1 April 2015

ABSTRACT
Several observations of transition discs show lopsided dust-distributions. A potential explanation is the formation of a large-scale vortex acting as a dust-trap at the edge of a gap opened by a giant planet. Numerical models of gap-edge vortices have so far employed locally isothermal discs in which the temperature profile is held fixed, but the theory of this vortex-forming or ‘Rossby wave’ instability was originally developed for adiabatic discs. We generalize the study of planetary gap stability to non-isothermal discs using customized numerical simulations of disc-planet systems where the planet opens an unstable gap. We include in the energy equation a simple cooling function with cooling timescale \( t_c = \beta \Omega_k^{-1} \), where \( \Omega_k \) is the Keplerian frequency, and examine the effect of \( \beta \) on the stability of gap edges and vortex lifetimes. We find increasing \( \beta \) lowers the growth rate of non-axisymmetric perturbations, and the dominant azimuthal wavenumber \( m \) decreases. We find a quasi-steady state consisting of one large-scale, over-dense vortex circulating the outer gap edge, typically lasting \( O(10^3) \) orbits. We find vortex lifetimes generally increase with the cooling timescale \( t_c \) up to an optimal value of \( t_c \sim 10 \) orbits, beyond which vortex lifetimes decrease. This non-monotonic dependence is qualitatively consistent with recent studies using strictly isothermal discs that vary the disc aspect ratio. The lifetime and observability of gap-edge vortices in protoplanetary discs is therefore dependent on disc thermodynamics.

Key words: accretion, accretion discs, protoplanetary discs, hydrodynamics, instabilities, planet-disc interactions, methods: numerical

1 INTRODUCTION

The interaction between planets and protoplanetary discs plays an important role in the theory of planet formation and disc evolution. Disc-planet interaction may lead to the orbital migration of protoplanets and modify the structure of protoplanetary discs (see Baruteau & Masset 2013, for a recent review).

A sufficiently massive planet can open a gap in a gaseous protoplanetary disc (Papaloizou & Lin 1984; Bryden et al. 1999; Crida, Morbidelli & Masset 2006; Fung, Shi & Chiang 2014), while low mass planets may also open gaps if the disc viscosity is small enough (Li et al. 2003; Dong, Rafikov & Stone 2011; Duffell & MacFadyen 2013). Support for such disc-planet interaction have begun to emerge in observations of circumstellar discs that reveal annular gaps (e.g. Quanz et al. 2013a; Debes et al. 2013; Osorio et al. 2014), with possible evidence of companions within them (e.g. Quanz et al. 2013b; Reggiani et al. 2014).

A recent theoretical development in the study of planetary gaps is their stability. When the disc viscosity is low and/or the planet mass is large, the presence of potential vorticity (PV, the ratio of vorticity to surface density) extrema can render planetary gaps dynamically unstable due to what is now referred to as the ‘Rossby wave instability’ (RWI, Lovelace et al. 1999; Li et al. 2000). This eventually leads to vortex formation (Li et al. 2001; Koller, Li & Lin 2003; Li et al. 2003; de Val-Borro et al. 2007), which can significantly affect orbital migration of the planet (Qu et al. 2007; Li et al. 2009; Yu et al. 2014; Lin & Papaloizou 2010).

Vortex formation at gap edges may also have observable consequences. Because disc vortices represent pressure maxima, they are able to collect dust particles (Barge & Sommeria 1995; Inaba & Barge 2006; Lyra & Lin 2013). Dust-trapping at gap-edge vortices have thus been suggested to explain asymmetric dust distributions observed in several transition discs (e.g. Casassus et al. 2013).
However, studies of Rossby vortices at planetary gap edges have adopted locally isothermal discs, where the disc temperature is a fixed function of position only (e.g. Lyra et al. 2009; Lin & Papaloizou 2011; Zhu et al. 2014; Fu et al. 2014). On the other hand, the theory of the RWI disc temperature is a fixed function of position only (e.g. Li et al. 2000; Lin 2013). In the context of planetary gaps, we found that increasing the sound-speed favours instability close to steady state. The cooling term $\mathcal{C}$ is defined as

$$\mathcal{C} \equiv \frac{1}{t_c} \left( e - e_i \right),$$

where $t_c = \beta \Omega_k^{-1}$ is the cooling time, $\Omega_k = \sqrt{GM/r^3}$ is the Keplerian frequency and $\beta$ is an input parameter. This cooling prescription allows one to explore the full range of thermodynamic response of the disc in a systematic way: $\beta \leq 1$ is a locally isothermal disc while $\beta \gg 1$ is an adiabatic disc.

Note that the energy source terms have been chosen to be absent at $t = 0$, allowing the disc to be initialized close to steady state. The $\mathcal{C}$ function attempts to restore the initial energy density (and therefore temperature) profile. In practice, this is a cooling term at the gap edge because disc-planet interaction leads to heating.

2.2 Disc model and initial condition

The disc occupies $r \in [r_{in}, r_{out}]$ and $\phi \in [0, 2\pi]$. The initial disc is axisymmetric with surface density profile

$$\Sigma(r) = \Sigma_{ref} \left( \frac{r}{r_{in}} \right)^{-s} \left[ 1 - \sqrt{\frac{r_{in}}{r + H(r_{in})}} \right],$$

where the power-law index $s = 2$, $H(r) = c_{iso}\Omega_k$ defines the disc scale-height where $c_{iso} = \sqrt{\gamma P/\Sigma}$ is the isothermal sound-speed. The disc aspect ratio is defined as $h \equiv H/r$ and initially $h = 0.05$. For a non-self-gravitating disc, the surface density scale $\Sigma_{ref}$ is arbitrary.

The initial azimuthal velocity $v_{\phi,i}$ is set by centrifugal balance with pressure forces and stellar gravity. For a thin disc, $v_{\phi,i} \approx r \Omega_k$. The initial radial velocity is $v_r = 3\nu/r$, where $\nu = \hat{v}^2_{in} \Omega_k (r_{in})$, and we adopt $\nu = 10^{-9}$, so that $|v_r/v_{\phi,i}| \ll 1$ and the initial flow is effectively only in the azimuthal direction. With this value of physical viscosity, the only source of heating is through compression, shock-heating (via artificial viscosity) and the $\mathcal{C}$ function when $\epsilon/\Sigma < \epsilon_i/\Sigma_i$.

2.3 Generalised potential vorticity

The planet potential is given by

\[ \Phi_p = -\frac{GM_p}{\sqrt{|r - r_p|^2 + e_p^2}} \]  

(7)

where \( M_p \) is the planet mass and we fix \( q \equiv M_p/M_\bullet = 10^{-3} \) throughout this work. This corresponds to a Jupiter-mass planet if \( M_\bullet = M_\odot \). The planet’s position in the disc \( r_p = (r_p, \phi_p) \) and \( e_p = 0.5r_h \) is a softening length with \( r_h = (q/3)^{1/3}r_p \) being the Hill radius. The planet is held on a fixed circular orbit with \( r_p = 10r_in \) and \( \phi_p = \Omega_h(r_p)t \). This also defines the time unit \( P_0 \equiv 2\pi/\Omega_h(r_p) \) used to describe results.

3 NUMERICAL EXPERIMENTS

The disc-planet system is evolved using the FARGO-ADSG code (Baruteau & Masset 2008, 2009, 2010). This is a modified version of the original FARGO code (Masset 2000) to include the energy equation. The code employs a finite-difference scheme similar to the ZEUS code (Stone & Norman 1992), but with a modified azimuthal transport algorithm to circumvent the original time-step restriction set by the fast rotation speed at the inner disc boundary. The disc is divided into \((N_r, N_\phi)\) zones in the radial and azimuthal directions, respectively. The grid spacing is logarithmic in radius and uniform in azimuth.

3.1 Cooling prescription

In this work we only vary one control parameter: the cooling time. The cooling parameter \( \beta \) is chosen indirectly through the parameter \( \tilde{\beta} \) such that

\[ t_c(r_p + x_s) = \beta t_{lib}(r_p + x_s), \]  

(8)

where \( x_s \) is the distance from the planet to its gap edge, and \( t_{lib} \) is the time interval between successive encounters of a fluid element at the gap edge and the planet’s azimuth. That is, we measure the cooling time in units of the time interval between encounters of a fluid element at the gap edge and the planet-induced shock.

Assuming Keplerian orbital frequencies and \( x_s \ll r_p \)
gives \( t_{lib} \simeq 4\pi r_p/(3\Omega_{kp}x_s) \), where \( \Omega_{kp} = \Omega_h(r_p) \). Therefore

\[ \beta = \tilde{\beta} \frac{4\pi r_p}{3x_s} \left( 1 - \frac{3x_s}{2r_p} \right), \]  

(9)

where \( x_s \ll r_p \) was used again. We use \( x_s = 2r_h \) in Eq. (8) For a planet mass with \( q = 10^{-3} \), Eq. (8) then gives \( \beta \simeq 23.9\tilde{\beta} \).

In terms of planetary orbital periods, this is

\[ t_c(r) = \frac{\beta}{2\pi} \left( \frac{r}{r_p} \right)^{3/2} P_0 \simeq 3.8\beta \left( \frac{r}{r_p} \right)^{3/2} P_0. \]  

(10)

3.2 Diagnostic measures

3.2.1 Generalised potential vorticity

The generalised potential vorticity is defined as

\[ \tilde{\eta} = \frac{\kappa^2}{2\Omega\Sigma} \times S^{-2/\gamma}, \]  

(11)

where \( \kappa^2 = r^{-3}\partial_r(r^4\Omega^2) \) is the square of the epicyclic frequency, \( \Omega = v_\phi/r \) is the angular speed, and \( S \equiv p/\Sigma^\gamma \) is the entropy. The first factor is the usual potential vorticity (PV, or vortensity).

The generalised PV appears in the description of the linear stability of radially-structured adiabatic discs (Lovelace et al. 1999, Li et al. 2000), where the authors show an extremum in \( \tilde{\eta} \) may lead to a dynamical instability, the RWI. In a barotropic disc where \( p = p(\Sigma) \), the entropy factor is absent and the important quantity is the PV.

3.2.2 Fourier modes

The RWI is characterized by exponentially growing perturbations. Though in this paper we do not consider a formal linear instability calculation, modal analysis will be useful to analyse the growth of perturbations with different azimuthal wavenumbers, which is associated with the number of vortices initially formed by the RWI.

The Fourier transform of the time-dependent surface density is

\[ \Sigma_m(r, t) = \int_0^{2\pi} \Sigma(r, \phi, t) e^{-im\phi} d\phi \]  

(12)

where \( m \) is the azimuthal wave number. We define the growth rate \( \sigma \) of the \( m^{th} \) component of the surface density through

\[ \frac{d\langle |\Sigma_m|_r \rangle}{dt} = \sigma \langle |\Sigma_m|_r \rangle, \]  

(13)

where \( \langle |\cdot|_r \rangle \) denotes the average of the absolute value over a radial region of interest. By using Eq. (13) the growth rates of the unstable modes can be found from successive spatial Fourier transforms over an appropriate period of time.

3.2.3 Rossby number

The Rossby number

\[ Ro = \frac{\hat{\bf z} \cdot \nabla \times \bf v - (\hat{\bf z} \cdot \nabla \times \bf v)_\phi}{2(\Omega)^2}, \]  

(14)

is a dimensionless measure of relative vorticity. Here \( \langle \cdot \rangle_\phi \) denotes an azimuthal average. Values of \( Ro < 0 \) correspond to anti-cyclonic rotation with respect to the background shear and thus can be used to identify vortices and quantify its intensity.

4 GROWTH OF NON-AXISYMMETRIC MODES WITHOUT THE INFLUENCE OF THE PLANET

In this section, the planet is introduced at \( t = 20P_0 \) and its potential is switched on over \( 10P_0 \). At \( t = 30P_0 \) we switch off the planet potential and azimuthally average the surface density, energy and velocity fields. (At this point the planet has carved a partial gap and the RWI has not yet occurred.) Effectively, we initialise the disc with a gap profile. We then perturb the surface density in the outer disc \((r > r_p)\) and
continue to evolve the disc. We impose sinusoidal perturbations with azimuthal wavenumbers \( m \in [1, 10] \) and random amplitudes within ±0.01 times the local surface density. This procedure allows us to analyse the growth of non-axisymmetric modes associated with the gap, but without complications from non-axisymmetry arising directly from disc-planet interaction (i.e. planet-induced wakes).

Note that these ‘planet-off’ simulations are not linear stability calculations because the cooling term in our energy equation restores the initial temperature profile corresponding to constant \( H/r = 0.05 \), rather than the heated gap edge. However, we will examine a nearly adiabatic simulation in \( \S 4.3.1 \) which is closer to a proper linear problem.

Simulations here employ a resolution of \((N_r, N_\phi) = (1024, 2048)\) with open boundaries at \( r = r_{in} \) and \( r = 25 r_{in} \). We compare cases with \( \tilde{\beta} = 0.1, 1, 10 \) corresponding to fast, moderately, and slowly cooled discs.

### 4.1 Gap structure

We first compare the gap structures formed by planet-disc interaction as a function of the cooling time. The azimuthally-averaged gap profiles are shown in Fig. 1 for different values of \( \tilde{\beta} \). Gaps formed with lower \( \tilde{\beta} \) (faster cooling) are deeper with steeper gradients at the gap edges. Faster cooling rates also increase (decrease) the surface density maxima (minima). However, a clean gap does not form in this short time period.

Increasing \( \tilde{\beta} \) leads to higher disc aspect ratios \( h = H/r \), i.e. higher temperatures. Heating mostly occurs at the gap edges due to planet-induced spiral shocks. Increasing the cooling timescale implies that this heat is retained in the disc. In the inviscid limit the gap opening condition is \( r_h \gtrsim H \) or \( q \gtrsim 3 h^3 \) (Crida, Morbidelli & Masset 2006), which indicates that for hotter discs (higher \( h \)), it becomes more difficult for a planet of fixed \( q \) to open a gap. This explains the shallower gaps in surface density when \( \tilde{\beta} \) is increased.

The important consequence of a heated gap edge is that the generalised vortensity profiles, \( \tilde{\eta} \), becomes smoother with increasing cooling times, with the extrema becoming less pronounced. Previous locally isothermal disc-planet simulations show the RWI associated with PV minima (Li et al. 2006; Lin & Papaloizou 2010). We can therefore expect the RWI to be associated with minima in the generalised vortensity (corresponding to local surface density maxima) in the non-isothermal case. Because the extrema are less sharp, the RWI is expected to be weaker and the gap to be more stable with longer cooling times.

However, we remark that the change in the gap structure becomes less significant at long cooling times, as Fig. 1 shows that the profiles with \( \tilde{\beta} = 1 \) and \( \tilde{\beta} = 10 \) are similar. This implies that the effect of cooling timescale on the RWI through the set up of the gap profile, becomes less important for large \( \tilde{\beta} \).

### 4.2 Axisymmetric stability

The initial planet-disc interaction form bumps and grooves in the gap profiles which can potentially be unstable due to axisymmetric instabilities. The generalised local axisymmetric stability condition is the Solberg-Holland criterion,

\[
\kappa^2 + N^2 \geq 0
\]

where

\[
N^2 = \frac{1}{\Sigma} \frac{\partial P}{\partial r} \left( \frac{1}{\Sigma} \frac{\partial \Sigma}{\partial r} - \gamma \frac{1}{P} \frac{\partial P}{\partial r} \right)
\]

is the square of the Brunt-Väisälä frequency. At the outer gap edge \( r = r_{p} + 2.5 r_{h} \), where the RWI is excited (see Fig. 1). Azimuthally averaged gap profiles at \( t = 30 P_0 \) for the initial partial gap opened before instability emerges for fast (solid, \( \tilde{\beta} = 0.1 \)), moderate (dashed, \( \tilde{\beta} = 1 \)), and slow cooling (dashed-dot, \( \tilde{\beta} = 10 \)). The relative surface density perturbation (top), disc aspect ratio (middle) and generalised vortensity perturbation (bottom) are shown.
Table 1. Dominant mode and growth rates for $\beta = 0.1, 1.0, 10.0$ (fast, moderate, and slow cooling) values during ‘planet-off’ simulations

| $\beta$ | $m$ | $10^2 \sigma/\Omega(r_p)$ | $m$ | $10^2 \sigma/\Omega(r_p)$ | $m$ | $10^2 \sigma/\Omega(r_p)$ |
|--------|-----|---------------------------|-----|---------------------------|-----|---------------------------|
| 0.1    | 6   | 7.3                       | 3   | 2.0                       | 1   | 1.1                       |
|        | 7   | 7.8                       | 4   | 2.2                       | 2   | 1.6                       |
|        | 8   | 7.9                       | 5   | 2.3                       | 3   | 1.7                       |
|        | 9   | 7.9                       | 6   | 1.6                       | 4   | 1.2                       |
|        | 10  | 6.8                       | 7   | 1.1                       | 5   | 0.1                       |

![Figure 2](image1.png)

**Figure 2.** Evolution of azimuthal Fourier modes of disc surface density, non-dimensionaized by the initial axisymmetric component $\Sigma_0(t = 0)$, for the ‘planet-off’ simulation with $\beta = 10$. Colours correspond to different $m$ values. The $m = 3$ component is the fastest growing mode during linear growth with a growth rate of $\gamma = 0.017\Omega(r_p)$.

below), we find $\kappa^2 + N^2$ reaches local minimum with a value $\sim 0.45\Omega^2(r_p)$ for all $\beta$. The Brunt-Väisälä frequency at the outer gap edge is $N \sim 0.1\Omega(r_p)$, decreasing marginally with longer cooling rate. The Solberg-Hoiland criteria is similarly satisfied for the entire 2D disc throughout the simulations.

Thus for all values of $\beta$ the planet-induced gaps are stable to axisymmetric perturbations.

4.3 Non-axisymmetric instability

We now examine the evolution of the gap for $t > 30P_0$, with the planet potential switched off, but with an added surface density perturbation. For all three cooling times $\beta = 0.1, 1.0, 10$, we observe exponential growth of non-axisymmetric structures. An example is shown in Fig. 2 for $\beta = 10$. We characterize these modes with an azimuthal wavenumber $m$ and growth rate $\sigma(m)$ as defined by Eq. 12—

![Figure 3](image2.png)

**Figure 3.** Generalised vortensity perturbation (relative to $t = 0$) for cases of $\beta = 0.1, 1, 10$ (left,middle,right) during the growth of non-axisymmetric modes. The planet potential has been switched off. The number of vortices decrease as $\beta$ increases. Note that snapshots are taken later for increasing $\beta$ because it takes longer for the vortices to grow and become visible with increasing cooling time.

Table 1 lists the growth rates measured during linear growth for 5 values of $m$ centred around that with maximum growth rate.

Table 1 show that as $\beta$ is increased from 0.1 $\rightarrow$ 10 the dominant azimuthal Fourier mode decreases from $m = 9 \rightarrow 3$ and the respective growth rate decreases from $\gamma/\Omega(r_p) = 0.079 \rightarrow 0.017$. However, despite two orders of magnitude increase in the cooling time, the instability remains dynamical with characteristic growth time $\lesssim 10P_0$. Snapshots of the instability in for the different $\beta$ are shown in Fig. 3.

These ‘planet-off’ simulations show that gap edges become more stable with longer cooling times. This is expected because larger $\beta$ results in hotter gap profiles at $t = 30P_0$ with less pronounced generalised vortensity minima. Stabilization with increased cooling time is therefore due to a smoother basic state for the instability, as it is more difficult for the planet to open a gap if the disc is allowed to heat up.

For completeness we also simulated a locally isothermal disc with $h = 0.05$ where the sound-speed is kept strictly equal to its initial value. This simulation yield a most unstable growth rate $\sigma/\Omega(r_p) \approx 0.05$ at $m = 5$, compared with a value of 0.085 at $m = 6$ for a corresponding simulation that includes the energy equation but with rapid cooling $\beta = 0.01$. However, the vortex evolution is similar.

4.3.1 Nearly adiabatic discs

The above ‘planet-off’ simulations are not formally linear stability calculations, because the cooling time is comparable or shorter than the instability growth time, $t_c \lesssim \gamma^{-1}$. Thus the disc cools back to its initial temperature corresponding to $h = 0.05$ before or during the instability growth, so we do not have a steady basic state to formulate a standard linear stability problem.

In order to capture the effect of a heated gap edge, we
ran a simulation with $\beta = 100$, corresponding to an almost adiabatic disc. In this simulation the cooling rate is slow enough that the gap temperature profile (e.g. middle panel of Fig. 4) changes only marginally over the instability growth timescale.

We find very similar gap profiles and mode growth rates for $\beta = 100$ as with $\beta = 10$. At $t = 30P_0$, the disc only heats up to values $h \simeq 0.06$ in the nearly adiabatic case. This is close to the original temperature of $h = 0.05$, so linear growth rates are not expected to change significantly (Li et al. 2000).

According to Li et al. (2000), increasing $h$ increases linear growth rates of the RWI because it is pressure-driven. However, in the case of disc-planet interaction, increasing $h$ has a stabilizing effect through the setting up the gap profile because it results in smoother gap edges. The fact that we observe smaller growth rates as $h$ is increased indicates that for planetary gaps, the importance of $h$ on the linear RWI is through setting up the gap profile, i.e. basic state for the instability (as opposed to the linear response).

### 4.4 Long term evolution

We also extended these ‘planet-off’ simulations into the non-linear regime. After the linear growth phase of the vortices, vortex merging takes hold on timescales of up to $150P_0$, until there is one vortex left. We find the vortex merging time is dependent on the growth rates of the modes and saturation timescales, with the slowest growing modes in $\beta = 10$ taking the longest to merge.

Fig. 4 shows evolution of the $m = 1$ surface density component, which represents the amplitude of the post-merger single vortex. For completeness we also ran intermediate cases with $\beta = 0.5$ and 5.0. The amplitude of the initially formed vortex was found to decrease with increased cooling rate. The vortices simply decay on a timescale of $O(10^3)$ orbits with faster decay for stronger vortices (which are obtained with faster cooling rates).

This decay is probably due to numerical viscosity. During the slow decay the vortex elongates (weakens) while its radial width remains $O(1)$, so its surface density decreases. In addition, for $\beta = 0.1, 0.5$ and 1.0 we also observe the appearance of spiral waves associated with the vortex, which may contribute to its dissipation (see below). We will see in the next section that this decay after linear growth is very different when the planet potential is kept on.

### 5 NON-LINEAR EVOLUTION OF GAP-EDGE VORTICES WITH FINITE COOLING TIME

We now examine long-term simulations of gap-edge vortices for $\beta = 0.1, 0.5, 1, 5, 10$. (Additional cases are presented in Fig. 4 when examining vortex lifetimes as a function of $\beta$.) The planet potential is kept on throughout. We employ a grid with $(N_r, N_\phi) = (512, 1024)$ in order for these simulations to be computationally feasible. We also use a larger disc with $r_{\text{out}} = 45r_m$ to minimise boundary effects on vortex evolution, and apply open boundaries at $r = r_{\text{in}}, r_{\text{out}}$.

We comment that lower-resolution simulations with $(N_r, N_\phi) = (256, 512)$ show similar behaviour and trends as the high-resolution runs reported below.

**Figure 4.** Long term simulations without the planet potential after the gap is set up. The $m = 1$ surface density component, non-dimensionalized by the initial $m = 0$ component, at the outer gap edge is shown as a function of the cooling timescale.

**Figure 5.** Evolution of the non-dimensionalized $m = 1$ surface density component for long term simulations with the planet potential kept on. Notice there is vortex growth after the initial linear growth, which contrasts to Fig. 4 where vortices decay in the absence of continuous disc-planet interaction.

#### 5.1 Generic evolution

The linear growth of the RWI and vortex-formation is followed by vortex merging. We now find merging timescales independent of $\beta$, and by $60P_0$ only one vortex remains. The evolution of the amplitude of the $m = 1$ surface density component, averaged over $r - r_p \in [2, 10]r_m$, is shown in Fig. 5 for different $\beta$. The initial, post-merger vortex amplitude is found to be weaker for longer cooling rates (which have smaller linear growth rates).

In all cases the system remains in a quasi-steady state for $\gtrsim 800P_0$ with a single vortex circulating the outer gap edge at the local Keplerian frequency. Fig. 6 shows a typical plot of the relative surface density perturbation in this state. During this stage, the vortex intensifies. This is better shown in Fig. 7 as the evolution of Rossby numbers measured at the vortex centres. The Rossby number increases in magnitude during quasi-steady state, but the maximum $|Ro|$ is similar.
Figure 6. Relative surface density perturbation for the $\tilde{\beta} = 0.1$ case during quasi-steady state with a single vortex at the outer gap edge. The plot for other values of the cooling time $\tilde{\beta}$ are similar. The decrease in the surface density near $r \approx 40r_h$ arises from mass loss due to the open boundary condition imposed at $r_{\text{out}}$.

Figure 7. Evolution of Rossby numbers at the centres of the vortices formed in discs with different cooling rates. A negative Rossby number implies anti-cyclonic motion. Boxcar averaging was used to remove contributions from the planet-induced spiral shock.

Figure 8. Average value of the relative surface density perturbation at vortex centres for various cooling times. Initial vortex over-densities decrease with cooling rate while vortex growth rates increase with cooling rate.

5.2 Additional analysis on vortex decay

In this subsection we examine the vortex decay observed in our simulations in more detail. Fig. 9 show snapshots of the vortex for the case $\tilde{\beta} = 1$. The plots show the surface density perturbation and the surface density gradient during quasi-steady state ($t = 700P_0$), when the $m = 1$ amplitude begins to decrease ($t = 1300P_0$) and just after the rapid amplitude decay ($t = 1510P_0$).

In quasi-steady ($t = 700P_0$) the vortex is elongated with a vortex aspect ratio $\approx 4$, but becomes more compact approaching a ratio of 2 during its decay ($t = 1300P_0$). This non-monotonic dependence suggests that there exists an optimal cooling rate to maximise the vortex lifetime. We will discuss this issue further in §5.4. Notice the decay timescale can be long with rapid cooling: for $\tilde{\beta} = 0.1$ it takes $\sim 400P_0$ whereas for $\tilde{\beta} = 10$ it takes $\sim 100P_0$ for the $m = 1$ amplitude to decay significantly after reaching maximum.

for all $\tilde{\beta}$: the vortex reaches a characteristic value of $Ro \approx -0.35$ for $\tilde{\beta} = 0.1$ and $Ro \approx -0.45$ for $\tilde{\beta} = 10$. We find the vortices become significantly over-dense. Fig. 5 plots the surface density perturbation measured at the vortex centres, showing $\Delta\Sigma/\Sigma_0 \gtrsim 7$ for all cases of $\tilde{\beta}$ in quasi-steady state, and $\max(\Delta\Sigma/\Sigma_0) \sim 11$ for $\tilde{\beta} = 5$. The maximum over-density typically increases with longer cooling times, despite the vortices are initially weaker at formation with increasing $\tilde{\beta}$. The large increase in the surface density is due to vortex growth as there is continuous generation of vorticity by planet-disc interaction. This is supported by the observation that in the previous simulations without the planet, the amplitude of the post-merger vortex does not grow (Fig. 6).

Fig. 9 shows that the duration of the quasi-steady state varies with the cooling rate: for $\tilde{\beta} = 0.1$ and 10, the vortex amplitude begins to decay around $t \sim 800P_0$, while for $\tilde{\beta} = 1, 5$ the decay begins at $t \sim 1200P_0$. This non-monotonic dependence suggests that there exists an optimal cooling rate to maximise the vortex lifetime. We will discuss this issue further in §5.4. Notice the decay timescale can be long with rapid cooling: for $\tilde{\beta} = 0.1$ it takes $\sim 400P_0$ whereas for $\tilde{\beta} = 10$ it takes $\sim 100P_0$ for the $m = 1$ amplitude to decay significantly after reaching maximum.

During the quasi-steady state the vortex orbits at $r \sim r_p + 6r_h$. We do not see significant vortex migration at this stage, since the vortex is located at a surface density maximum (Paardekooper, Lesur & Papaloizou 2010). However, simultaneous with the appearance of the wakes, we observe the vortex begins to migrate inwards to $r \sim r_p + 5r_h$. During quasi-steady state the average value of the sur-
Figure 9. The vortex in the case with $\tilde{\beta} = 1$ during quasi-steady state (left), start of decay (middle), and just after the decay in the $m = 1$ amplitude (right). The surface density perturbation (top) and the associated surface density gradient (bottom) are shown. Wake-like features corresponding to large density gradients are found to originate from the vortices during the late phase of their quasi-steady states and into dissipation times. This plot is to be considered in conjunction with Fig. 5.

face density gradient along the wakes is $|w_s \nabla \Sigma/\Sigma| \sim 0.4$, where $w_s \simeq 0.1$ (code units) is a typical length scale of the surface density variation across the wake. Just before the $m = 1$ amplitude begins to decrease, we observe this quantity sharply increases to $\sim 0.6$, and remains around this value until the vortex dies out, at which point the associated Rossby number begins decreasing to zero. After the vortex reaches small amplitudes ($1 \lesssim \Delta \Sigma/\Sigma$), it migrates out to $r \sim r_p + 6.5 r_h$.

We also measured large increases in the Mach number near the vortex as the $m = 1$ surface density amplitude reaches maximum and begins to decay. Fig. 10 plots the Mach number $M = |v - v_{vor}|/c_s$, where $v_{vor}$ corresponds to the bulk velocity of the vortex around the disc. Values in Fig. 10 have been averaged over a region within $2H$ of the vortex centre. During the quasi-steady state the Mach number increases steadily, and for all cases $M$ maximizes about $\sim 100P_0$ after the start of the $m = 1$ surface density amplitude starts to decay.

Putting the above observations together, we suggest that vortex decay (in the $m = 1$ surface density amplitude) is due to shock formation by the vortex. When the vortex reaches large amplitude, it begins to induce shocks in the surrounding fluid, as supported by the increase in Mach number and the appearance of wakes with large surface density gradients. The vortex may lose energy through shock dissipation. In addition, a strong vortex (or shock formation) can smooth out the gap structure that originally gave rise to the RWI, which would oppose vortex growth. We examine this below.

5.3 Vortex decay and gap structure

We find vortex decay modifies the gap structure. Fig. 11 shows the gap profile before and after vortex decay for the case $\tilde{\beta} = 1$. The vortex resides around the local surface density maximum at the outer gap edge ($r \sim r_p + 6 r_h$). We see that after its amplitude has decayed ($t \sim 1500P_0$, Fig. 5), this local surface density maximum is also smoothed out.

We characterize the smoothness of the outer gap edge with a dimensionless gap edge gradient parameter

$$\delta \Sigma(t) = \left\langle \frac{\partial (\Sigma(t, r))}{\partial r} \right\rangle_{\phi} \frac{r}{\langle \Sigma(t = 0, r) \rangle_{\phi} \Delta r} \tag{17}$$

where $\Delta r = r \in [r_p, r_p + 6r_h]$ is the radial range of averaging, spanning from centre of the gap to the radius of the surface density maximum. A larger $\delta \Sigma$ characterizes a sharper gap edge and larger local surface density maxima.

A plot of the gradient parameter over time for the $\tilde{\beta} = 1.0$ case is shown in Fig. 12. During vortex decay, the outer
The vortex quasi-steady state the gap edge is found to have a large gradient and sharp peak while vortex dissipation, which occurs at \( t \approx 10^3 P_0 \) as seen in Fig. 5, works to smooth out the gap edge.

Dissipation, which occurs at steady state the gap edge is drastically smoothed out, changing from a value of \( \delta \Sigma = 1.2 \) during quasi-steady state to 0.4 after dissipation.

This can be interpreted as the vortex providing a viscosity, and we measure a typical alpha viscosity \( \alpha = O(10^{-2}) \) associated with the vortex. This acts against gap-opening by the planet, and smooths out the outer surface density bump, so the condition for the RWI becomes less favourable. In order to re-launch the RWI, the surface density bump should reform. However, this is difficult as there is no more material in the planet’s vicinity to clear out (Fig. 11) to form a surface density bump outside the gap. This may explain why vortices do not reform again (at least within the simulation timescale). After full decay the aspect ratio at the outer gap edge is \( h \sim 0.05 \).

5.4 Vortex lifetimes as a function of cooling rate

We now examine vortex lifetimes as function of the imposed cooling times. For this study, additional simulations with \( \beta = 0.01, 0.25, 0.75, 2.5, 7.5 \) were also performed. We define the vortex lifetime, \( t_{\text{life}} \), as the time at which the over-density of the vortex returns to \( \Delta \Sigma/\Sigma_0 \sim 1 \) after reaching maximum (which is on the order of the initial over-density associated with the gap formation).

We plot \( t_{\text{life}} \) with respect to cooling times in Fig. 13. We also plot \( t_{\text{diss}} \), the time elapsed before the vortex to begins to dissipate (when the \( m = 1 \) surface density amplitude begins to decay); and \( t_{\text{Mach}} \), the time taken for the average Mach number around the vortex to maximise.

For fast cooling rates (\( \beta \lesssim 1 \)), the vortex lifetime is maximized for \( \beta \to 0 \); we find \( t_{\text{life}} \approx 2100 P_0 \) for \( \beta = 0.01 \) and decreases to \( t_{\text{life}} \approx 950 P_0 \) for \( \beta = 0.25 \). Note that for very small \( \beta \), there is significant contribution to the overall vortex lifetime due to a long decay timescale. For longer cooling times (\( \beta \gtrsim 1 \)) the vortex lifetimes maximizes at \( \beta = 2.5 \) with \( t_{\text{life}} \approx 1650 P_0 \).

We comment here that a locally isothermal simulation, where the disc sound-speed is kept constant in time, was also performed for comparison. In this case we did not observe significant vortex decay within the simulation timescale (implying \( t_{\text{diss}} \gtrsim 2000 P_0 \)). We expect the corresponding vortex lifetime to exceed that for \( \beta = 0.01 \). Including an energy equation with rapid cooling (or setting \( \gamma \) close to unity), could still lead to discrepancies with a locally isothermal disc. This is due to the advection-creation of specific entropy within the planet’s horseshoe region with the former case, thereby affecting the generalized vortensity and therefore the instability (13.3) and subsequent vortex evolution. Nevertheless, a longer vortex lifetime in a locally isothermal disc would be consistent with the above trend of increasing vortex lifetimes as \( \beta \to 0 \).

In the previous section, we observed that vortices began to decay when it starts to induce shocks. We thus suggest that the time needed for the vortex to grow to sufficient amplitude to induce shocks in the surrounding fluid, which may be considered as the duration of the quasi-steady state or \( t_{\text{diss}} \), is an important contribution to the overall vortex lifetime. We discuss below some competing factors that may result in a non-monotonic dependence of \( t_{\text{diss}} \) on the cooling rate.

5.4.1 Factors that lengthen vortex lifetimes

It has been shown that the amplitude at which the RWI saturates increases with the growth rate of the linear instability (Meheut, Lovelace & Lai 2013). Our “planet-off” simulations yield slower growth rates with increasing cooling times, which suggest weaker vortices are formed initially with increasing \( \beta \). This is consistent with the present simulations: at the beginning of the quasi-steady state \( (t \sim 100 P_0) \) we find the over-density at the vortex centre is \( \Delta \Sigma/\Sigma_0 = 2.5 \) for \( \beta = 0.1 \) and \( \Delta \Sigma/\Sigma_0 = 1.48 \) for \( \beta = 10 \).

The growth of the post-merger single vortex is mediated by disc-planet interaction. However, gap-opening becomes
more difficult in a hotter disc, and we find the generalised vortensity profiles are smoother with increasing $\bar{\beta}$. This opposes the RWI. Furthermore, the vortex should reach larger amplitudes to induce shocks on account of the increased sound-speed.

These considerations suggest, with increased cooling times, it takes longer for the post-merger vortex to grow to sufficient amplitude to induce shocks and dissipate. This factor contributes to a longer quasi-steady state with increasing $\bar{\beta}$.

### 5.4.2 Factors that shorten vortex lifetimes

Notice in Fig. 5 and Fig. 8, the vortex growth during the quasi-steady state is actually faster for $\bar{\beta} = 10$ than for $\bar{\beta} = 5$. For example, at $t \sim 500P_0$ the vortex with $\bar{\beta} = 10$ has a larger amplitude than for $\bar{\beta} = 5$. This is also reflected in Fig. 10 where the Mach number reaches its maximum value sooner for $\bar{\beta} = 10$ than for $\bar{\beta} = 5$.

This observation is consistent with the RWI being favoured by higher temperatures (Li et al. 2009; Fu et al. 2014) through the perturbations (as opposed to its effect through the set up of the gap profile discussed previously), which corresponds to longer cooling times in our case. While our ‘planet-off’ simulations indicate this is unimportant for the linear instability, it may have contributed significantly to the vortex growth during quasi-steady state at very long cooling times (e.g. $\bar{\beta} = 10$). This effect shortens the vortex lifetime by allowing it to grow faster and induce shocks sooner.

### 6 SUMMARY AND DISCUSSION

In this paper, we have carried out numerical simulations of non-isothermal disc-planet interaction. Our simulations were customized to examine the effect of a finite cooling time on the stability of gaps opened by giant planets to the so-called vortex or Rossby wave instability. To do so, we included an energy equation with a cooling term that restores the disc temperature to its initial profile on a characteristic timescale $t_c$. We studied the evolution of the gap stability as a function of $t_c$. This is a natural extension to previous studies of on gap stability, which employ locally or strictly isothermal equations of state. We considered the inviscid limit which favors the RWI (Li et al. 2009; Fu et al. 2014) and avoids complications from viscous heating other that shock heating. However, this means that the vortex lifetimes observed in our simulations are likely longer than in realistic discs with non-zero physical viscosity.

We considered two types of numerical experiments. We first used disc-planet interaction to self-consistently set up gap profiles, which were then perturbed and evolved without further the influence of the planet potential. This procedure isolates the effect of cooling on gap stability through the set up of the initial gap profile. We find that as the cooling time $t_c$ is increased, the gaps became more stable, with lower growth rates of non-axisymmetric modes and the dominant azimuthal wavenumber also decreases. This is consistent with the notion that increasing $t_c$ leads to higher temperatures or equivalently the disc aspect ratio $h$, which opposes gap-opening by the planet. This means that the gaps opened by the planet in a disc with longer $t_c$ are smoother and therefore more stable to the RWI.

In the second set of calculations, we included the planet potential throughout the simulations and examined the long-term evolution of the gap-edge vortex that develops from the RWI. The vortex reaches a quasi-steady state lasting $O(10^3)$ orbits. Unlike the ‘planet-off’ simulations, in which vortices decay after linear growth and merging, we find that with the planet potential kept on, the vortex amplitude grows during this quasi-steady state, during which no vortex migration is observed, until it begins to induce shocks, after which the vortex amplitude begins to decay.

For our main simulations with $\bar{\beta} > 0.1$, the duration of the quasi-steady state increases with increasing cooling timescales until a critical value, beyond which this quasi-steady state shortens again. We find the timescale for the vortex to decay after reaching maximum amplitude can be long for small $\bar{\beta}$, which contributes to a long overall vortex lifetime with rapid cooling. We do observe vortex migration during its decay, which may influence this decay timescale.

We suggest a non-monotonic dependence of the quasi-steady state on the cooling timescale $\bar{\beta}$ can be attributed to the time required for the vortex to grow to sufficient amplitude to induce shocks in the surrounding fluid, thereby losing energy and also smooth out the gap edge.

For short cooling timescales, the planet is able to open a deeper gap which favours the RWI, leading to stronger vortices. For long cooling timescales, we find the vortex grows faster during the quasi-steady state. In accordance with previous stability calculations (Li et al. 2000), we suggest the latter is due to the RWI being favoured with increasing disc temperature, and that this effect overcomes weaker gap-opening for sufficiently long cooling times. These competing factors imply for both short and long cooling timescales, the vortex reaches its maximum amplitude, shock, and begins to decay, sooner than intermediate cooling timescales.

(However, for very rapid cooling, e.g. $\bar{\beta} = 0.01$, the quasi-steady state is also quite long. This suggests that the above effects themselves do not have a simple dependence on the cooling timescale when considering $\bar{\beta} \rightarrow 0$ and/or that other factors become important in this limit. This should be investigated in future works.)

We remark that a non-monotonic dependence of the vortex lifetime was also reported by Fu et al. (2014), who performed locally isothermal disc-planet simulations with different values of the disc aspect ratio. In their simulations the optimum aspect ratio is $h = 0.06$. In our simulations, $h$ is a dynamical variable, but by analyzing the region where the vortex is located ($r - r_p \in [2, 10]r_o$), we find for a dimensionless cooling timescale of $\bar{\beta} = 2.5$, which has the longest vortex lifetime in the presence of moderate cooling, that $h \approx 0.058$ on average. Our result is consistent with Fu et al. (2014).

### 6.1 Caveats and outlooks

There are several outstanding issues that needs to be addressed in future work:

**Convergence.** Although lower resolution simulations performed in the early stages of this project gave similar results (most importantly, the non-monotonic dependence of vortex lifetimes on the cooling timescale), we did find the lower resolution typically yield longer vortex lifetimes than that reported in this paper. This could be due to weaker
Gaps in non-isothermal discs

RWI with low resolution. It will be necessary to perform even higher resolution simulations in order to obtain quantitatively converged vortex lifetimes.

**Orbital migration.** We have held the planet fixed on a circular orbit. However, gap-edge vortices are known to exert significant, oscillatory torques on the planet [Li et al. 2009] which can lead to complex orbital migration. This will affect vortex lifetimes as it may alter the planet-vortex separation, as well as leading to direct vortex-planet interactions [Lin & Papaloizou 2010; Ataiee et al. 2014]. Thus, future simulations should allow the planet to freely migrate. Similarly, the role of vortex migration on its lifetime should be clarified.

**Cooling model.** Our prescription for the disc heating/cooling is convenient to probe the full range of thermodynamic response of the disc. However, in order to calculate vortex lifetimes in actual protoplanetary discs, an improved thermodynamics treatment, e.g. radiative cooling based on realistic disc temperature, density, opacity models etc., should be used in future work.

**Self-gravity.** We have ignored disc self-gravity in this study. Based on linear calculations, Lovelace & Hohlfeld (2013) concluded self-gravity to be important for the RWI when the Toomre parameter $Q < O(1/h)$, or $Q \lesssim 20$ for $h \sim 0.05$, as was typically considered in this work. This suggests that self-gravity may affect vortex lifetimes even when $Q$ is not small. In particular, given that we observe vortices can reach significant over-densities (up to almost an order of magnitude), it will be important to include disc self-gravity in the future.

**Three-dimensional (3D) effects.** A vortex in a 3D disc may be subject to secondary instabilities that destroy them (Lesur & Papaloizou 2009; Raillton & Papaloizou 2014). This may be an important factor in determining gap-edge vortex lifetimes in realistic discs. For example, if these secondary instabilities set in before the vortex grows to sufficient amplitude to shock, then the dependence of the vortex lifetime on the cooling timescale will be its effect through the 3D instability (as opposed to the effect on the RWI itself, which is a 2D instability). This problem needs to be clarified with full 3D disc-planet simulations.

**ACKNOWLEDGMENTS**

This project was initiated at the Canadian Institute for Theoretical Astrophysics (CITA) 2014 summer student programme. The authors thank the anonymous referee for an insightful report. Computations were performed on the GPC supercomputer at the SciNet HPC Consortium.
