist in Welch’s t-tests (Equation (2)), whose power can be computed with respect to a minimum distance ε between the means that the test is expected to detect (Equation (3)). Figure 7 shows the results in our testbed macro ABM, evaluating the effects that changes in the degree of risk aversion of agents (C) produce on the number of bankruptcies. Caiani and co-authors show that when the risk aversion of the agents increases, the economy tends to completely avoid the recession phase experienced in the baseline configuration. While they did not offer a statistical analysis of these differences, our approach automatically embeds it. In particular, we contrast model behaviours across the baseline value of C and a 50% increase of the latter. The two top-plots of Figure 7 show the results of our tests comparing the set-up of the original analysis (i.e., with

22These experiments are repeated in Appendix B.2 using the u-test rather than the t-test.
(a) CIs width for $\alpha = 0.025$ and $N = 100$ simulations. T-tests “are means point-wise equal?” not rejected for significance $a_w = 0.025$

(b) CIs width for $\alpha = 0.025$ and $\delta = 0.5$. T-tests “are means point-wise equal?” not rejected for significance $a_w = 0.025$

(c) Power of t-test in (a) for difference $\varepsilon = 0.5$

(d) Power of t-test in (b) for difference $\varepsilon = 0.5$

Figure 7: Evolution of bankruptcies for two different risk aversions $C$ for consumption firms: are they point-wise equal? The left-column considers an analysis setup involving $n = 100$ simulations for each time point, while in the right-column we let our algorithms find automatically the correct $n$ for each time point. The top-row provides the confidence intervals of the estimations computed for the two values of $C$. The same row also provides results of the t-tests on the results obtained for the two values of $C$ (where yellow dots denote initial steps with variances so small to get intermediate results below the numerical tolerance of our implementation of the test, 1E-15). The bottom row shows the power of the computed t-tests.

$n = 100$ for all properties and time points, left column) to our approach ($n$ automatically determined for each property and time point, right column). In each plot we compare the estimated average bankruptcies obtained for the two values of $C$ (we show the CIs rather than the actual estimations, which are the centre of the CIs) and show the results of the t-tests. While increasing risk aversion delays the peak of bankruptcy rates, we find that, independently on the analysis set-up (the choice of $n$), no statistical difference between the two experiments is found but for the central part of the simulation, that is when the economy first experiences a deep crisis and then recovers (see Figure 2 in Caiani et al., 2016). This suggests that doubling risk-aversion modifies the shape of the crisis (smoother surge of bankruptcies and slower decline) but not its existence nor duration, partially contradicting the original results. $^{23}$

$^{23}$We also highlight that our approach identifies a statistically significant difference between the two experiments for the slight increase in
Though using $n = 100$ or our approach (left- and right-column of Figure 7, respectively) makes little difference in terms of type 1 errors, a key advantage is evident when comparing powers of t-tests provided in the bottom-plots of Figure 7. Indeed, our setup (right-column) guarantees a much higher power of the tests, thereby reducing dramatically the chance of not rejecting the null hypothesis of equality across experiments when it is actually false (see also Secchi and Seri, 2017). Further, our approach delivers - for given significance $a$, and setting $\varepsilon$ equal to the $\delta$ used for the transient analysis - a good and stable power across the simulation horizon, i.e., above 0.8, which is usually considered an acceptable threshold in the applied statistics literature (see, e.g., Secchi and Seri, 2017; Cohen, 1992; Lehr, 1992). This comes by the fact that for each property and time point, we run the correct number of samples to obtain a constant width of the CI embedded in the choice of $\delta$ (and by the assumption that the minimum difference we want to detect – $\varepsilon$ – is equal to $\delta$). Indeed, it is interesting to note how the t-test for bankruptcies obtained for the setting with 100 simulations (Figure 7 bottom-left) has a low power which appears to decrease specularly to how the corresponding CI width increases in Figure 6 (bottom-right). Hence, we can derive a rule of thumb to support the modeller’s choice of the two free parameters in a set-up that compares different experiments: first of all, $a$, can be set equal to the $\alpha$ used for the transient analysis, from 5% to 1%, whose extrema are the most diffused levels of statistical significance in the social sciences. Then, by setting $\delta$ in the transient analysis equal to the $\epsilon$ of interest, we expect to obtain t-tests with good power. If this is not the case, one can perform the transient analysis for smaller values of $\delta$ while keeping constant $\epsilon$. In case the maximum budget of simulations that have been originally chosen does not allow to meet such conditions, a trade-off exists in accepting an higher chance of type II error (not detection of false negatives) and the computational resources at disposal of the modeller. However, we stress that while increasing the size of the simulation exercise might come at the expenses of computational time, the proposed tool automatically parallelise model’s runs to speed-up the analysis. Appendix F shows the efficiency of our approach in parallelizing tasks.

5.4. Experiment comparison and statistical testing: A policy experiment

Macro ABM are ubiquitously employed to perform ex-ante policy experiments. Just to make few examples, Dosi et al. (2015) compare a series of rules for monetary and fiscal policy, Lamperti et al. (2020) explore feed-in tariffs and R&D subsidies, and Caiani et al. (2019) extend the model analysed in this section to study various progressive tax schemes and their effects on growth and inequality. Here we focus on a fiscal policy exercise where we let vary the tax rate that the government charges on gross incomes of households and study the economy-wide effects of such alternative policies, leaving government spending unaltered. Similarly to the previous section, we employ the means, variances, confidence intervals and number of runs from each experiment to provide pairwise t-tests comparing the baseline to alternative tax regimes. Results are shown in Figure 8. First, we notice that cutting and raising the income tax rate induce asymmetric effects. Higher taxes with respect to the baseline (i.e. 18% vs. 21%) smooth inflation and boost real output in the short run (with a significant difference with respect to the baseline), delaying the rise in bankruptcies that leads to the recession observed in the middle of the simulation; finally, they allow the economy stabilizing on a regime characterized by higher output while statistically indifferent bankruptcy and unemployment business insolvencies between period 200 and 250.

24Figure B.14 provides a similar study for the unemployment rate which confirms the same results, though the discrepancy is less marked.

25We remark that when using the original code and simulation environment (JMAB) of the Caiani et al. paper alone, it is not possible to perform any form of statistical analysis automatically, requiring to process CSV files created by the framework. Our integration of MultiVeStA provides JMAB with analysis capabilities described so far, encompassing both the transient and the steady-state analysis, while leaving the simulation environment unaltered.

26As for the t-tests presented in Figure 7, all t-tests have high power as reported in Figure B.16.
rates. Conversely, lower income taxes (i.e. 18% vs. 15%) spur inflation by raising demand, which leads to over-investment episodes that anticipate the increase in bankruptcies bringing about a longer recession than in the baseline, finally forcing the model to stabilize on a lower output regime with higher bankruptcies.

These experiments let us conjecture that the long-run dynamics of the model are influenced by its transient behaviour, though heterogeneously across “state” variables. This reinforces the urgency of adequate tools to rigorously inspect behaviours of models across the phases of their simulation.

Figure 8: Evolution of bankruptcies (a), unemployment rate (b), real GDP (c) and nominal GDP (d) for three different income tax rate: the baseline 18%, and variations 15% and 21%. Are the two variations point-wise equal to the baseline? For each parametrization we provide the CIs computed by MultiVeStA for the given $\alpha$ and $\delta$. At the bottom of each plot we provide the non-rejected t-tests for equal means of the variations against the baseline 18%. We note that yellow dots in (a) and (b) denote initial steps with variances so small to get intermediate results below the numerical tolerance of our implementation of the test, 1E-15. Moreover, the t-tests are always rejected in (d), and always rejected for case 18 vs 15 in (b).
6. Steady-state analysis in a model of market selection

Here we use our proposed techniques and algorithms to perform a statistical analysis of the steady-state expected value of wealth shares and market price in a simple repeated prediction market model. We consider an accepted ABM model extensively studied in the literature (Beygelzimer et al., 2012; Kets et al., 2014; Bottazzi and Giachini, 2017, 2019b). We believe that it offers a good testbed for our procedures for automated steady-state analysis because its steady-state properties have been investigated by Kets et al. (2014) via simulation-based analysis and, later on, studied analytically in Bottazzi and Giachini (2019b) showing that the numerical results of Kets et al. (2014) were inaccurate both qualitatively and quantitatively. In addition, we can use the analytical solutions from Bottazzi and Giachini (2019b) as an oracle to compare with the results obtained using our algorithms. As briefly reported by Bottazzi and Giachini (2019b) and as we shall see, the source of inaccuracy can be traced back to the strong autocorrelation and initial condition bias that process possesses. The post-mortem, or offline, nature of the numerical analysis carried on by Kets et al. (2014), where the number of steps and of performed simulations is decided a priori while the analysis is performed afterwards, is unable to properly deal with those issues. Our approach, instead, uses statistical tests and procedures able to manage both autocorrelation and the initial condition bias in an automated way. Thus, in what follows, we first introduce the model, then we repeat the numerical analyses of Kets et al. (2014) showing how and why the inaccuracies emerge, and finally we use autoRD and autoBM to accurately perform the steady-state analyses. In fact, we match the correct analytical results from Bottazzi and Giachini (2019b).

6.1. The prediction market model by Kets et al. (2014)

The model consists in a pure exchange economy in discrete time where \( N \) agents repeatedly bet on the occurrence of a binary event. The probability of observing the event is \( \pi^* \) in each period. Such a probability is unknown to agents: each agent \( i \in \{1, 2, \ldots, N\} \) assigns a subjective probability \( \pi_i \) to the realization of the event. Agent \( i \) has initial wealth equal to \( w_{i0} \) and at the end of every betting round it evolves in \( w_{it} \) depending on the results of her betting. Every agent \( i \) bets on the occurrence of the event at time \( t \) a fraction \( \alpha_i^t \) of her wealth \( w_{i,t-1} \), while \( 1 - \alpha_i^t \) is the fraction bet against the occurrence. As in Kets et al. (2014); Bottazzi and Giachini (2017, 2019b), we focus on the so-called fractional Kelly rule, that is

\[
\alpha_i^t = c \pi_i^t + (1 - c) p_t ,
\]

with \( c \in (0, 1] \) and \( p_t \) the price at time \( t \) of the security paying 1 if the event occurs. Security prices are fixed in every period according to market clearing conditions or, equivalently, to a parimutuel procedure.\(^{27}\) In this setting, Kets et al. (2014) want to explore the selection dynamics of the model and are particularly interested in the asymptotic (steady-state) value of expected wealth shares and price for \( c \to 0 \). Indeed, they conjecture that in such a limit the steady-state expectation of \( p_t \) matches \( \pi^* \) and use the case \( c = 0.01 \) as a proxy.

In Section 6.2, we replicate exactly the analysis of Kets et al. (2014), reproducing their Figures 3(c) and 3(d). Thus, we follow the procedure proposed in Kets et al. (2014) to estimate steady-state expected wealth shares and price for several values of \( \pi^* \) under the parametrization in Table 1, where we stress that we have \( N = 3 \) agents. In doing that, we highlight some issues related to initial condition bias and strong autocorrelation. Indeed, the warmup period appears not correctly determined, and the autocorrelation within the observations of each performed simulation not correctly accounted for. This is due to the procedure for computing CIs used in Kets et al. (2014) and has the result of producing extremely wide CIs.

\(^{27}\)See Appendix C for the details of the model. Notice that the mathematical specification we use may appear different from the one presented in Kets et al. (2014). However, as explained in Bottazzi and Giachini (2019b), the two specifications are indeed equivalent.
After this, in Section 6.3, we perform the steady-state analyses using our approach. We show that, thanks to the provided automatic procedures, our estimates (and the corresponding confidence intervals) of steady-state expected wealth shares and price are correctly determined. Our conclusions differ not just quantitatively, but also qualitatively from those in Kets et al. (2014), and match those from Bottazzi and Giachini (2019b). Overall, our analysis shows the importance of using an automated procedure provided with statistical guarantees.

### 6.2. Steady-state analysis with manualRD using original wrong warmup estimation

In order to replicate exactly the erroneous analysis in Figures 3(c) and 3(d) of Kets et al. (2014), we implemented also a manual version of autoRD named manualRD which allows one to manually set an a-priori estimate of the warmup period, and to fix the maximum number of simulations used in an analysis based on independent replication. In general it is always advisable to do not fix such parameters a-priori, but to use the offered automated procedures so to avoid bias in the estimates and excessively large CIs. In this section we exemplify these issues by fixing a priori the erroneous warmup estimate and number of simulations used in Kets et al. (2014), and discuss the problems this introduced in the obtained results.

Kets et al. (2014) performed an RD-based steady-state analysis of the wealth of the agents \((w_1, w_2, w_3)\) and market price \(p\) using the parametrization of Table 1. The authors arbitrarily estimated the end of the warmup period after 90,000 steps, and fixed the time horizon of each simulation to 100,000 steps and the number of performed simulations to 1,000. This means that estimates were computed averaging the last 10,000 observations in each simulation (the horizontal means of Figure 1(c)) and then further averaging the so-computed means from each simulation (the vertical means). We shall see how this led to estimates highly biased by the initial conditions.

Regarding computations of confidence intervals, Kets et al. (2014) did not follow the standard approach relying on the central limit theorem used by our approach. Rather, Kets et al. (2014) considered how the above discussed 1,000 averages built for each simulation distribute. In particular, the 5-th and 95-th percentiles of such distribution are taken as the bounds of confidence intervals with 10% statistical significance. The problem with this approach is that, differently from ours, it is based on the assumption that each of the considered 1,000 averages has the same distribution of an average across independent replications computed at a time \(t\) large enough to have reached steady state. This is not correct because, as well as the initial condition bias, the process is characterized by strong autocorrelation. We shall discuss how this led to erroneous interpretation of the results.

#### Wealth of the agents

In Figure 9 we report the outcomes of the exercise replicating those from Figures 3(c) and 3(d) in Kets et al. (2014) considering model variants for 39 different values of \(\pi^*\). Looking at the left panel one should conclude that there exist model configurations in which all agents have strictly positive expected wealth share in steady state. This is, however, in contrast with the analytical analysis from Proposition 4.1 of Bottazzi and Giachini (2019b), which proves that no more than two agents can have asymptotic positive wealth share. Thus, the fact that Kets et al.

| Beliefs | Wealth |
|---------|--------|
| N       | c      | \(\pi^1\) | \(\pi^2\) | \(\pi^3\) | \(w^1_0\) | \(w^2_0\) | \(w^3_0\) |
| 3       | 0.01   | 0.3      | 0.5      | 0.8      | 0.33   | 0.33   | 0.34   |

Table 1: Parameters used for the prediction market model.

---

28See also Appendix E.3.
Figure 9: Steady-state analysis of expected agents’ wealth and market price according to the manual warmup and simulation length settings of Kets et al. (2014). We obtain these results by setting the end of the warmup periods to 90,000, and the time horizons to 100,000. By setting both \( R \) (the number of simulations in a block) and the maximum number of simulations performed to 1,000, we use precisely 1,000 simulations to estimate each property, perfectly matching the setting used in Kets et al. (2014). We consider 39 equally spaced values for \( \pi^* \), from 0.025 to 0.975, each requiring a separate MultiVeStA analysis on a correspondingly parametrized instance of the model (we automated this process using an external Octave script). Confidence intervals computed by MultiVeStA for agents’ wealth, not reported in the left panel, are such that the maximum recorded width for a statistical confidence of 90% is below 0.0025. Confidence intervals for the market price are reported in the right panel, with maximum recorded width below 0.00065 for statistical confidence of 90%.

(2014) incorrectly suggest that more than two traders can have positive expected wealth in steady state is an artefact of the initial condition bias that affects their analysis. Notice that the convergence to zero of the wealth share of at least one trader is asymptotic, thus wealth shares show a bias for any \( t \). However, such bias decreases with \( t \) and can be made negligible choosing a sufficiently long warmup and simulation length. What we observe is that discarding the first 90,000 observation of every run is simply not enough.

Market price. The right panel of Figure 9 shows the average price and should support one of the main results of Kets et al. (2014): the expected market price matches \( \pi^* \) when \( c = 0.01 \) and \( \pi^* \) is strictly between the lowest and the highest beliefs of the agents. Bottazzi and Giachini (2019b) suggest that such a conclusion is not correct and the source of inaccuracy should be found in the way in which CIs are built by Kets et al. (2014). In order to better understand this aspect, we create a new plot in Figure 10 focusing on the difference between market price and \( \pi^* \). In the left panel of the figure we report the CIs (dashed lines) obtained by applying the procedure of Kets et al. (2014), while in the right panel we show those obtained by following our approach. As one can notice, the procedure of Kets et al. (2014) produces large CIs, backing the claim of the authors. Instead, the CIs obtained by our approach based on the central limit theorem are much tighter and disprove the claim of the authors. To understand the source of disagreement between the two approaches, consider the following argument: if the 10,000 observations of \( p_t \) from each simulation used to compute the average price of every replication were independent and at steady state, then we would not have spotted any significant difference. Indeed, according to the Central Limit Theorem, we have that each time average is (approximately) distributed as a normal random variable with mean the steady-state expectation of the price and variance the steady-state variance of price over \( \sqrt{10,000} \). The initial condition bias lets the expected time average be different from the steady-state expectation. The strong autocorrelation in the price process (Bottazzi and Giachini, 2019b) lets confidence intervals be too wide. While the manualRD procedure used here can do nothing about the initial
Figure 10: Estimates of steady-state difference between the expected price and \( \pi^* \) using the settings from Figure 9. We consider 49 equally spaced values for \( \pi^* \), from 0.31 to 0.79. The dashed lines are CIs built using two different procedures. Left: CIs are erroneously computed according to the procedure in Kets et al. (2014). Right: CIs as computed by MultiVeStA using the approach based on the central limit theorem. MultiVeStA does not allow for the procedure of Kets et al. (2014), hence the left panel has been produced by an external Octave script. The different pseudo-random number generator is responsible for the small discrepancies in estimated steady-state values with respect to the right panel.

condition bias, with respect to confidence intervals our approach does not assume anything about the distribution of time averages, simply relies on the Central Limit Theorem. Indeed, the average across 1 000 independent replications of the 10 000-period time averages is (approximately) distributed as a normal random variable with variance the one of the time averages over \( \sqrt{1 000} \).

This exercise shows the importance of correctly building confidence intervals when testing hypothesis on steady-state quantities from simulated models. We proceed showing that setting the required statistical significance (\( \alpha \)) and confidence interval width (\( \delta \)) instead of the total number of independent replicas is a much more reliable and efficient procedure to test hypotheses on steady-state expectations.

**Market price for different \( \alpha-\delta \)**. In Figure 11, we test the hypothesis from Kets et al. (2014) that no difference between the average price and \( \pi^* \) exists under the parametrization in Table 1. We use again manualRD keeping the same, erroneous, settings for warmup estimation and time horizon discussed in advance, while we do not impose a maximum number of simulation, which is therefore automatically chosen according to Equation (1) for the different values of \( \delta \) (0.002, 0.001, and 0.0005), for \( \alpha = 0.025 \) (i.e., a statistical confidence of 97.5%). If the hypothesis from Kets et al. (2014) were correct, the difference should be almost never significantly different from zero for any \( \delta \) considered. Instead, we notice that \( \delta \) plays an important role in assessing the hypothesis testing outcome. Indeed, while with \( \delta = 0.002 \) the computed CIs for the difference among market price includes 0 for almost all \( \pi^* \), with \( \delta = 0.001 \) the CIs almost never includes 0. This confirms the point of Bottazzi and Giachini (2019b) and the results we have obtained in Figure 10 right panel: the hypothesis of no difference between the average price and \( \pi^* \) is generically rejected. Focusing on \( \delta = 0.0005 \) and looking at the number of required simulations, one notices that there exist cases in which the hypothesis that no difference between the average price and \( \pi^* \) exist can be rejected with less than 1 000 simulations.\(^{29}\) In other cases, instead, 1 000 independent replications are not enough and one may risk to get to the

\(^{29}\)This is typically the case at the extrema, indeed 0.31 and 0.79 require, respectively, 420 and 480 replicas.
Figure 11: Estimates of steady-state difference between the expected price and $\pi^*$ using the settings from Figure 9 for warmup estimation and time horizon. The number of simulations is automatically chosen by MultiVeStA according to the used values of $\delta$, for $\alpha = 0.025$. As in Figure 10, we consider 49 equally spaced values for $\pi^*$, from 0.31 to 0.79. Left: $\delta = 0.002$, the number of simulations varies between 60 and 120. Center: $\delta = 0.001$, the number of simulations varies between 120 and 360. Right: $\delta = 0.0005$, the number of simulations varies between 420 and 1440.

Figure 12: Steady-state levels of average wealth shares. Left: autoRD. Right: autoBM. We set $\alpha = 0.025$ and $\delta = 0.001$, while we consider 39 equally spaced values for $\pi^*$, from 0.025 to 0.975, each one of these points requires a separate MultiVeStA analysis that has been invoked and aggregated with the others by means of an external Octave script.

A wrong conclusion simply because of an insufficient number of replicas. 30

Notice, however, that due to the arbitrary choice of the end of the warmup period, all the estimates are biased by the initial conditions. We next use our automated steady-state analysis techniques (autoRD and autoBM) to accurately estimate steady-state expectations and to finally assess on such obtained results the hypothesis of Kets et al. (2014).

6.3. Steady-state analysis with autoRD and autoBM using automatic warmup estimation

Now we repeat the exercises using our proposed automated algorithms for steady-state analysis. 31

Wealth of the agents. Our results are displayed in Figure 12. In the left panel we use the RD approach (autoRD) while on the right we use the BM one (autoBM). As one can notice: i) our results comply with the theoretical and

---

30 This may occur for $\pi^*$ around 0.55, where our algorithms need 1440 simulations to reach the required interval width.

31 In Appendix D we compare the results showed here with those obtained replacing the default Anderson-Darling normality test with the Cramer-Von Mises test. No remarkable differences are spotted.
numerical ones of (Bottazzi and Giachini, 2019b, cf. Figure 7) and ii) no significant difference can be spotted between the two pictures. Hence, our automated procedures allow one to avoid (or, at least, reduce) biases generated by initial conditions. As a practical example, let us consider the statistical analysis of steady-state expectations for \( \pi^* = 0.6 \). The \texttt{manualRD} procedure, using the settings from Section 6.2, estimates the expected wealth share of agents 1, 2, and 3 to, respectively, 0.089, 0.519, and 0.392. Instead, \texttt{autoRD} and \texttt{autoBM} estimate the expected wealth shares to, respectively, 0.668, and 0.332, in agreement with the results from Bottazzi and Giachini (2019b). Looking at the estimated warmup end, our algorithm proposes values much higher than the threshold set by Kets et al. (2014), see Figure D.19 in Appendix D. This confirms how manually setting the warmup end to 90,000 generates a large initial condition bias in the estimation of steady-state expectations of the wealth of the agents. Our analysis, other than correctly estimating steady-state expected wealth shares, clearly highlights the source of inaccuracy in the exercise of Kets et al. (2014), and stresses the importance of using a reliable automated procedure to pursue steady-state analyses.

While there are no significant differences in the estimates generated by \texttt{autoRD} and \texttt{autoBM}, the time required for producing them changes. Indeed, the analysis runtime of \texttt{autoRD} (using parallelism degree 3) is about 3 times that of \texttt{autoBM}. As discussed in Section 3.2.4, cases like this with large warmup periods tend to favour \texttt{autoBM}.

\textbf{Market price}. Next, we estimate the expected value in steady state of the market price. As we did in Figures 10 and 11, in order to magnify confidence bands in Figure 13 we show our estimates of the difference between the expected price and \( \pi^* \) for different values of \( \pi^* \in (0.3, 0.8) \). In the left and right panels we show the \texttt{autoRD} and \texttt{autoBM} results, respectively. We notice that, for any value of \( \pi^* \) considered, the estimated difference between the expected price and \( \pi^* \) does not change in a significant manner between the two plots. The emerging expected difference presents a clear pattern: it is larger (in absolute value) when \( \pi^* \) is close to the belief of one of the agents. Moreover, the expected difference appears to be negative when \( \pi^* \) is closer to the belief of the agent whose belief is, relatively, the smallest (i.e., among the surviving ones) while it tends to be positive when it is the other way round. These features are in line with the results obtained by Bottazzi and Giachini (2019b) in Figure 4. Hence, the reliability of the steady-state analysis performed by our techniques is confirmed. Moreover, we can conclude that, contrary to what Kets et al. (2014) argue, the steady-state value of the average price does not generally match \( \pi^* \) when \( c = 0.01 \).
The analysis presented in Section 6.3 satisfies all tests of the methodology for ergodicity diagnosis from Section 4, confirming the reliability of the analyses. We show in the next section examples of analysis where this does not hold.

7. Ergodicity diagnosis in a CRRA prediction market model with noise

We apply our methodology for ergodicity diagnosis to variants of the prediction market model. For all analyses we set $\alpha = 0.05$ and $\delta = 0.01$.

7.1. Three variants of the prediction market with 2 CRRA traders: IID noise, AR noise, ergodic

Here we modify the model studied in the previous section to allow violations of the ergodicity assumption. Following Bottazzi and Giachini (2019a), it is enough to assume that in the market there are $N = 2$ traders who bet maximizing their next-period CRRA utility to obtain non-ergodic price and wealth dynamics. Such a different behavioural assumption changes the betting rules. Indeed, we keep the assumption that agents 1 and 2 have heterogeneous beliefs ($\pi_1^t$ and $\pi_2^t$, respectively, with $\pi_1^t < \pi_2^t$) and we add risk preferences, assuming that the relative risk aversion coefficient of agent $i$ is $\gamma_i > 0$, with $i = 1, 2$. Thus, we replace Equation (6) with

$$a_1^t = (1 - b_1^t)p_t \quad \text{and} \quad a_2^t = (1 - b_2^t)p_t + b_2^t,$$

where

$$b_1^t = \frac{(p_t(1 - \pi_1^t))^\frac{1}{\gamma_1} - \pi_1^t(1 - p_t)^\frac{1}{\gamma_1}}{(p_t(1 - \pi_1^t))^\frac{1}{\gamma_1} + p_t(\pi_1^t)^\frac{1}{\gamma_1}(1 - p_t)^\frac{1}{\gamma_1}},$$

and

$$b_2^t = \frac{(\pi_2^t(1 - p_t))^\frac{1}{\gamma_2} - (p_t(1 - \pi_2^t))^\frac{1}{\gamma_2}}{(\pi_2^t(1 - p_t))^\frac{1}{\gamma_2} + (1 - p_t)(1 - \pi_2^t)^\frac{1}{\gamma_2}(p_t)^\frac{1}{\gamma_2}}.$$

Bottazzi and Giachini (2019a) show that, depending on the values of the parameters – in particular $\gamma_1$ and $\gamma_2$ – several long-run selection scenarios are possible. Indeed, one can generically have that: i) one of the two agents has asymptotic unitary wealth share, ii) both agents maintain positive wealth share asymptotically, iii) path dependent scenarios in which either agent 1 obtains unitary wealth share asymptotically while agent 2 loses everything or vice-versa. Focusing on the market price $p_t$, in case i) $p_t$ converges to $\pi^t$ (with $i$ the dominating agent), in case ii) $p_t$ fluctuates in the interval $(\pi_1^t, \pi_2^t)$, and in case iii) $p_t$ either converges to $\pi_1^t$ or to $\pi_2^t$ depending on the particular sequence of events realized. Case iii) is the one we are interested in: in such a case the ergodicity assumption is violated. However, the asymptotic convergence of the price to one out of two points makes quite easy to spot the lack of ergodicity and the presence of the two possible long-run price values. Hence, we complicate the setting assuming that there exists a third agent in the model who does not trade nor interacts in any way with agents 1 and 2. He simply observes the price and reports it. Such report is, however, noisy. Defining $\tilde{p}_t$ the price such external agent reports, we assume $\tilde{p}_t = p_t + \nu_t$ with $\nu_t = \theta \nu_{t-1} + u_t$ and $u_t$ a uniformly distributed random variable; $u_t \sim \mathcal{U}(-\eta, \eta)$, $\eta > 0$. Such price reports are not taken into account by agents 1 and 2, hence all the properties of $p_t$ deriving from the analysis of Bottazzi and Giachini (2019a) remain unaffected. Moreover, $\nu_t$ is an autoregressive process of order 1 with zero mean. Hence, assuming $|\theta| < 1$, we have that in the long-run $\tilde{p}_t$ fluctuates around either $\pi_1^t$ or $\pi_2^t$ depending on the sequence of realized events. Thus, the lack of ergodicity $\tilde{p}_t$ shows is somehow “well-behaved”. That is, if one isolates the sequences in which $p_t$ converges to a given $\pi^t$, one will obtain that the time averages (i.e., horizontal means) of the relative observations of $\tilde{p}_t$, for $t$ large enough, are approximately normally distributed with mean $\pi^t$. Hence, we can say that $\tilde{p}_t$ presents two stationary points. At the same time, studying ergodicity of $\tilde{p}_t$ is much more complicated than performing the same tasks on $p_t$. In what follows, we set $\eta = 0.5$ and consider two scenarios for $\theta$. In the first one, we consider $\theta = 0$. We refer to it as “IID noise” scenario, since we have that, in the long-run, the fluctuation described
by \( \hat{p}_t \) around either \( \pi^1 \) or \( \pi^2 \) are IID. In the second scenario, instead, we consider the opposite case: setting \( \theta = 0.9 \) we analyse the performance of our methodology when the noise is highly autocorrelated. We refer to it as the “AR noise” scenario. Finally, as a robustness check, we apply our methodology to a case in which ergodicity should be ensured. We choose a scenario belonging to case ii): long-run survival of both agents. This makes \( p_t \) fluctuate in the interval \((\pi^1, \pi^2)\) indefinitely. Moreover, we set \( \theta = 0.9 \) as in AR noise. These two assumptions, even if not affecting the ergodic properties of \( \hat{p}_t \), should make relatively harder for our methodology to work. We refer to this case as “Ergodic”. Table 2 summarizes the parametrization used in our analyses. While the setting for IID noise and AR noise scenarios ensure the emergence of multiple stationary points, leading to a non-ergodic scenario, the assumptions for the Ergodic scenario guarantee the persistent fluctuation of \( p_t \) (Bottazzi and Giachini, 2019a).

| Scenario | Beliefs | Risk Aversion | Wealth | Noise |
|----------|---------|---------------|---------|-------|
|          | \( N \) | \( \pi^* \) | \( \pi^1 \) | \( \gamma^1 \) | \( \gamma^2 \) | \( w^1_0 \) | \( w^2_0 \) | \( \eta \) | \( \theta \) |
| IID noise| 2       | 0.45          | 0.2     | 0.5   | 2      | 0.5   | 0.5   | 0       | 0 |
| AR noise | 2       | 0.45          | 0.2     | 0.5   | 2      | 0.5   | 0.5   | 0      | 0.9 |
| Ergodic  | 2       | 0.45          | 0.2     | 0.8   | 2      | 2     | 0.5   | 0.5   | 0 |

Table 2: Parameters used for the prediction market model with CRRA traders and noisy price reporting.

7.2. Application of the methodology for ergodicity analysis

IID noise. We start our analysis by applying autoBM and autoRD to the IID noise case. The former requires 33,792 steps of simulation. It signals that the warmup ends after the first batch of 1,024 steps, and estimates the steady-state mean as 0.498. Instead, autoRD signals that the warmup ends after 1,032 steps. After 2,604 independent replications, it estimates the steady-state mean as 0.426. With reference to our methodology for ergodicity analysis in Figure 4, we performed step 1, and passed the termination check of step 2. After that, step 4 requires to compare the results of autoBM and autoRD. The difference among the two results is larger than \( \delta \), suggesting an ergodicity problem. According to our method, we already have an indication of non-ergodicity. However, for illustrative reasons we also performed the Anderson-Darling normality test on the horizontal means computed by autoRD (step 5), obtaining a p-value equal to 6.092E-251, which allows us to reject the null hypothesis that the horizontal means are normally distributed. Hence, our methodology is able to correctly spot that the IID noisy price lacks ergodicity.

AR noise. We consider now the AR noise case starting with autoBM. The algorithm estimates the warmup to end in 1,024 steps, and the steady-state mean as 0.499. Instead, by performing autoRD we obtain that the warmup is estimated to end after 1,032 steps. The total number of independent replications needed by autoRD to reach the IC width is 2,709, obtaining as result 0.426. Therefore, the two algorithms provide significantly different results for the used \( \delta \), suggesting an ergodicity problem (step 4). This is confirmed by the Anderson-Darling normality test of step 5 which computes a p-value of 1.458E-136, rejecting the normality assumption. Therefore, our methodology is able to correctly spot that also the AR noisy price lacks ergodicity.

Ergodic. Finally, we perform a robustness check on our methodology by applying it to the Ergodic scenario. Using autoBM, the warmup is estimated to end after 1,024 steps producing as result 0.4027. Using autoRD, one gets that the warmup is estimated to end after 1,032 steps.32 The number of independent replications needed for reaching CIs

32As one can notice, the estimated warmup is the same for every model specification we considered. This is due to the shortness of the model’s warmup phase. Thus, our techniques signal that the warmup is over after the first check (which, for implementation reasons, is 1024 steps for
of width $\delta$ is 210, obtaining as result 0.4035. Thus, the two algorithms give results within the tolerance of $\delta$ (step 4).
The normality test from step 5 cannot reject the null hypothesis of normality, as we get a p-value of 0.691. Therefore,
our methodology correctly suggests that no violation of ergodicity is observed.

8. Conclusion

In this article we presented a fully automated framework of techniques and algorithms for the statistical analysis of
simulation models and, in particular, agent-based models (ABM). The framework, that we have implemented in the
statistical analyser MultiVeStA, provides a novel methodological and practical toolkit to the ABM community. These
techniques range from transient analysis, with statistical tests to compare results for different model configurations,
to warmup estimation and the exploration of steady-state properties, including a procedure for diagnosing ergodicity
– and hence the reliability of any steady-state analysis.

Our approach can be easily applied to simulators written in Java, Python, R or C++. We also support JMAB, a
framework for building macro stock-flow consistent ABMs. Our techniques allow modellers to automate the explo-
ration of the models, save time and avoid mistakes originating from semi-automated and error-prone tasks. Impor-
tantly, this facilitates reproducibility of experiments and promotes the use of a minimal set of default analyses that
should be performed when proposing or studying a model.

We validated our approach on two ABMs widely studied in the literature: a large-scale macro financial ABM
and a small scale prediction market ABM (and variants thereof). We obtained new insights on these models, and
we identified and fixed erroneous results from prior analyses. Our framework also allows one to easily parallelize
simulations within the cores of a machine or in a computer network. For instance, we reduced the analysis runtime
for the macro ABM from 15 days to 16 hours on a machine with a CPU with 20 cores. Indeed, our toolkit enables
modellers to run extensive tests in a unique environment (i.e., without the need of exporting data) and optimizing
computational time (which is often precious; see also the discussion in Lamperti et al., 2018).

Our approach is rooted in results from the simulation, computer science and operations research communities,
which we aim to make available to the ABM community. Connecting these communities is critical to leverage the
most effective techniques and approaches across fields. For example, the stationarity analysis proposed by Grazzini
(2012) mentioned in Section 2 can be viewed as a non-automated version of the batch means approach by Conway
(1963) and Law and Carson (1979).

In the near future, we plan to integrate our tool-implementation of the approach, MultiVeStA, with other popular
platforms used to build and analyse simulation models – including the LSD environment for ABMs (Valente, 2008),
the JASMINE environment for discrete-event simulations (Richiardi and Richardson, 2017) and NetLogo (Wilensky,
1999). We see this article as a first step in bringing practices from the statistical model checking (SMC) tool-set from
computer science to the ABM computational economics community. Of particular interest in this respect are SMC
techniques developed to mitigate two classic problems of Monte Carlo methods: dealing with models that present rare
events (Legay et al., 2016), and using machine learning techniques to reduce the number of simulations (Bortolussi
et al., 2015). Finally, we will expand the family of proposed automated analysis techniques. For instance, we will
extend and refine our ergodicity diagnostics procedure, e.g., tackling the problem of identifying multiple stationary
points (assuming they are finitely many) by means of clustering algorithms. Of course, the analysis of an ABM
typically goes beyond estimation of average behaviours as we consider here, which however is often considered as a
necessary first step in ABM analysis. For this reason, we also plan to further improve our proposals for the analysis of simulation output, e.g., by introducing corrections for multiple testing across the time domain, and move beyond it, e.g., by considering bifurcation analysis, sensitivity analysis and parameter calibration, which are prominent in the ABM community. For instance, our methodology for estimating the steady-state average offers a reasonable solution for those who would like to perform sensitivity analyses on models whose target outcome is not (or cannot be) well-specified. Indeed, under the assumptions we make, any parameter setting is uniquely related to a steady-state average of the variable of interest. This connection allows one to perform sensitivity analysis exercises in a well-defined manner. Thus, our methods should be considered instrumental and complementary with respect to other types of analysis, like the global sensitivity analysis of Saltelli et al. (1999).

\[ y = f(x) \]

\[ \text{In the models we consider here, selecting the outcome } y \text{ is not straightforward since we obtain time series as output instead of single values. One may choose a given time horizon and record the value of the variable of interest at that horizon, but this solution appears rather arbitrary.} \]

\[ \text{Notice that the exercises we perform in Figures 9, 10, 11, 12, 13 can be considered as simple local sensitivity analyses in which we observe how the average wealth shares or price change as we increase } \pi^*. \]

Appendix A. Multiple hypothesis problem, a critical discussion

Here we provide a critical discussion on the problem of multiple hypothesis testing in our framework and propose a solution to such an issue when it may negatively affect our results.\(^{35}\) First of all, notice that the multiple comparison problem may occur in three points: when conducting counterfactual analysis in the macro ABM model, when testing for the warmup end, when testing for significant differences between estimated average price at steady state and true expectations of one long run versus independent replications in steady-state simulation.

Concerning the tests we performed to check for significant changes in average dynamics produced by the macro ABM under different parametrizations, we assumed a nominal significance value of \(\alpha\) for each single test. In particular, for each experiment \(T = 400\) statistical tests are conducted. Under independence of tests, the family-wise (series-wise in our case) type-I error is \(1 - (1 - \alpha)^T\). The correlation in time series data may generate dependencies between the test we perform at a given time step \(t\) and the tests we perform for subsequent time steps, invalidating the independence of tests assumption. Standard procedures may still control the family-wise error under positive dependence (Sarkar and Chang, 1997), but more accurate procedures require some information on the underlying data-generating process (see, e.g., Sun and Tony Cai, 2009). Alternative methods are based on the false discovery rate, but they still require independence of test. However, as shown by Benjamini and Yekutieli (2001) and Sarkar (2002), the algorithms of Benjamini and Hochberg (1995) and of Benjamini and Liu (1999) for controlling false discovery rate still work well under positive dependence of tests. Hence, addressing the multiple hypothesis testing problem in a consistent way should require some form of assessment of the dependence structure in synthetic data. A promising approach for our case may be the factor-analysis-based approach of Friguet et al. (2009). We have to notice that a very simple, but rather coarse and a bit time consuming, procedure one can immediately implement in our framework to limit the consequences of multiple testing is controlling if the test results are stable as \(\delta\) decreases. Indeed, decreasing \(\delta\) standard errors become lower and estimates more precise. Thus, the series-wise probability of committing a type-I error in the comparison between the two different settings naturally decreases. Hence, if decreasing the value of \(\delta\) the results provided by the tests remain rather stable, we can provide reasonable conclusions about the comparison without explicitly controlling for the multiple hypothesis testing problem.

The second case in which the multiple comparison problem is potentially affecting our results is when we use statistical tests to assess whether the warmup has ended or not. We argue that such a problem does not invalidate our procedures, it actually makes them more conservative. Indeed, following the previous approaches of Steiger et al. (2005) and Gilmore et al. (2017), we use statistical tests to check whether the distribution of batch means is significantly different from a normal distribution or not. The inflation of type-I error, in this case, implies that we might reject the null of the distribution being normal when it actually is. However, this has the only effect of letting

---

\(^{35}\)See Austin et al. (2014) for a review of the multiple hypothesis testing problem.
us increase the length of the simulation and, thus, of estimating a larger warmup period. Even if potentially costly in terms of computational time, a longer warmup horizon does not negatively affect the estimation of steady-state values.

Finally, the multiple comparison problem may be an issue when we perform significance tests for the difference between average market price and true probability over several different values of $\pi^*$. Here the same caveats discussed in advance concerning the counterfactual analysis apply and observing how the results change as $\delta$ decreases may help to control the multiple testing problem.

Appendix B. Application: Transient analysis of a large macro ABM - more on counterfactual analysis

We present further experiments related to counterfactual analysis for the macro ABM by Caiani et al. (2016).

Appendix B.1. Automatic experiment comparison and statistical testing: unemployment rate

In this section we extend the analysis performed on the macro ABM by Caiani et al. (2016). In particular, we extend the counterfactual analysis done in Section 5.3 for bankruptcies by considering the unemployment rate.

The results are shown in Figure B.14, which has the same structure of Figure 7 from the main text. The figure provides the same study done for bankruptcies for the unemployment rate. The results are confirmed, even though the discrepancy among the dynamics of the two model variants is less marked.
Appendix B.2. Counterfactual analysis with u-test

As discussed in Section 3.1.2, our framework allows for counterfactual analysis on results obtained from two different parametrizations of a model, to decide whether the changes in the parameters led to significant changes in the average dynamics. In particular, we do this for transient analysis by comparing the obtained point-wise average behaviours using Welch’s t-test (Welch, 1947). In the main text, we opted for such test because, as further demonstrated in Section 5, it is possible to compute its power as in Chow et al. (2002). However, there exist further tests for this type of analysis which make weaker assumptions than Welch’s t-test. An example is the so-called Wilcoxon-Mann-Whitney test, or just u-test (Mann and Whitney, 1947). Differently from Welch’s t-test, the u-test does not assume that the two populations being compared are normally distributed, however, to the best of our knowledge, no closed-formula exists for estimating its power.

Despite the asymptotic normality of our random variables (batch means) lets us deem the assumptions underlying the t-test as not too strict in our framework, we also support the u-test. This test can be used for performing counterfactual analyses as those performed in Section 5.3. We hereby reproduce the experiments from Section 5.3 using the u-test rather than Welch’s t-test. The results are depicted in Figure B.15 for bankruptcies (first row) and unemployment rate (second row). The figure considers the settings from Figure 7 (a) and (b) for the first row, and those from Figure B.14 (a) and (b) for the second row. The provided t-tests are those presented in the corresponding original figures.

From the figure we can see that, for the considered macro ABM and analysis of interest, the results of the two tests are very similar.

Appendix B.3. Automatic experiment comparison and statistical testing: Experiment on policy tax rate - Power

In this section we provide the power for the t-tests computed in Section 5.4, and in particular in Figure 8. The power is of the t-tests is shown in Figure B.16. In all cases, the power is high, an in particular higher than the threshold of 0.8 mentioned in the main text.
Appendix C. Detailed description of the prediction market model

The model is a pure exchange economy in discrete time, indexed by $t \in \mathbb{N}$, where $N$ agents repeatedly bet on the occurrence of a binary event. That is, in every $t$ two contracts are available for wagering: the first pays 1 dollar if the event occurs and zero otherwise, while the second pays 1 dollar if the event does not occur and zero otherwise. We model the event by means of a Bernoulli random variable $s_t$, such that $s_t = 1$ means that the event at time $t$ has occurred, and $s_t = 0$ otherwise. The probability of observing $s_t = 1$ is a constant $\pi^* \in (0, 1)$. Every agent $i \in \{1, 2, \ldots, N\}$ assigns a subjective probability $\pi_i$ to the realization of the event at any time $t$. Agent $i$ has initial wealth equal to $w_i^0$ and at the end of every betting round it evolves in $w_i^t$ depending on the results of her betting. The total initial wealth in the market is normalized to 1, such that, since wealth is only redistributed by the betting system, it is $\sum_{i=1}^{N} w_i^t = 1$ for all $t$.$^{36}$ In every period, the agents trade in the competitive market according to rules as in Equation (6) and contracts’ prices are fixed by means of market clearing conditions. Without loss of generality, we assume that contracts are in unitary supply. Hence, calling $p_{1,t}$ and $p_{2,t}$ the price of the first and second contract, respectively, we have $\forall t$

$$1 = \sum_{i=1}^{N} \frac{\alpha_{i,t}}{p_{1,t}} w_{i,t-1} \quad \text{and} \quad 1 = \sum_{i=1}^{N} \frac{1 - \alpha_{i,t}}{p_{2,t}} w_{i,t-1}.$$  

Since wealth sums up to 1 in every period, one has $p_{1,t} + p_{2,t} = 1$, hence we call $p_{1,t} = p_t$ and $p_{2,t} = 1 - p_t$. Substituting with Equation (6) and applying simple algebraic manipulations, one obtains

$$p_t = \sum_{i=1}^{N} \pi_i w_{i,t-1} \quad \forall t. \tag{C.1}$$

$^{36}$Hence, one can indifferently refer to $w_i^t$ as both the wealth and the wealth share of agent $i$ at time $t$. 

Figure B.16: Powers for the t-tests presented in Figure 8. Yellow dots denote initial steps with variances so small to get results below the numerical tolerance of our implementation, 1E-15.
After the market round, the outcome of the binary event is revealed and the wealth of agent $i$ evolves according to

$$
w_i^t = \begin{cases} 
\frac{\alpha_i^j}{p_t} w_{j-1} = \left(1 - c + c \frac{\pi^j}{p_t}\right) w_{j-1} & \text{if } s_t = 1, \\
\frac{1 - \alpha_i^j}{1 - p_t} w_{j-1} = \left(1 - c + c \frac{1 - \pi^j}{1 - p_t}\right) w_{j-1} & \text{if } s_t = 0. 
\end{cases}
$$

(C.2)

Appendix D. Application: steady-state analysis in a model of market selection using Cramer Von-Mises normality test

In this section we further discuss the normality tests supported in our algorithms for steady-state analysis, namely the one by Cramer Von-Mises, and replicate the analysis performed in Sections 6 and 7 replacing the Anderson-Darling test with the Cramer-Von Mises one.

Notice that, when we test for normality of batch means inside autoWarmup, we are taking as input of the test variables that are only approximately normal. One can reasonably assume that these random variables are closer to normality in the centre of the distribution rather than in the tails. This may create problems with the Anderson-Darling test we provide as default. Thus, we provide the option of using the Cramer-Von Mises normality test, that, weighting the tails less than the Anderson-Darling, should be less affected by the approximated normality of batch means.

Here we report the results of the steady-state analysis performed on the market model replacing the Anderson-Darling normality test with the Cramer-Von Mises test. As one can notice in Figures D.17-D.18, the results are very close to the ones reported in Figures 12-13.

We control whether the two tests produce large differences in estimated warmup ends in Figure D.19. As one can notice, the two tests generically yield coherent estimates, with the Anderson-Darling test generating more conservative estimates when differences are observed.

Appendix E. Operationalizing the framework: Statistical Model Checking and MultiVeStA

This section discusses how we operationalise our approach. In particular, we frame our approach to ABM analysis in the context of Statistical Model Checking and show how we integrate it into MultiVeStA, a model-agnostic statistical model checker that can be integrated with existing simulators.
Appendix E.1. Statistical Model Checking

Statistical Model Checking (SMC) (Agha and Palmskog, 2018; Legay et al., 2019) is a successful simulation-based verification approach from computer science. SMC allows to study quantitative properties of large-scale models through completely automated analysis procedures equipped with statistical guarantees. Following the principle of separation of concerns, the idea is to offer a simple external language to express properties of interest that can be queried on the model using predefined analysis procedures. The goal of SMC is therefore that of offering a one-click-analysis experience to the modeller which is freed from the burden of modifying the model to generate large CSV files every time a new analysis is required, and then analysing such CSV files in an error-prone semi-automated manner. This guarantees that the analysis procedures are written once and then extensively tested, decreasing the possibility of errors. Making a parallel with databases, we do not have to explicitly manipulate the internal representation of the data every time a new query is needed, rather we define the data to be selected using compact languages (e.g., SQL).

Several statistical model checkers exist, most of which require to implement models into proprietary languages. We consider black-box SMC (Sen et al., 2004; Younes, 2005), where the idea is to offer a model-independent analysis framework that can be easily attached to existing simulation models, effectively enriching them with automated statistical analysis techniques. In particular, we use MultiVeStA (Sebastio and Vandin, 2013; Gilmore et al., 2017), maintained by one of the authors, redesigned and extended here with the techniques presented in this paper to tailor it for the ABM community.

Appendix E.2. Simulator integration

MultiVeStA only needs to interact with a simulator by triggering 3 basic actions: (i) $\text{reset}(\text{seed})$, to reset the simulator to its “initial state”, and update the random seed used to generate pseudo-random numbers. This is necessary to reset the model before performing a new simulation. MultiVeStA takes care of random-seed generation, meaning that it generates adequate sequences of seeds for the necessary simulations. MultiVeStA allows for random-seed control, i.e., the user can fix such sequence across different experiments by providing a seed-of-the-seeds, a parameter used to univocally generate all necessary seeds; (ii) $\text{next}$, to perform one step of simulation; (iii) $\text{eval}(\text{obs})$, to evaluate an observation in the current simulation state, where an observation ($\text{obs}$) can be any feature of the aggregate model or of any group of agents. A new model can be integrated with MultiVeStA by implementing an adaptor between MultiVeStA and the considered simulator, obtained by instantiating MultiVeStA’s (Java) interface. As a consequence, it natively supports Java-based simulators, but it has been also integrated with C- and Python-based simulators, and it has been recently extended to support R-based ones. We remark here that our algorithms assume that the model at hand always computes well-defined numeric observations. By providing adequate implementation of the $\text{eval}(\text{obs})$, one can provide a model-specific handling for unexpected/special cases like infinity or not-a-number.

Figure D.18: Steady-state levels of average price. Left: $\text{autoRD}$. Right: $\text{autoRD}$. Same settings of Figure 13, the only difference is the use of the Cramer-Von Mises test to check for the normality of batch means.
Figure D.19: Comparison between warmup end estimated using the Cramer-Von Mises test (CvM) and using the Anderson-Darling test (AD). The value 90000 set by Kets et al. (2014) has been added for reference.

For the ABM macro model from Section 5 we are interested in two aggregate features of the model: the number of bankruptcies and the unemployment rate in a given step. Therefore, the model has been integrated such that these can be obtained using `eval("bankruptcy")`, and `eval("unemploymentRate")`, respectively. Instead, the prediction market models from Sections 6 and 7 have been integrated such that `eval(i)` gives a particular feature of agent `i` (its current wealth), and `eval("price")` gives a certain aggregate feature of the model (the prevailing price).

Appendix E.3. MultiVeStA query language and supported analysis

MultiVeStA offers a powerful and flexible property specification language, MultiQuaTEx, which allows to express transient and steady-state properties, including warmup analysis.

**Transient properties.** Intuitively, a MultiQuaTEx query might describe a random variable (e.g., the number of bankruptcies in an ABM macro model at a certain point in time during a simulation). Following the discussion in Section 2, the expected value of a MultiQuaTEx query is estimated as the mean $\bar{x}$ of $n$ samples (taken from $n$ simulations), with $n$ large enough (but minimal) to guarantee that the $(1-\alpha) \cdot 100\%$ CI centred on $\bar{x}$ has size at most $\delta$, for given $\alpha$ and $\delta$.

MultiQuaTEx actually allows to express more random variables in one query, all analysed independently reusing the same simulations. Listing 1 depicts a MultiQuaTEx query used in Section 5 to study the evolution of the number of bankruptcies and of the unemployment rate in an ABM macro model.

Coming to the structure of a MultiQuaTEx query, it contains a list of parametric operators that can be used in an `eval autoIR` command to specify the properties to be estimated. Lines 1–4 of Listing 1 define the parametric operator...
obsAtStep(t, obs) = if (s.eval("steps") == t) 
  then s.eval(obs) 
  else next(obsAtStep(t, obs)) 
fi ;
eval autoIR(E[obsAtStep(t,"bankruptcy")],E[obsAtStep(t,"unemploymentRate")],t,1,1,400);

Listing 1: A transient MultiQuaTEx query

obs(o) = s.eval(o) ;
eval warmup(E[obs(0)],E[obs(1)],E[obs(2)],E[obs("price")]) ;
eval autoBM(E[obs(0)],E[obs(1)],E[obs(2)],E[obs("price")]) ;
eval autoRD(E[obs(0)],E[obs(1)],E[obs(2)],E[obs("price")]) ;

Listing 2: A steady-state MultiQuaTEx query. Only one of the three eval commands should be used at a time.

obsAtStep having two parameters, \( t \) and \( obs \), respectively the step and observation of interest. Such operator is evaluated, in every simulation, as the value of \( obs \) at time point \( t \). Before discussing the body of the operator, we note that Line 5 uses it twice for observations the number of bankruptcies and the unemployment rate for each step from 1 to 400 (with increment 1). Therefore 800 properties will be studied (400 for each observation), all evaluated using the same simulations and with their own CI. The body of an operator (Lines 1-4) might contain:

1. conditional statements (the if-then-else-fi);
2. real-valued observations on the current simulation state (the s.eval in Line 1 and Line 2);
3. a next operator that triggers the execution of a simulation step (Line 3);
4. recursion, used in Line 3 to evaluate obsAtStep(t, obs) in the next simulation step;
5. arithmetic expressions.

This is general enough to express a wide family of properties at varying of time. In the case of Listing 1, we check whether we have reached the step of interest (Line 1), in which case we return the required observation (Line 2). Otherwise, we perform a step of simulation (Line 3), and evaluate recursively the operator in the next simulation state.

Steady-state properties and warmup analysis. MultiQuaTEx has been extended to support MultiVeStA’s extension with steady-state and warmup analysis capabilities discussed in Section 3.2. Listing 2 provides a steady-state MultiQuaTEx query used in Section 6 to study the average value at steady state of the wealth of three agents (0, 1, and 2), and of the price in our testbed market selection model. The query is simple, as in this case the operator obs just returns the observation of interest, while Lines 2-4 show how to run the three types of supported analysis. In particular, a steady-state query is composed of two parts: A list of next-free operators, and one of the three eval commands in Listing 2, provided with a list of operators to study.

Intuitively, a steady-state MultiQuaTEx query defines observations on single simulation states, implicitly studied at steady state. In particular, warmup performs the warmup estimation procedure (Section 3.2.2) for each of the listed properties. Indeed, every random variable defined on a process might have a different warmup period. We have seen examples of this in Section 6. Instead, autoBM performs a warmup estimation on each property, and begins computing the batch means procedure (Section 3.2.3) on each of them as soon as the property completes its warmup period. The command autoRD is similar, but it first completes the warmup analysis for all considered properties, and then feeds this information to the replication deletion procedure from Section 3.2.1. In all cases, the default values described in Section 3 will be used if not otherwise specified by the user when running the analysis.

MultiQuaTEx supports two further eval commands: manualBM and manualRD. These behave the same as autoBM and autoRD, respectively, but skip the warmup analysis phase and required as input an estimation of the warmup period. These might be useful in case one has this information due to previous analyses. In Section 6 we use them to replicate erroneous steady-state analyses from the literature based on a wrong estimation of the warmup period.

Appendix E.4. MultiVeStA’s distributed architecture

MultiVeStA has a client-server architecture as sketched in Figure E.20. This is a classic software architecture for distributing tasks in the cores of a machine or in the nodes of a network. We distribute the simulations of autoIR and autoRD. In the figure, arrows denote visibility/control/activation of the source component on the target one:
• A user runs the client specifying the model, query, CI, and the parallelism degree $N$. Transparently to the user, the client will trigger, distribute, and handle the necessary simulations providing to the user the results.

• The client creates $N$ servers among whom distributes the analysis tasks.

• Each server runs independently, therefore in parallel, the required simulations. Each server creates its own instance of the simulator, and controls it through the adaptor to perform the simulations.

As discussed, we extended MultiVeStA with a number of analysis techniques. In particular, we mainly extended the client, where the analysis logic is localized. The new architecture of the client is depicted in Figure E.21. It consists of a number of modules, the central ones regarding steady-state and transient analysis. Further modules regard: post-processing of analysis computed by MultiVeStA like t-tests and power computation to compare results obtained for different model configurations (Section 3.1.2), or the methodology for ergodicity analysis (Section 4); support for the creation and parsing of MultiQuaTEx queries, offered by a novel compiler for MultiQuaTEx queries; visualization of the analysis results through a plotter and of a CSV file creator.

Figure E.21: The novel architecture of the MultiVeStA client

Appendix F. Parallelization study

One of the key issues in the analysis of ABMs in social sciences concerns computational time; while some approaches have recently proposed to take advantage of machine learning surrogates (Lamperti et al., 2018; van der Hoog, 2019), the most direct approach to speed-up simulation is an efficient parallelisation of the experiments. In this section we discuss how MultiVeStA can efficiently and automatically parallelize the various runs. Notably, we demonstrate the potential analysis speed-ups showing an analysis that requires about 15 days when performed in sequential, and about 16 hours when parallelizing it on a machine with 20 cores. In particular, we show the actual runtime gains obtained on the analysis of our case studies when using different degrees of parallelism on a machine with 1 CPU.
Intel Xeon Gold 6252 (20 physical cores) and 94GB of RAM. This machine allows to perform up to 20 processes in parallel, but hyperthreading further allows for limited speed-ups also with parallelism degrees higher than 20.

Figure F.22 (left) shows the results of our study considering the sequential case and parallelism degrees \( N \) multiple of 5 up to 60. Intuitively, in the ideal case an analysis using parallelism degree \( N \) should take \( \frac{1}{N} \) of the time required by a sequential analysis (i.e., with \( N = 1 \)). For this reason, the red dashed line provides the optimal obtainable speed-ups: 1 (no speed up) for the sequential case, and \( \frac{1}{N} \) for all considered \( N \). The blue and yellow dots, instead, show the actual speed-ups obtained for our two case studies. In particular, in order to compare with the optimal speed-up, for each value of \( N \) we provide the ratio among the runtime obtained with parallelism degree \( N \) over the one of the sequential case. For the prediction market model, we consider the autoRD analysis from Figure 12 (left) for \( \pi^* = 0.45 \), while for the macro model we consider the analysis from Figure 5. Notably, the analysis of the macro model took about 15 days when executed sequentially, while it goes down to about 18 hours for \( N = 20 \), and 16 hours for \( N = 25 \). The analysis failed for higher values of \( N \) due to the high memory requirements of the model. Instead, the analysis of the prediction market model requires about 14 minutes in sequential and about 50 seconds for \( N = 20 \). The analysis could be performed for all considered \( N \), with a minimum runtime of about 38 seconds for \( N = 40 \).

Overall, for both case studies we note speed-ups very close to the optimal ones up to \( N = 20 \), while they tend to deteriorate for higher values of \( N \). Figure F.22 (right) focuses on the values of \( N \) from 15 onwards. We see that the speed-ups obtained for the macro model tend to be closer to the optimal ones. This is because simulations are computationally intensive, taking more than 1 hour. Therefore, the overhead (i.e., the extra computations) introduced by the communications among the MultiVeStA client and servers has almost no impact on the overall runtime. Instead, the prediction market model is not particularly computationally expensive, making the extra communications influence more the overall runtime. In particular, the figure shows that relatively limited speed-ups are obtained for \( N \) greater than 25. This is expected, as discussed. Interestingly, increasing \( N \) further than 40 actually worsens the performances, as the processor is not anyway able to perform more than 20 processes in parallel while the overhead costs increase.
