Abstract: The main goal of this work is to provide a general description of the negative photoconductivity effect observed in Ag/AgO films grown by the spray-pyrolysis technique. X-ray diffractograms display hybrid films with high texturized AgO and metallic Ag phases. Scanning electron microscopy images show small Ag particles on the surface. Due to its surface nature, X-ray photoelectron spectroscopy revealed the predominance of the metallic character of Ag 3d spectra as compared to Ag2+. Negative photoconductivity with photoresponse in the order of seconds is observed under several wavelengths of excitation. We found that the amplitude of the negative photoresponse is strongly dependent on the optical absorbance and enhanced by surface plasmon resonance. The low-cost technique employed and the special features regarding negative photoconductivity provide an exciting platform for developing optical-electronic devices with low power consumption.

Keywords: oxides; photoconductivity; silver; surface plasmon resonance

1. Introduction

Metal oxides films present exciting features such as the semiconductor behavior and optical transparency associated with several ways to synthesize them. The high reactivity of oxygen bounds is also attractive to develop surface-based devices such as gas and liquid sensors [1,2]. In addition, the surface decoration with noble metal structures is a powerful tool to enhance sensing response in light-assisted devices [3]. In such a case, the use of Ag structures increases the local electromagnetic field by surface plasma absorbance that strengthens hot electron-based processes important to photochemical reactions [4]. Regarding Ag-based nanostructures, Ag nanoparticles and Ag nanowires are well employed in chemical engineering, aerospace, medicine, and electronics. Particularly, the Ag nanowires are good candidates to replace indium tin oxide (ITO) in several applications [5,6]. Additionally, the introduction of metallic nanoparticles in thin films would have a drastic influence on the mechanical and optoelectronic properties of electro-optical devices opening the possibility of improvement or development of sensor devices in a wide range of applications including plasmonics and photocatalysis phenomena [7–9]. In addition, metallic nanoparticles allow the fabrication of stretchable conductive thin films due to their mechanical properties that includes greater flexibility. This is important for thin films electrodes on plastic substrates, for example. A complete review of the type and importance of metallic nanoparticles in thin films for new optic-electronic devices is provided in reference [10]. Besides nanostructures, silver oxides have many technological applications as electrodes for batteries and photocatalytic degradation systems for pollutants [11–13].
Although the electrical and optical properties are being employed in current applications, the literature misses reports about the photoconductivity of silver oxides, restricted to the conventional positive photoresponse \cite{14,15} with the increase in conductivity under illumination. In contrast, negative photoconductivity (NPC), which presents a decrease in electrical conductivity in the presence of light, also emerges as an exciting mechanism to be applied in photodetection and nonvolatile memory that requires low power consumption \cite{16,17}.

Due to its d-shell configuration, many oxidation states give rise to several oxides such as Ag$_2$O$_3$, Ag$_2$O, Ag$_2$O, and AgO, depending on the growth conditions, mainly the reaction kinetics and the availability of oxygen required for the oxidation. Furthermore, controlled oxidation of Ag for a large-scale process is still a challenge. Among many physical and chemical processes, spray pyrolysis (SP) seems a suitable technique to produce hybrid films of silver oxides employing the process of silver acetate decomposition and oxidation at moderated temperatures \cite{11}. This process is a hybrid method based on the evaporation of solvent followed by the pyrolysis of solute. A fundamental issue is the quantity of the available precursor molecules present in the micrometric droplets employed to form a film or a coating.

This investigation presents the synthesis of Ag/AgO hybrid thin films grown by spray pyrolysis and their structural and optical-electrical characterization. The experimental data reveal a well-textured AgO thin film with the presence of an Ag metallic phase on the surface. Under illumination, the electrical conductivity decreases for excitations of several wavelengths in the visible range. A decrease in the negative photoconductivity, followed by an increment in response times, is observed when the wavelengths match the range of plasmon absorbance of the Ag phase.

2. Materials and Methods

Silver oxide thin film was grown on a soda-lime substrate with spray pyrolysis technique, presenting versatility and economic viability. Figure 1 displays the setup consisting of an atomizer fed by a carrier gas (dry compressed air) at 0.1 MPa and a pumped liquid precursor solution. Considering the definition of molarity (M) as the solute number of mols in a volume of 1 liter, the low molarity (M) precursor solution (M = 4 x 10$^{-3}$ mol/L) consists of solid silver nitrate (AgNO$_3$ by Synth, with a molar mass of 169.87 g/mol) as solute diluted in distilled water. The growth is based on cycles described elsewhere \cite{18}, and the low molarity condition tends to increase the crystallinity of films grown by spray pyrolysis \cite{19}. Each cycle has duration of 2 min, and the growth starts with the deposition of layers at 300 °C by atomized microdroplets formed in a precursor flux of 0.25 mL/min. During this period, the substrate temperature drops up to 220 °C when the spraying is interrupted. The substrate temperature increases to 300 °C, and a new cycle starts. This temperature range is enough to break silver nitrate molecules and form nucleation zones at the substrate. The typical number of cycles is 20.

![Figure 1. Experimental setup employed to grow oxide thin films at low molarity conditions.](image-url)
The crystallographic structure and phases were analyzed using a Shimadzu X-ray diffractometer (XRD-6100) (Shimadzu Corp., Kyoto, Japan) with Cu-K$_\alpha$ radiation ($\lambda = 1.5406$ Å) in the range of 10–90 °C with a step size of 0.2°/min. A JEOL JSM 5800 LV microscope (JEOL, Tokyo, Japan) performed scanning electron microscopy images (SEM). The optical transmittance was analyzed with a spectrophotometer Agilent Cary 5000 UV–VIS-NIR (Agilent Co., Santa Clara, CA, USA) in the range 200–1200 nm at room temperature. X-ray photoelectron spectroscopy (XPS) employed a ThermoScientific K-Alpha spectrometer (Thermo Fisher Scientific, Waltham, MA, USA) using Al-K$_\alpha$ (1486.6 eV) radiation at Brazilian Nanotechnology National Laboratory (LNNano/CNPEM). Using Shirley’s baseline, the spectra were corrected on C 1s (284.8 eV) and analyzed by CasaXPS software (Casa Software Ltd., Teignmouth, UK). The photoconductivity was evaluated by measuring the voltage changes by a Keithley 2001 multimeter (Keithley, Cleveland, OH, USA) when a Keithley 237 source applies a constant electrical current of 1 nA. The illumination was provided by different light-emitting diodes (LEDs): ultraviolet (400 nm—3.10 eV), blue (477 nm—2.60 eV), green (533 nm—2.33 eV), yellow (591 nm—2.10 eV), and red (634 nm—1.95 eV).

3. Results and Discussion
3.1. Structural Characterization

The characterization by X-rays (XRD) shows well-defined diffraction peaks at 32.25°, 38.12°, 44.17° and weak peaks at 64.45° and 67.40° in Figure 2. The most intense peak at 32.25° is associated with monoclinic AgO (JCPDS 43-1038), far enough to exclude Ag$_2$O phases (hexagonal—JCPDS 72-2108 and cubic—JCPDS 41-1104) up to the limit of detection. Applying Bragg law ($d_{hkl} = \frac{\lambda}{2 \sin \theta}$), the AgO interplanar is $d_{111} = (1.443 \pm 0.001)$ Å. The other peaks are attributed to the cubic metallic silver (JCPDS 04-0783) phase. The calculated interplanar distances for a non-deformed Ag crystal are $d_{111} = (2.359 \pm 0.001)$ Å and $d_{200} = (1.443 \pm 0.001)$ Å, which corresponds to the lattice parameter $a = 4.086$ Å of cubic metallic silver (JCPDS 04-0783). There is no evidence of texturization for metallic Ag meanwhile, and it is worth noting the texturization for the AgO phase at (111) direction.

Figure 2. X-ray diffraction exhibits polycrystalline metallic Ag and high texturized AgO phases—the inset attests to the higher crystallinity of the AgO phase.
The crystallinity and texturization of AgO film are remarkable, considering the relative simplicity and rapidity of the growth technique. The inset attests to the higher crystallinity of the AgO phase by comparing the relative width of main peaks. Crystallite sizes, obtained by the Scherrer equation [20], are 49.3 nm and 39.4 nm for AgO and metallic Ag at (111), respectively. Usually, physical and chemical deposition techniques evidence the dependence on growth conditions to achieve AgO, Ag2O, and metallic Ag phases. For instance, sputtering provides either amorphous films [21], AgO films [22], and Ag-embedded nanocrystallites [23], while chemical routes privilege the formation of AgO followed by Ag2O and Ag if subjected to annealing [24] or in oxygen-rich conditions in case of pulsed laser deposition [25]. Alternatively, the spray pyrolysis technique is a quasi-chemical vapor deposition process when it employs a low molarity precursor solution. The low content of solid precursors in the interior of water microdroplets breaks during solvent evaporation near or on the heated substrate, and nucleation centers are formed on top of the substrate, which could induce some orientation.

In contrast, for higher molarities, the layers present a powder-like character. In the case of zinc oxide, we recently demonstrated the influence of low molarities in the growth of transparent thin films, which are well oriented at the c-axis even in an amorphous substrate, such as soda-lime glass [19]. In addition, the technique enables the formation of doped layers and alloys with Cd, Co, or Mn [18,26,27] in systematic and reproducible processes. For the Ag/AgO film obtained by spray-pyrolysis, a possible growth route is considered if the dissociation of silver nitrate obeys AgNO3 → AgO + 1/2 N2 + O2 in such a way that an aqueous vapor atmosphere near the substrate favors a stoichiometric relation with Ag2+ rather than Ag1+, which occurs in a deficient oxygen environment. Furthermore, there is a tendency to form metallic Ag clusters, as clearly observed in XRD characterization. However, further investigations are required to understand the complete overview considering other parameters such as growth temperature and annealing procedures.

The SEM overview reveals a pallet-like film with the presence of grooves, as noted in Figure 3a. Small cubic silver microstructures with sizes in the range of micrometers are clear for higher amplification (Figure 3b,c). The SEM images corroborate that the metallic Ag phase observed in XRD characterization is due to these structures rather than embedded clustered Ag.

Figure 3. Scanning electron microscopy images show films with extended grooves (a) and the presence of small silver microcrystallites (b) with cubic structure (c).

High-resolution XPS was employed to analyze the chemical state of the Ag/AgO film surface. Figure 4a shows the Ag 3d and O 1s (Figure 4b) spectra. Figure 4a shows two strong sharp peaks at 367.98 eV (with full width at half maximum—FWHM = 1.01 eV) and 373.98 eV (FWHM = 1.12 eV) assigned to Ag3d5/2 and Ag3d3/2 [13,28,29]. The shape of these emissions is well-known and indicates the presence of AgO, Ag2O, and Ag on the surface. A slight asymmetry is observed at lower energies tail, and a careful fitting by CasaXPS software considered a 0.7 Gaussian/0.3 Lorentzian profile. To correct the asymmetry of the main metal peak, we employed the Lorentzian Assymetric (LA) tool which considers the spread of tails in the Lorentzian component and the width of Gaussian [30]. The main intense peaks with binding energies at 367.95 eV and 373.97 eV are assigned
to metallic silver and the weaker emissions in lower binding energies at 367.42 eV and 373.5 eV to Ag$^{2+}$ specimens. This unusual redshift of binding energies for Ag$^{2+}$ is attributed to factors other than electronegativity differences between the metal atom and cation, such as lattice potential, work function changes, and extra-atomic relaxation energy [13,31]. Thus, together with the SEM images, the XPS results match metallic silver structures on the surface rather than embedded clustered Ag.

![Figure 4](image-url)  
**Figure 4.** High-resolution XPS spectra. (a) Ag 3d spectra show the metallic character of the surface due to strong emission from Ag as compared to Ag$^{2+}$. (b) O 1s is a mixed-valence state signature associated with AgO film.

The peak shape of the O 1s level centered at 531.68 eV (FWHM = 2.50 eV) in Figure 4b indicates that a single Gaussian–Lorentzian peak function cannot be applied to fit it. Therefore, the O 1s level was deconvoluted into three splitting peaks. At higher energies and low percentage (2.6%), the binding energy centered at 532.7 eV is assigned to adsorption of oxygenated species as C=O and C–OH [13,32]. The most intense binding energy (76.2%) at 530.94 eV is related to the binding to metal at +2 valence, which characterizes the formation of AgO [33]. Nevertheless, the non-negligible low energy tail implies a peak centered at 529.35 eV, associated with a mixed-valence state of the structurally equivalent oxygen atoms [34,35].

3.2. Electro-Optical Characteristics

Figure 5 exhibits the optical transmittance of Ag/AgO film. The film has high transmittance in the infrared range ($\lambda > 800$ nm) and a significant broad absorption centered at 500 nm. This absorption is related to surface plasmon resonance (SPR) due to metallic Ag clusters [3,36]. It is worth noting a UV optical window centered at 330 nm (FWHM = 0.85 eV).

![Figure 5](image-url)  
**Figure 5.** The optical transmittance through Ag/AgO film shows characteristics of a UV window with the coexistence of optical effects due to metallic Ag, such as the SPR absorption around 500 nm.
The development of optical sensing devices is an exciting topic considering fundamental and applied physics. Optical stimulation in semiconductors usually promotes electrons from the valence band to the conduction band, which causes an increase in conductivity. The behavior observed in the Ag/AgO film investigated in this work is the opposite. Figure 6 shows the relative photoresponse (PR), defined as

\[ PR = \frac{R_D - R}{I_{LED} - R_D} \]

where \( R_D \) is the measured electrical resistance in the dark, \( R \) under illumination, and \( I_{LED} \) is the normalized intensity of LED emissions in respect to the red one, correcting the PR for each wavelength excitation. For Ag/AgO film, a substantial increase in resistance and a decrease in photoconductivity are measured for all wavelengths, from red to UV. After evaluating the dark resistance during 100 s (null photoresponse in Figure 6), the illuminated sample presents a fast response, in the order of seconds, consolidating a plateau. With its stabilization, the light is switched off, and the system recovers its initial condition after 15 s. The critical ranges in Figure 6 are normalized to the plateau when the light is switched-on or switched-off. This procedure emphasizes the time dependence on wavelength excitation. However, it is worth noting that the recovery is not straightforward, presenting an additional step with the photoresponse above zero, indicating a decrease in electrical resistance. After a further time, the resistivity increases up to initial conditions again.

![Figure 6. The transient photoconductivity response of Ag/AgO film under illumination by several wavelengths exhibits negative behavior typical of defects presence. The normalization of the plateau in the crosshatched ranges evidences the issues related to response and recovery times depending on the wavelength excitation.](image)

Negative photoconductivity (NPC) is attributed to shallow traps, acting as donor or acceptor states. In fact, any LED emission energies excite the AgO film directly. The photons seem to excite either the carrier from a band to a defect state or detrapping a defect state, which can then capture free carriers from the electronic bands [17]. From a qualitative point of view, the primary mechanism responsible for NPC is the ratio between...
recombination and generation rates in the presence of light [37]. The role of additional levels and/or bands on the photoconductivity mechanisms was previously modeled by Salis et al. [38] and recently by Paiva et al. [37] with a set of rate equations considering the presence of deep and shallow traps. The nature of shallow traps responsible for the negative photoconductivity in AgO requires further systematic investigations.

The strength of NPC is evaluated by comparing the plateau due to different excitations. As the energy increases, from the red to yellow excitations, around 2.0 eV, the NPC exhibits a substantial boost with faster response times (Figure 7a,b). Despite low optical absorbance of film, photons act to liberate charge from traps that capture the free carriers of AgO. In contrast, in the range of green illumination, the strong optical absorbance by SPR affects the NPC, and the negative photoresponse declines substantially. Furthermore, response times increase with the LED energy (lower wavelengths). For UV illumination, with the highest energy but below the AgO bandgap, the response time is more than 5 sec with a low negative PR. The silver particles, responsible for the additional absorption in localized states, do not contribute to electrical behavior.

![Figure 7. Comparison between photoconductivity behavior for different excitations. (a) The negative photoconductivity decreases when the excitation energy is near the surface plasmon resonance from Ag clusters measured by optical absorbance. (b) The response times present a systematic increase when LED energies rise.](image)

4. Conclusions

Spray pyrolysis emerges as a suitable technique to grow Ag-decorated AgO thin films. Our results indicate that the negative photoresponse observed for Ag/AgO film is dependent on two factors: shallow traps in the electronic structure of the AgO phase and the presence of metallic Ag acting as an additional absorber center.
