ABSTRACT: This study investigated whether jump training with blood flow restriction (BFR) improves jump performance compared to jump training without BFR under similar exercise intensity in healthy young humans. The participants were twenty healthy males who were assigned to either jump training with BFR (n = 10) or jump training without BFR (control (CON); n = 10) groups. All subjects completed five sets of 10 repetitions with one-minute intervals of half-squat jumps (SJ) at maximal effort, four days a week for four weeks. In the BFR group, circulatory occlusion around both thigh muscles was applied at a pressure of 200 mmHg, and physical characteristics, muscle strength and jump performance were evaluated before and after training. A significant main effect of training period on lean body mass, percentage of body fat and leg circumference in both groups was observed (P < 0.05). For jump training with BFR, only knee flexion strength increased (P < 0.05), while in the CON group, both knee extension and flexion strength increased (P < 0.05). BFR training did not improve SJ or counter-movement jumps (CMJ) (P > 0.05), whereas training without BFR (CON) improved the performance of both jumps (SJ: pre 35.7 ± 5.1 vs. post 38.9 ± 4.1 cm, P = 0.002: CMJ: pre 41.6 ± 3.6 vs. post 44.6 ± 3.8 cm, P < 0.001). These results indicate that jump training with BFR may not be an effective strategy for improving jump performance.

INTRODUCTION

The central goal of muscle strength or power training in any sport is to improve players’ specific and relevant athletic activities inherent to each sport. It has been suggested that low and/or moderate intensity resistance exercises with blood flow restriction (BFR) lead to dramatically greater muscle hypertrophy and strength gain [1-6] and result in adaptations equal to those of high-intensity resistance training [5]. However, most previous studies on BFR training have focused on muscle strength and/or muscle volume [1-6], and few have investigated whether BFR training improves sports performance and muscle strength in relation to unaltered jump performance [7].

BFR training increases the muscle cross sectional area, which is assessed using magnetic resonance imaging (MRI), but it does not affect counter movement jump (CMJ) performance [8]. This could be due to training methods; improved jump performance results from high-intensity resistance training or jump training [9], and training with sport-specific movements can significantly improve sports performance (e.g., basketball specific plyometric training [10], sports specific background [11], and plyometric jump training [12]). Previous studies have included classical BFR training, such as low-intensity resistance training with BFR (i.e., combined squats and leg curls at 20% of one-repetition maximum (RM) for eight days) followed by performance evaluations of three types of jumps (i.e., standing jumps, standing triple jumps and standing five-step jumps) and horizontal squats at 30-40% of the one RM followed by evaluation of CMJ height [7, 8]. Thus, little is known about whether or not actual sport movement with BFR training may have beneficial effects on sports related performance.

From these considerations, we hypothesized that jump training with BFR improves jump performance induced by an increase in muscle strength compared to jump training without BFR. To test this hypothesis, we compared two young groups under jump training with or without BFR.
TABLE 1. Changes in physical characteristics between the two groups.

|                           | CON (n = 10) | BFR (n = 10) | P values |
|---------------------------|-------------|--------------|----------|
|                           | Pre-training| Post-training| Pre-training| Post-training| Group | Time | Group×Time |

**TABLE 2. Coefficient of variations in jump performance and muscle strength between the two groups.**

|            | CON     | Pre  | Post | BFR     | Pre  | Post |
|------------|---------|------|------|---------|------|------|
| SJ         | 14.3    | 10.5 | 10.7 | 11.4    |      |      |
| CMJ        | 8.7     | 8.5  | 17.5 | 15.0    |      |      |
| KE         | 13.8    | 18.2 | 11.2 | 14.0    |      |      |
| KF         | 19.6    | 20.4 | 18.4 | 17.4    |      |      |

All units are represented as percentages. SJ, squat jump; CMJ, counter movement jump; KE, knee extension; KF, knee flexion.

flexor contractions at 60°/s as one set for both legs, separately. Subjects performed this test three times, and after each set they took a 90-second rest between the sets. The details of the position were checked carefully and used as the same position in the second test session. The thigh strap was released during each rest period to ensure unrestricted blood flow to the quadriceps muscle. Strong verbal encouragement was given throughout the test session. The tester established contraction velocity because most daily activities are related to the ability to generate power at low velocity [14]. Bilateral maximal KE and KF strengths were calculated by averaging values of three measurement sets.

**Statistics**

Data are expressed as mean ± standard deviation (SD). An unpaired t-test was used for comparison in age and height between groups. Two-way repeated measured analysis of variance (ANOVA: groups × time) was conducted for comparison in all other variables. A Bonferroni post-hoc test was used for further analysis, and \( P < 0.05 \) was set for statistical significance.

**RESULTS**

**Physical characteristics**

Pre- and post-training physical characteristics are shown for both groups in Table 1. In both groups, thigh circumference significantly increased (\( P = 0.011 \) in CON vs. \( P = 0.009 \) in BFR), whereas no statistically significant main effect of time on lean body mass or percentage of body fat was observed in CON and BFR groups.

**Jump performance**

No significant effect of BFR training on jump performance in SJ or CMJ was observed (\( P = 0.103 \) for SJ and \( P = 0.277 \) for CMJ). However, jump training without BFR significantly improved the performances (9.0% improvement for SJ, \( P = 0.002 \), and 7.2% improvement for CMJ, \( P < 0.001 \); Figure 1).

**Muscle strength**

Figure 2 shows changes in KE and KF strength between the pre- and post-training for both groups. BFR training did not increase KE

![FIG. 1. Comparison of squat jump (SJ) and countermovement jump (CMJ) between the control (CON) and blood flow restriction (BFR) groups. Values are mean ± standard deviation (SD). White bars represent pre-training values and black bars represent post-training values. * \( P < 0.05 \) between pre- and post-training within the same group.](image-url)
Masahiro Horiuchi et al.

The results of the present study can provide useful information for athletes who want to improve jump performance as well as muscle strength. Our results demonstrated that jump training with BFR did not improve jump performance and only increased KF strength, whereas jump training without BFR significantly improved jump performance as well as increasing KE and KF strength. These findings suggest that BFR training using sports-specific movements, at least jump performance, may not be an effective strategy for improvement of sports performance.

Significant improvements in jump performance were observed in the CON group, while no improvements in jump performance were observed in the BFR group. It has been reported that better jump performance is related to greater muscle strength and the rate of strength development in the lower limbs, suggesting that the muscle strength in lower limb joints is a primary determinant of vertical jump performance [15]. In addition, studies have demonstrated that strength-training-induced improvements in jump performance are the result of increased muscle strength and size [16, 17]. A previous study demonstrated that 14.6% and 21.7% increases in one RM for leg presses and squats resulted in a 9.3% increase in the height of CMJ [18], while other studies using BFR training reported a 9.6% increase in one RM for leg presses and a 19.3% increase in one RM for squats, without improved jump performance [7, 8]. In the present study, significant increases in maximal KE and KF strengths were observed in the CON group; however, the magnitude of these improvements may be related to the different training modes and evaluation outcomes between the present study and the literature. In contrast, jump training with BFR significantly increased KF strength only by ~6% and did not increase KE strength, indicating that there were no beneficial effects of the BFR training on jump performance, although the reason for this result remains unclear. The current researchers previously reported that four weeks of plantar flexion training with BFR at 20% maximal voluntary contraction significantly increased calf muscle cross sectional area (CSA) based on MRI results [14]. This may be attributed to enhanced metabolites [19]. Based on this past research, the training period used in the present study was of sufficient duration to improve muscle strength; thus, BFR training should be beneficial for improving muscle bulk and strength [19]. However, the results presented here do

**DISCUSSION**

The results of the present study can provide useful information for athletes who want to improve jump performance as well as muscle strength. Our results demonstrated that jump training with BFR did not improve jump performance and only increased KF strength, whereas jump training without BFR significantly improved jump performance as well as increasing KE and KF strength. These findings suggest that BFR training using sports-specific movements, at least jump performance, may not be an effective strategy for improvement of sports performance.

Significant improvements in jump performance were observed in the CON group, while no improvements in jump performance were observed in the BFR group. It has been reported that better jump performance is related to greater muscle strength and the rate of strength development in the lower limbs, suggesting that the muscle strength in lower limb joints is a primary determinant of vertical jump performance [15]. In addition, studies have demonstrated that strength-training-induced improvements in jump performance are the result of increased muscle strength and size [16, 17]. A previous study demonstrated that 14.6% and 21.7% increases in one RM for leg presses and squats resulted in a 9.3% increase in the height of CMJ [18], while other studies using BFR training reported a 9.6% increase in one RM for leg presses and a 19.3% increase in one RM for squats, without improved jump performance [7, 8]. In the present study, significant increases in maximal KE and KF strengths were observed in the CON group; however, the magnitude of these improvements were 7.4% and 6.5%, respectively, resulting in significant improvements in both SJ and CMJ. These lower magnitudes of improvement in muscle strength may be related to the different training modes and evaluation outcomes between the present study and the literature. In contrast, jump training with BFR significantly increased KF strength only by ~6% and did not increase KE strength, indicating that there were no beneficial effects of the BFR training on jump performance, although the reason for this result remains unclear. The current researchers previously reported that four weeks of plantar flexion training with BFR at 20% maximal voluntary contraction significantly increased calf muscle cross sectional area (CSA) based on MRI results [14]. This may be attributed to enhanced metabolites [19]. Based on this past research, the training period used in the present study was of sufficient duration to improve muscle strength; thus, BFR training should be beneficial for improving muscle bulk and strength [19]. However, the results presented here do

![Comparison of knee extension (KE) and knee flexion (KF) strengths between the CON and BFR groups. Values are mean ± SD. Bar representation is the same as in Figure 1.](image-url)

* $P < 0.05$ between pre- and post-training within the same group.
not support these expectations, despite both group having used maximal effort in the training, which could be due to different training volumes and loads between the CON and BFR groups. BFR training might restrict movement during exercise due to vascular occlusion, but because training intensity in this study was vertical jump training at individual maximal effort, it was difficult to control exercise intensity between participants. Therefore, it is possible that variability exists in the study results, even though each subject performed jump training under the supervision of a training specialist throughout the training period. A recent study demonstrated that differences in physical characteristics, such as body mass index, thigh circumference and thigh muscle–bone CSA, may relate to different degrees of BFR [20]. We applied the same absolute pressure of ~ 200 mmHg for blood occlusion to all subjects in the present study; therefore, training with BFR might have constrained jump movement throughout the training periods, resulting in different training loads and volume, no increases in KE strength and no improvements in jump performance. However, the precise mechanisms of these effects on muscle strength and jump performance are still unknown, and future studies are warranted.

**Methodological considerations**

Several limitations must be considered when interpreting the findings from the present study. First, this study conducted a subject comparison between legs, with one leg trained with BFR and the other leg without BFR. Therefore, we could not completely rule out between-subject effects although subjects had similar physical characteristics before and after training and similar physical activity levels. Second, jump performance was only evaluated based on muscle strength, and the influence of other related factors, such as muscle CSA and storage and release of elastic energy [21-24], on jump performance remains uncertain and requires future investigation.

**CONCLUSIONS**

In summary, the present results suggest that jump training with BFR does not improve jump performance, while normal jump training improved jump performance as well as KE and KEF strengths. The results indicate that sport-specific movement training with BFR may not be necessary to improve sport performance, at least in this type of sports performance and with the population in this study.
