Inadvertent flow alterations in the parent artery during microsurgical clipping might produce postoperative ischemic complications. Intraoperative recognition of such alterations and its correction might improve operative outcomes in these patients. We present the case of a thirty-five-year-old male with an incidental small left anterior choroidal aneurysm. Microsurgical clipping induced an external compression of the anterior choroidal artery against the posterior clinoidal process which was identified in situ through surgical exploration and the loss of arterial doppler signal in the vessel. After failed attempts at clip repositioning, a posterior clinoidectomy was performed to decompress the artery. This resulted in arterial flow recovery. The aneurysm was successfully treated, and a severe ischemic complication was likely avoided. This intraoperative phenomenon has not yet been described in the literature.

INTRODUCTION

Treatment of anterior choroidal artery (AChA) aneurysms remains a challenging task due to the artery’s complex anatomy and vascular distribution. Frequent ischemic complications have been reported with devastating consequences.⁸⁹¹⁰ Occasionally, unnoticed flow alterations in the parent artery due to microsurgical clipping have resulted in postoperative ischemic complications.³ On-site recognition of such alterations and their correction might improve operative outcomes in these patients. We present a case of an AChA aneurysm which developed flow impairment in the parent artery during surgical clipping due to compression against a prominent posterior clinoid process.
Posterior clinoidectomy for anterior choroidal aneurysm

CASE PRESENTATION

A thirty-five-year-old male with a history of chronic headaches was referred for neurosurgical evaluation due to the incidental finding of a small left AChA saccular aneurysm (Fig. 1A, B). The patient's past medical history was positive for arterial hypertension, smoking and a history of aneurismal subarachnoid hemorrhage in the family. Conservative management vs. treatment alternatives were discussed, and the patient opted for surgery. Due to the aneurysm's broad neck, surgical clipping was favored over endovascular coiling.

The patient was positioned supine in the operating table with the head fixed with a Mayfield clamp, slightly elevated from the level of the right auricula. Positioning was completed with slight extension and a 20-degree rightward head rotation. A mini-pterional craniotomy was performed (Fig. 1C). The proximal sylvian fissure was split and the carotid cistern dissected. A brain retractor was positioned to elevate the frontal lobe with gentle retraction. The optic nerve (ON) and internal carotid artery (ICA) were identified. At the origin of the AChA, on the posterolateral aspect of the ICA, the aneurysm was observed (Fig. 1D). The origin of the AChA was identified on the anterior aspect of the aneurysm sac. The neck of the aneurysm was dissected, and clipping was performed with a 7 mm straight Yasargil permanent clip (Aesculap, Braun GmbH, Frankfurt, Germany) (Fig. 1E). The arterial doppler microprobe (Mizuho Medical, Tokyo, Japan) was brought into the operative field (Fig. 1F), and an absence of flow in the AChA was noticed. After clip removal, the doppler probe was used again, and robust flow in the AChA was found. A new slight curved 6.5 mm clip was applied, and the maneuver again resulted in sonographic signs of flow impairment.

After careful exploration, the surgeon realized that the absence of flow within the artery was due to a direct

Fig. 1. (A) CT angiography with bone reconstruction (lateral view): an aneurysm arising in the left AChA is observed. Inferiorly and medial to the aneurysm, the PCP with two bony prominences projecting superiorly and posteriorly. (B) Superior view of the same CT angiography. (C) Exposure of the sylvian fissure via a mini-pterional approach. (D) Surgical view under the operative microscope after the carotid cistern was dissected. The aneurysm sac was exposed and the origin of the AChA was identified. The PCP is medial to the aneurysm. (E) Intraoperative image of the clipped aneurysm, the compression of the AChA against the PCP is evidenced. (F) Use of Doppler probe on the AChA, which showed absence of flow. (G) Posterior clinoidectomy using Kerrison rongeur. (H) AChA liberated after the posterior clinoidectomy. compression of the AChA against the posterior clinoidal process (PCP). Several attempts were made to reposition clips with different settings (straight, slight curved, curved, angled tip) to avoid the arterial compression, but they proved to be unsuccessful. A posterior clinoidectomy with a Kerrison rongeur was then performed. This

maneuver allowed for free movement of the AChA, with the arterial compression subsiding (Fig. 1G, H). Flow restoration was verified with a new doppler sonographic control. Fig. 2 shows the operative field after the definitive clipping and an artistic illustration of the procedure. The patient had no neurological deficits postoperatively and was discharged on day 3 of the hospital admission.

DISCUSSION

The treatment of AChA aneurysms remains challenging, not only because of the complexity of the vascular anatomy and the small caliber of the AChA, but also because of the fearsome ischemic complications derived.\textsuperscript{1,4,6,8,11} Previous reports describe the risk of AChA territory ischemia at 12–16%.\textsuperscript{2,3,5,6,9}

Among the causes for AChA ischemic complications are: unintentional clipping resulting in arterial occlusion,\textsuperscript{3,9} thromboembolism due to temporary clipping of a parent vessel and arterial kinking due to clip rotation.\textsuperscript{5} Ischemic complications were previously noted even with preserved arterial diameter. The presence of atheromatous plaques on the aneurysm neck may also be a cause of AChA occlusion.\textsuperscript{31} For this reason, intraoperative monitoring techniques should be performed to ensure that the blood flow within the artery remains patent.\textsuperscript{5} Intraoperative angiography with intravenous indocyanine green (ICG) or micro-doppler ultrasound are useful tools that surgeons can use to avoid ischemic complications.\textsuperscript{9}

During the case presented, vascular anatomy seemed to be preserved but an absence of flow in the AChA was noticed. The \textit{in situ} identification of a mechanical compression of the parent artery and the ulcerterior surgical decompression, likely prevented a devastating ischemic complication. Of note, the PCP is rarely involved in AChA compression. However, in this case, a very prominent PCP, in association with a closely located trajectory of the supraclinoid ICA, could have favored this rare intraoperative event.

To the best of our knowledge, there are no reports in the literature of direct external compression of the AChA against the PCP induced by aneurysm clipping.

CONCLUSIONS

We present the case of an external clip-induced AChA compression against the PCP during aneurysm surgery. This phenomenon has not been described in the literature before. A posterior clinoidectomy proved to be effective in restoring normal flow in the AChA after several attempts at clip repositioning failed.
