ABSTRACT Impaired function or insufficient expression of glutamate N-methyl-D-aspartate (NMDA) receptors underlies a number of brain pathologies; these receptors are, therefore, regarded as a pharmacological target for many neuroactive drugs. It was shown that in the CNS, this type of glutamate receptors participate in the processes of neuronal excitation, synaptic plasticity [1, 2], and excitotoxicity in neurodegenerative diseases and are also involved in the pathogenesis of epilepsy and seizures. However, until recently, the presence and activity of NMDA receptors beyond the CNS had never been considered. This research shows that activation of NMDA receptors at the mammalian neuromuscular junction alters the resting membrane potential of the postsynaptic cell evoked by cation entry through the receptor-associated channel.

KEYWORDS Neuromuscular transmission, NMDA receptor, glutamate, glycine, electrophysiology.

ABBREVIATIONS NMDA – N-metyl-D-aspartate; ACh – acetylcholine; GABA – γ-aminobutyrilic acid; ATP – adenosine triphosphate; CNS – central nervous system; RMP – resting membrane potential; 5,7-DCKA – 5,7-dichlorokynurenic acid; AP5 – DL-2-amino-5-phosphonopenthatoic acid.

INTRODUCTION

Neuromuscular synaptic transmission is indispensable for the process of human life, as it is the mechanism that transfers cerebral commands to activate muscle contractions. The neuromuscular junction (NMJ) is a synapse composed of the presynaptic motor nerve terminal, the synaptic cleft, and the postsynaptic region of muscle fiber. The NMJ is a chemical-type synapse in which transmission of basic signals is mediated by acetylcholine (ACh). However, it is worth mentioning that other neurotransmitters (glutamate, ATP, GABA) have been shown to exist in this presumably cholinergic synapse, whose putative role is fine-tuning of ACh release [3, 4, 5].

NMDA receptors (NMDAR) are ionotropic ligand-gated receptors associated with the cation-permeable channel [6]. Simultaneous presence of two co-agonists (glutamate and glycine) and removal of the magnesium block are required to activate them [7]. It has been shown that Mg²⁺ blockade can be voided by membrane depolarization under native conditions or by using a Mg²⁺-free Ringer solution, in experiments.

We have previously shown the role played by these receptors in the modulation of ACh release [8] and regulation of acetylcholinesterase activity [9] at mammalian NMJ. Furthermore, postsynaptic localization of the NMDA receptor NR1-subunit has been demonstrated [10]. Such localization suggests that the agonists of these receptors may change membrane excitability (namely, the resting membrane potential) with the development of depolarization.

MATERIALS AND METHODS

Male Wistar rats (200–300 g body weight) were used for all the experiments. The experiments were carried out in compliance with the guidelines for using labora-
Glycine, co-agonist glycine (700 μM) in a Mg

This effect was due to the activation of NMDARs, we performed the experiments using APV (DL-2-amino-5-phosphonopentanoic acid), a selective reversible NMDAR blocker. Addition of 500 μM APV had no effect on the RMP; subsequent application of glutamate and glycine in the presence of the blocker evoked a smaller depolarization amounting to only 1.5% (78.15 ± 0.39 mV vs. 79.37 ± 0.24 mV in the control; n = 127, p < 0.05).

The infeasibility of total blockade by APV can be explained by the fact that APV is a reversible blocker that competitively binds to the glutamate-binding site of NMDAR and its affinity is close to that of glutamate; therefore, the amino acid could displace the blocker. In order to completely eliminate the effect of amino acids, we additionally applied 5,7-dichlorokynurenic acid (5,7-DCKA), an NMDAR glycine binding site blocker, at a concentration of 100 μM. Neither addition of 5,7-DCKA nor simultaneous application of APV and 5,7-DCKA affected the resting membrane potential (n = 79), but the combined action of 5,7-DCKA and APV prevented the effect of amino acids on the resting membrane potential (78.8 ± 0.22 mV vs. 79.37 ± 0.24 mV in control; n = 85, Figure).
Magnesium blockade is an alternative physiological way to block NMDAR. If the observed effects on the membrane potential are caused by the activation of these receptors, the presence of magnesium in solution should prevent the development of depolarization after NMDAR agonists are applied. Indeed, amino acids had no effect on the membrane potential in the presence of Mg$^{2+}$. Hence, the membrane potential value in the Mg$^{2+}$-containing solution was 78.91 ± 0.32 mV and remained unchanged (78.26 ± 0.31 mV, n = 105, Figure) after glycine and glutamate addition. These results provide grounds to infer that a population of functional NMDARs is localized on the postsynaptic membrane; their activation causes statistically significant changes in the membrane potential. This depolarization, evoked by a cation current through the receptor channel, is blocked by a selective blocker of NMDAR glutamate and glycine binding sites: it is not observed when the magnesium block is preserved.

**CONCLUSIONS**

Hence, a functionally active population of NMDA receptors is present on the postsynaptic membrane of mammalian muscle fibers; their activation can change the excitability of muscle fiber and trigger a wide variety of intracellular reactions through the system of calcium-dependent secondary messengers, due to the relatively high permeability of the NMDA receptor channel to calcium ions. Given the variety of possible functions mediated by the NMDA receptor, further research into their role in the neuromuscular synapse seems to be an important and highly topical task.
