Abstract

In this article we present a case of incidental auto-atticotomy in a patient presenting with headache and otorrhea.

Auto-atticotomy also known as “Nature’s atticotomy” is a phenomenon that occurs in very few patients who have a cholesteatoma, whereby spontaneous drainage occurs into the external auditory canal, resulting in an air filled cavity, which is in the shape of the original cholesteatoma. Our case study highlights that although rare, auto-atticotomy can be considered as a differential diagnosis in patient’s presenting with headache and spontaneous otorrhea.

Keywords: Auto-atticotomy; Cholesteatoma; Neuroradiology

Introduction

Cholesteatoma is a nonmalignant cyst like growth consisting of squamous epithelium that is located in the middle ear or mastoid air cells which can lead to the erosion of structures within the temporal bone [1-3]. This may then lead to central nervous system complications, which in turn may be potentially fatal [4-6].

The treatment depending on the age of the patient is usually a surgical excision known as atticotomy, whereby the scutum and the lower lateral wall of the attic are removed. In a minority of patients a spontaneous atticotomy may occur, called auto-atticotomy, where there is spontaneous drainage of the cholesteatoma into the external auditory canal [2].

Here we present a patient with an auto-atticotomy, who presented with headache and otorrhea.

Case Report

A 62-year-old woman presented with a 2 day history of constant headache with no history of preceding trauma. The patient had no significant past medical history or ongoing medication. On clinical examination, she had a painless right-sided otorrhea; otherwise, there were no abnormalities detected on her neurological or head and neck examination.

The patient underwent a non-contrast CT brain that showed extensive right mastoid air cell opacification and no other abnormality. This was further investigated with CT temporal bones (Figure 1), which demonstrated erosion of the right scutum and right lateral attic wall and some demineralisation of the right ossicles, with an enlarged air filled right aditus ad antrum, which communicated with the right middle ear cavity. There was marked retraction of the right tympanic membrane and no residual soft tissue abnormality was detected in the right middle ear cavity.

Discussion

Cholesteatomas were first described by Duverney et al in 1683 in “Traité de l’Organe de l’Ouïe” as “Caries of the bone accompanied with bad smell and symptoms” [7]; and, in 1838, Müller et al were the first to introduce the term cholesteatoma [8,9].

However, the term cholesteatoma is a misnomer, as it neither contains cholesterol “chole” or fat “steat”, and therefore over the years, other names have been proposed, such as “margaritoma” in 1891 by Graigie and “keratoma” in 1974 by Schuknecht, but none of these names were adopted, and cholesteatoma remained as the dominantly used term [10].

Cholesteatoma is a relatively rare condition with an incidence of 3 and 9.2 per 100,000 population in children and adults respectively. There is a slight male predominance of 1.4:1, and a higher incidence of middle ear cholesteatoma occurring in patients younger than 50 years of age [11].

Macroscopically cholesteatomata appear as pearly grey structures with a thin membrane. Microscopically they are divided into three layers: cystic content, matrix and perimatrix. The cystic content is the primary component of the cholesteatoma that demonstrates fully differentiated anucleate keratin lined by stratified keratinizing squamous epithelium [12,13]. Once a cholesteatoma sac is formed, it starts accumulating keratin debris and grows in size with invasion and destruction of the surrounding structures, which depending on the age of the patient, extent of the disease and location, various surgical treatments should be performed to avoid the potential complications that may occur, such as meningitis or brain abscesses [14].

CT temporal bones are the imaging modality of choice for diagnosing cholesteatomata. Typical findings include an expansile soft-tissue lesion with associated retraction of the tympanic membrane. This in turn leads to blunting of the scutum and erosion of the ossicles [2]. MRI imaging with Diffusion Weighted Imaging (DWI) may also be performed in cases where tissue differentiation is helpful for diagnosis [15].

Cholesteatomata are classified as congenital or acquired depending on the disease pathogenesis. Congenital cholesteatoma, being specific to children have an incidence of 0.12 per 100,000 children [16,17], while acquired cholesteatomata which affects both children and adults is further subdivided into primary (80% of all middle ear cholesteatomata), and secondary cholesteatoma (18% of all middle ear cholesteatoma). On the other hand, the middle ear cholesteatoma are more commonly classified based on their location (Table 1) [11].

Congenital cholesteatomata are generally asymptomatic, behind an intact tympanic membrane [18] and are usually an incidental finding. As for primary acquired cholesteatoma, they also usually have an intact tympanic membrane, and are localised to the pars flaccida, and present with recurrent ear symptoms, such as conductive hearing loss, discharge and vertigo [19].

Secondary cholesteatomata, on the other hand are usually a result of surgical intervention, infections or trauma, and grow into the middle ear through a perforated tympanic membrane [20]. In advanced stages of congenital cholesteatoma, they may present with symptoms similar to acquired cholesteatoma.

Primary acquired cholesteatoma or retraction pocket cholesteatoma, most commonly forms in the Prussak’s space lateral to the ossicles [2], with lateral expansion. This may result in erosion of the lower lateral wall of the attic and the scutum [21,22], resulting in spontaneous drainage into the external auditory canal known as auto-atticotomy, with an air filled cavity remaining, which reflects the dimensions of the cholesteatoma [2,23]. This bony destruction likely result from a combination of different mechanisms, mass effect of the growing cholesteatoma, cytokines secreted within the environment, and osteoclastic activity of the cholesteatoma [23]. The exact incidence of auto-atticotomy is unknown; however, it is considered quite rare with incidental cases likely being very uncommon.

Conclusion

Cholesteatomata have been well described in the literature, however in our knowledge only a few cases of auto-atticotomy have been published. In patients with headache and spontaneous otorrhea, although a rare diagnosis, careful attention should be made to the temporal bones, as an auto-atticotomy may be the underlying diagnosis.

Table 1: Location based classification of middle ear cholesteatomata [11].

| Initial Location       | Pathogenesis          |
|------------------------|-----------------------|
| Pars flaccida (attic)  | Epitympanum (Lateral to ossicles) |
|                        | Congenital            |
|                        | Primary acquired      |
|                        | Secondary acquired    |
| Pars tensa (sinus)     | Mesotympanum (Medial to ossicles) |
|                        | Congenital            |
|                        | Secondary acquired    |
