hOGG1 encodes a DNA repair enzyme responsible for the excision of reactive oxygen species (ROS) in damaged DNA. Previous studies have obtained inconsistent results. To validate the association between the hOGG1Ser326Cys polymorphism and lung cancer risk, we performed an updated meta-analysis of 20 studies (8739 cases and 10385 controls) using STATA version 11.1. With this approach, we tested the overall and subgroup association between the SNP and lung cancer susceptibility stratified by ethnicity, control sources, cell histotypes, and smoking status. We demonstrated a novel, significant correlation between the hOGG1 Ser326Cys polymorphism and increased lung cancer susceptibility in Caucasians. Our findings indicate a need for larger-scale studies to verify the association of this SNP with lung cancer risk in Caucasians.

Human 8-oxoguanine DNA glycosylase -1 (hOGG1) is located at chromosome 3p26.2. It encodes an enzyme responsible for removing the most common product of oxidative damage in DNA, namely 8-hydroxyguanine (8-OH-G). 8-OH-G can induce G→T or A→C base mismatches during DNA replication, thereby possibly triggering the onset of carcinogenesis. Codon 326 at position 1245 in exon 7 of hOGG1 holds a single nucleotide polymorphism (SNP) with a C→G variation, thereby the amino acid translation of codon 326 can be changed from serine (Ser) to cysteine (Cys). Experiments have illustrated that the DNA glycosylase encoded by the Cys326 variant exhibits remarkably lower 8-OH-G excision activity than the wild-type Ser326 allele, because the Cys326 variant enzyme has a lower affinity to lesions of damaged DNA than Ser326 enzyme. Thus, hOGG1 Ser326Cys polymorphism is speculated to associate with multiple types of cancer due to the compromised cleavage of 8-OH-G.

Lung cancer is the most commonly diagnosed cancer (1.61 million diagnoses, 12.7% of the total cancer diagnoses), and is estimated to be the leading cause of cancer death (1.38 million deaths, 18.2% of the total cancer deaths) worldwide. Numerous investigations have studied the association between the hOGG1 Ser326Cys polymorphism and this malignancy. However, the results of these studies have been inconsistent, partly due to genetic or other sources of heterogeneity, including differences in eligibility criteria and analysis approaches, small sample sizes, publication biases, and exogenous confounders. For this reason, meta-analyses with robust statistical power have been frequently performed to validate the association between the hOGG1 Ser326Cys polymorphism and the risk of lung cancer. Li et al. found no association between the hOGG1 Ser326Cys polymorphism and increased risk of lung cancer susceptibility except in Asians, while Kiyohara et al. found a significant association between the hOGG1 Ser326Cys polymorphism and the risk of lung cancer in the overall population and in an Asian subgroup. In another study, Guan et al. uncovered a potential trend of significant linkage between hOGG1 Ser326Cys polymorphism and lung cancer risk in Caucasians. Since these publications, more studies of the hOGG1 Ser326Cys polymorphism in relation to lung cancer susceptibility have been completed. Thus, we conducted an updated meta-analysis by adding the latest data and avoiding sample overlapping with the aim of gaining a more reliable evaluation of the association between hOGG1 Ser326Cys polymorphism and lung cancer susceptibility.
Results

Study characteristics. Twenty-eight articles were identified to meet the inclusion criteria. We thoroughly reviewed these articles to detect overlapping samples. Studies by Vogel et al., Sorensen et al., Hatt et al., and Loft et al. were found to share a common sample sources from a Danish prospective follow-up study. Therefore, only the study by Sorensen et al., which had the largest sample size, was used in our meta-analysis. The studies by Sunaga et al. and Kohno et al. consisted of the same lung adenocarcinoma cases; we included only the study by Kohno et al. because it had a larger sample size. The studies by Liang et al., Zienolddiny et al., and Liu et al. were excluded because the genotype distribution among the controls was deviated significantly from HWE (P<0.05). Finally, 20 articles, including 8739 lung cancer cases and 10385 controls were ascertained for use in our meta-analysis.I,20,24–41. We treated each,

Heterogeneity and model. All heterogeneity statistic I^2 values except that in smoking subgroup (I^2 = 53.4%) were observed less than 50% in the present study, which indicated that the appropriate pooling model should be fixed effects (Inverse Variance). For the smoking subgroup, a random effects model was used. Furthermore, using a suitable underlying genetic model in genetic association studies is crucial for combining data biologically rather than just statistically. According to the methodology for genetic model selection developed by Thakkinstian et al., we decided to use the recessive genetic model. After a sensitivity analysis, no individual study was found to affect the overall result robustly, which implied the magnitude of the summary evaluation.

Gene effect. The overall frequency of the Cys allele in the case group was significantly higher than that in the control group (39.7% versus 35.1%, P<0.01). Among the Asian subgroup, the Cys variant frequency was 54.0% in the cases and 51.7% in the controls (P<0.01). More or less, the higher frequency of the Cys allele in cases suggested a potential association of the variant with risk of lung cancer.

The overall results of the genetic analysis indicated a significant association between the hOGG1 Ser326Cys polymorphism and lung cancer risk (OR = 1.20, 95%CI: 1.10–1.30) (Table 2). In the subgroups by ethnicity, a significant association was observed in Caucasians (OR = 1.32, 95%CI: 1.05–1.67), and in Asians (OR = 1.18, 95% CI: 1.07–1.29) respectively (Figure 1). In the stratified analysis based on control sources, our study also showed a significant linkage of the hOGG1 Ser326Cys polymorphism with lung cancer risk in both population-based (OR = 1.18, 95%CI: 1.04–1.34) and hospital-based controls (OR = 1.21, 95%CI: 1.08–1.35) (Figure 2).

For the study stratified by smoking status, only eight studies were available,20,26,29,30,33,36–38. No correlation was found between hOGG1 Ser326Cys polymorphism and lung cancer among non-smoking (OR = 1.09, 95%CI: 0.92–1.29) or smoking subgroups (OR = 1.24, 95%CI: 0.95–1.61). Another stratified study referring to histological subtypes, due to a lack of well-documented pathologic data in most original studies, only ten studies were useful for stratification by the following histological subtypes: small cell carcinoma, squamous cell

| Hospital       | 37.8 / 33.8                                             | 1.21 (1.08–1.35)                           | 41.8        |

\textsuperscript{a}Only Asian and Caucasian ethnicities are shown. Multietnic data were extracted for the subgroup analysis based on ethnicity as a separate independent study.

\textsuperscript{b}In this analysis, \( P \_\text{caucasian} = 0.514 \) by Chi-Square analysis. All others were \( P < 0.05 \).

Figure 1 | Stratified analysis based on ethnicity for the association between \textit{hOGG1} Ser326Cys polymorphism and lung cancer risk using a recessive genetic model.
ibility among smokers in the Asian population (OR = 1.25, 95% CI: 1.04–1.51), but an assessment of Caucasians was not possible due to the limited data available. Similar to the results of the combined analysis, the hOGG1 Ser326Cys polymorphism showed a significant association with lung cancer susceptibility only in the adenocarcinoma cell type subgroups in the Asian and Caucasian populations respectively (Table 4).

The weight of each study contributing to the overall result was calculated. Of the statistical power, 81.83% was from the Asians, while 13.01% was from the Caucasians. The weight of each individual study varied widely, from 22.85% to 0.17%. The hospital-based controls contributed more power than the population-based controls (55.56% versus 44.44%), with the heterogeneity statistic $I^2$ being remarkably higher in the hospital-based control group than that in the population-based controls (41.8% versus 10.4%).

Publication bias. The publication bias was accessed using Begg’s ($P = 0.303$) and Egger’s ($P = 0.185$) tests. The funnel plot displayed a symmetric shape (Figure 3), indicating the absence of a publication bias for both positive and negative or non-significant findings from published studies.

### Table 3 | Stratified analysis of hOGG1 Ser326Cys association by histotype and smoking status

*Random effects model was used.
Discussion
Genetic epidemiological studies have proposed that there is a relationship between SNPs and diseases. However, large and well-designed genotype-phenotype investigations with robust statistical power are required to detect these mild to moderate associations. Additionally, there has been increased focus on the modified effects of certain exogenous factors. A predominant DNA glycosylase, encoded by hOGG1, has the ability to recognise and remove an oxidative DNA damage product, namely 8-OH-G. This substance is generally treated as a mutagen because of its ability to induce mutation. Studies have revealed that the Cys-mutant enzyme is less effective at repairing DNA than Ser wild type enzyme6–8.

In a published pooled analysis, Li et al reported that there is no relationship between hOGG1 Ser/Cys polymorphism and lung cancer11. However, Kiyohara et al found a significant association between this genetic polymorphism and lung cancer by adding several additional case-control studies12. With more studies about hOGG1 and lung cancer were available recently, our updated meta-analysis, which has the largest sample size thus reported, yielded a positive relationship between the genetic variant and lung cancer in Caucasians (OR 1.32, 95%CI: 1.05–1.67). In addition, a recent meta-analysis by Guan et al has predicted a potential connection between the variant and lung cancer in Caucasians13.

Our novel finding may be due to an increase in sample sizes and the avoidance of sample overlapping. Another reason may be that we objectively and precisely stratified the population based on ethnicity subgroups. Because the detection for mild to modest risk genetic risk effects requires sufficient statistical power, we proposed that large case-control studies may help to further validate the true association between the genetic variant and lung cancer among Caucasians.

Based on source of controls, we were able to observe that the heterogeneity statistic $I^2$ in the hospital-based subgroup was higher than that in the population-based subgroup (41.8% versus 10.4%). To some extent, hospital-based controls were recruited as lung cancer-free individuals regardless of their status concerning other diseases, which might be a potential source of heterogeneity because of a mixture of other diseases, particularly if the disease had effect upon genotyped results11. We suggested that the use of population-based controls should be more representative.

In another analysis, stratified according to smoking status, no significant association was observed between the hOGG1 Ser326Cys polymorphism and lung cancer susceptibility. Contrary to this finding, Cys allele has been reported to be associated with lung cancer risk among heavy smokers39. Another study by Li et al identified a marginally increased risk of hOGG1 Ser326Cys polymorphism in non-smoking subjects harbouring the Cys allele39. To the best of our best knowledge, multiple tobacco-related chemicals are capable of inducing DNA mutations and initiating carcinogenesis, especially

Table 4 | Analysis of hOGG1 Ser326Cys association adjusted for study design and ethnicity

| Ethnicity | Status/histotypes | Cys/Cys versus Ser/Ser + Ser/Cys OR (95%CI) | $I^2$ (%) |

|           | Squamous cell    | 1.10 [0.74–1.63]                          | 41.9    |
|           | Adenocarcinoma   | 1.82 [1.22–2.71]                          | 43.1    |

NA: data of the group were not available from the original study.

Figure 3 | Begg’s funnel plot displaying a symmetric shape.
in lung cancer. Thus, the complexities of exogenous modification to gene and gene-environment interactions remain a field to be explored. We attributed the inconsistency of different studies to a lack of universal standards when delineating subgroups, including different category criteria such as smoking duration and intensity. Otherwise, the data were primarily obtained from self-reported data from questionnaires of participants, so inaccurate confounders should be taken into account. In addition, the current study employed analyses adjusted for study design and ethnicity and yielded a positive association between the hOGG1 condon326 polymorphism and increased lung cancer risk in smoking group among Asians. We assumed that modification of the study design and ethnicity could lower the heterogeneity and reduce the potential of confounders. It also implied the important role of the modified analyses in pooled studies.

Given the diversity of histopathologic categories in lung cancer, stratified evaluation was conducted for small cell carcinoma, squamous cell carcinoma, and adenocarcinoma. We found a significant association between the hOGG1 Ser/Cys polymorphism and lung adenocarcinoma. Our result was consistent with one former meta-analyses in pooled studies.

Asians. We assumed that modification of the study design and ethnicity heterogeneity. Indeed, more relevant studies of Caucasians were essential. Second, due to the limitation of eligible data, the subgroups based on smoking status were crudely classified into smoking and non-smoking subgroups, regardless of the smoking duration and consumption. Thus, potential sources of heterogeneity were included when the data were combined. Although the interaction between smoking status and hOGG1 condon326 is of great interest, the limited data available for use in the current meta-analysis were not sufficient to identify an association between the genotype and cigarette smoking. Third, the small sample size of lung cancer cell subtypes might have restricted the power of our meta-analysis to reveal a potential connection.

Methods

Eligibility of relevant studies. All original articles published in English that examined the association of the hOGG1 Ser326Cys polymorphism with lung cancer (published before November 2011) were considered for our meta-analysis. The PubMed, Embase, HuGENet, and Ovid databases were searched to identify appropriate studies. The following combinations of terms were used in our database searches: ("Lung cancer" or "Lung Neoplasms" or "Pulmonary Cancer" or "Pulmonary Neoplasms") and ("polymorphism" or "SNP" or "allele" or "variant") and (("OGG1" or "hOGG1" or "OGGI enzyme" or "hOGG1: Human 8-oxoguanine DNA glycosylase-1")). Furthermore, the searches were supplemented by references cited in other papers. Inclusion criteria were (1) studies assessed linkage of hOGG1 Ser326Cys polymorphism with lung cancer risk; (2) lung cancer cases should be diagnosed explicitly; (3) controls should be unrelated cancer-free individuals. When multiple reports had overlapping sample populations, only the study with largest sample size was retained.

Data extraction. For each available study, the following information was extracted: the first author, year of publication, ethnicity of participants, source of controls, number of genotyped cases/controls, method for quality control of genotyping result, smoking status, and histological sub-type. The data were primarily extracted from tables and supplemented by significant information presented in texts and/or figures. Two investigators (Y.L H and D-N Z) handled the data simultaneously and separately.

Statistical analysis. Hardy-Weinberg equilibrium (HWE) was assessed for each study using the chi-square test. Studies were considered to deviate from HWE at P<0.05. The inconsistency index, I², was calculated to evaluate the variation among studies using heterogeneity (0%–25% was considered to have no heterogeneity; 25%–50% was considered to have moderate heterogeneity; 50%–75% was considered to have large heterogeneity; 75%–100% was considered to have extreme heterogeneity). The data were combined using logistic regression with the fixed-effects pooling model if there was no or moderate heterogeneity (I²<50%). Alternatively, the random effects model was used (I²>50%). Sensitivity analysis was performed by excluding one study at a time to determine the corresponding magnitude of the weight of each study to the summary results. The most biologically fit genetic model was selected according to the comprehensive effect of the gene using logistic regression. To extensively explore the genetic heterogeneity, stratified analyses were conducted by ethnicity, source of controls, smoking status, and histological sub-types. The association between hOGG1 Ser326Cys polymorphism and lung cancer risk was evaluated using the odds ratio (OR) and the 95% confidence interval (CI). Funnel plots, used to observe the publication bias, were complemented with Egger’s regression and Begg’s rank correlation test (P > 0.10). The statistical analyses were performed using STATA version 11.1 (Stata Corporation, USA). All p values were two-sided.
