Quantum correlations display one of the crucial - and arguably the least understood - qualitative differences between classical and quantum systems. While we start to develop some kind of intuition for nonclassical correlations which arise in quantum systems composed of two subsystems, our comprehension remains rather strained when we deal with a larger number of constituents. This qualitative difference between bi- and multi-partite quantum systems originates - among others - from the fact that in bipartite quantum systems there are no qualitatively different quantum correlations, i.e. any state $\rho$ can be prepared with local operations and classical communication (locc), starting out from a maximally entangled state. Therefore, the entanglement of bipartite states can be well characterised by a single scalar quantity, such as, e.g., the entanglement of formation [1]. In multi-partite systems this is no more true. For example, the label 'maximally entangled' can be justified for both GHZ- and W-states, though none of them can be prepared from the other using only locc [3]. Hence, they are characterized by qualitatively different, inequivalent quantum correlations.

Also the very definition of multi-partite separability and entanglement requires some refinement as compared to bipartite systems: An $N$-partite system is described by a Hilbert space $\mathcal{H}$ that decomposes into a direct product of $N$ subspaces $\mathcal{H} = \mathcal{H}_1 \otimes \ldots \otimes \mathcal{H}_N$, where the dimension of the space $\mathcal{H}_i$ will be denoted by $n_i$. A multi-partite state acting on $\mathcal{H}$ is separable [4], if it can be written as a convex sum of direct products of sub-system states

$$\rho = \sum_i p_i \rho_i^{(1)} \otimes \ldots \otimes \rho_i^{(N)} = \sum_i p_i \bigotimes_{j=1}^{N} \rho_j^{(i)} , \quad p_i > 0 .$$

In such a state all correlations between any of the subsystems are of classical nature, and can be described in terms of the classical probabilities $p_i$. However, the tensorial structure of $\mathcal{H}$ holds room for qualitatively distinct quantum correlations which go beyond the classical framework. A state is bi-separable, if it can be written as a convex sum of states which each decompose into a direct product of at least two factors. This definition can be immediately generalized to m-separability ($m \leq N$), what provides a fine graduation of states according to their different degrees of separability.

In general, it is an open problem to decide on the degree of separability of a given state $\rho$. Some substantial progress has been achieved with entanglement witnesses [2, 4], which allow to distinguish some multi-partite entangled states from bi-separable ones. Though, their use also has two severe drawbacks: some a priori knowledge on the considered state is required, in order to construct a suitable witness – and there is no general prescription for such construction. Moreover, a witness can give reliable information only if it actually does detect the considered state – if not, this can either be due to the fact that the witness is not well-adapted for the given state, or that the state simply does not contain the quantum correlations sought for. A secure answer is only obtained if all (infinitely many) different witnesses are consulted.

In the present Letter, we follow an alternative route, by formulating a general recipe for the characterization of targeted separability properties of arbitrary mixed $N$-partite states. No a priori knowledge on the state under scrutiny will be needed here. Our approach is built upon suitable generalizations of the concurrence of bipartite quantum states, and on recently derived [7, in general tight [8] lower bounds thereof.

Let us start with a novel definition of pure state concurrence which is different from the ones familiar from the published literature [3, 10], though comprises these as special cases. A simple definition on the level of pure states is an indispensable prerequisite for the treatment of mixed states, which we are finally aiming at.

By analogy to the expectation value of an observable, the expectation value of a suitably chosen linear, hermitian operator comes to mind as a simple choice. However, there is none such that all expectation values with respect to entangled states are strictly positive, whereas they vanish for all separable states - so that entanglement can be identified unambiguously. Though, we will see that the expectation value of linear, hermitian operators $A$ with respect to two copies of a pure state can capture entanglement properties very well, what provides a solid basis for generalizations for multi-partite mixed states.

So which operators $A$ serve our purpose? Of course, concurrence needs to be invariant under local unitaries. Since this must hold for any state, it is natural to require that $A$ itself bears this invariance property. The projectors $P_L^{(i)}$ and $P_R^{(i)}$ onto the anti-symmetric and symmetric...
FIG. 1: The concurrence of a pure state $|\Psi\rangle$ is defined in terms of two copies (shown schematically as grey boxes) of $|\Psi\rangle$, and of an operator $A$ acting on them. $A$ is composed of projectors $P^{(i)}$ acting on the two copies of subsystem $i$ only (shown as circles in different greyscales).

In eq. (2), the respective concurrence will be sensitive to vanishing entanglement between subsystem concurrence necessarily vanishes, thus highlighting the

rest. If, instead, one choses to incorporate the term $\sum_{i} V_{ij} V_{ik}$, with the additional constraint that the complex prefactors $V_{ij}$ define a unitary matrix, i.e. $\sum_{i} V_{ij} V_{ik} = \delta_{jk}$. The above optimization over decompositions into pure states is thus equivalent to an optimization over left unitary trunfrations, acting on the tensor $A$, with elements $A^{\text{lm}}_{jk} = \langle \phi_{j} \otimes \langle \phi_{k}| A |\phi_{l} \otimes \phi_{m} \rangle$.

Since left unitary transformations define a high dimensional, continuous set, the explicit evaluation of eq. 1 tends to be rather cumbersome for a general mixed state. However, techniques which were devised to ease that task in the bipartite case 7 can be generalized in a straightforward manner, because the algebraic structure of the above $N$-partite concurrences 2 is strictly identical to the bipartite definition: $A$ and therefore also $A$ is hermitean and positive, what allows the decomposition $A^{\text{lm}}_{jk} = \sum_{\alpha} T_{\alpha}^{ij} (T_{\alpha}^{ij})^{*}$, in terms of the matrices $T_{\alpha}^{ij} = \langle \phi_{j} \otimes \langle \phi_{k}| \chi_{\alpha} \rangle$, which in turn are defined via the spectral decomposition $A = \sum_{\alpha} |\chi_{\alpha}\rangle \langle \chi_{\alpha}|$. Analogous to 6 one can invoke the Cauchy-Schwarz- and the triangle inequality and bound the concurrence of an arbitrary mixed state from below by

$$c(\rho) = \inf_{V} \sum_{i} \sqrt{\sum_{\alpha} \| V T^{\alpha} V^{\dagger} \|^{2}_{i} } \geq \inf_{V} \sum_{i} \| [V^{\dagger} T^{\alpha}]_{i}^{2} \| ,$$

with $\tau = \sum_{\alpha} \tau_{\alpha} T^{\alpha}$, and the inequality holds for an arbitrary set of complex numbers $\tau_{\alpha}$, such that $\sum_{\alpha} |\tau_{\alpha}|^{2} = 1$.

Without loss of generality, we can assume the number of factors $P_{i}^{(i)}$ in the explicit representation of $A$ to be even, since otherwise the concurrence vanishes identically 22. Therefore, any $|\chi_{\alpha}\rangle$ is symmetric with respect to the exchange of the two copies of $H$, and thus, the matrices $T^{\alpha}$ are complex symmetric. Consequently, the infimum on the right hand side of eq. 4 can be evaluated algebraically 14 15, and the explicit solution in terms of the singular values $\lambda_{j}$ (labeled in decreasing order) of $\tau$ reads $\lambda_{1} - \sum_{j>1} \lambda_{j}$. The choice of the prefactors $\tau_{\alpha}$ - that determine $\tau$ - can be optimized numerically in order to approach the optimal lower bound. Furthermore, a purely algebraic, and in most cases excellent 14 15 approximation for $c(\rho)$ can be obtained by substituting $\tau$ by the matrix $\tau^{\text{op}}$ with elements $\tau_{ij}^{\text{op}} = \langle \phi_{i} \otimes \langle \phi_{i}| A |\phi_{j} \otimes \phi_{j} \rangle / \sqrt{\langle \phi_{i} | A |\phi_{i} \rangle \langle \phi_{j} | A |\phi_{j} \rangle}$. Herein $|\phi_{i}\rangle$ is the eigenvector associated with the largest eigenvalue in the spectral decomposition of $\rho$.

The above does not only apply to the discrete set of concurrences discussed so far, but also to the following continuous interpolation between them: Instead of a single direct product of projectors onto symmetric and antisymmetric subspaces, one may equally well consider con-
vex combinations thereof,
\[
A = \sum_{\forall \{s_i = \pm\} \II \{i = 1, s_i = \pm\}}^N p_{(s_i)} \bigotimes_{j=1}^{N} P_{s_j}^{(j)}, \quad p_{(s_i)} \geq 0 \tag{5}
\]
where \(\forall \{s_i = \pm\}\) represents all possible variations of an \(N\)-string of the symbols + and −, and the summation is restricted to contributions with an even number of projectors onto anti-symmetric subspaces. Hence, through the arbitrariness of the choice of the \(p_{(s_i)}\), there is actually a continuous family of concurrences, and we leave the interpretation of such \(N\)-particle concurrences for arbitrary \(p_{(s_i)}\) as an open (and intriguing) question.

However, a discrete subset of \(N\)-partite concurrences has a transparent physical interpretation, and precisely allows to distinguish different categories of multi-partite entanglement. As an illustration, let us focus on some exemplary tri- and four-partite concurrences, which target at specific types of multi-partite quantum correlations (see also table II, in the remainder of the present contribution. Note that contenting ourselves with pure states, does not imply any restriction, since the concept of convex roofs guarantees that all properties on the level of pure states immediately convey to mixed states, as, e.g., also utilized in [12].

Bi-separability with respect to specific partitions of tri-partite systems is easily detected by \(c^{(3)}_1\), with
\[
A = 4P_{1}^{(1)} \otimes P_{2}^{(2)} \otimes P_{3}^{(3)} \tag{6}
\]
except for \(c^{(3)}_2\), with
\[
A = 4P_{-1}^{(1)} \otimes P_{+2}^{(2)} \otimes P_{3}^{(3)} \tag{7}
\]
and, analogously, by \(c^{(3)}_3\), with
\[
A = 4P_{-1}^{(1)} \otimes P_{-2}^{(2)} \otimes P_{3}^{(3)} \tag{8}
\]
whereas \(c^{(3)}_1\) and \(c^{(3)}_2\) vanish identically for bi-separable states like \(|\psi\rangle = |\varphi^{(12)}\rangle \otimes |\zeta^{(3)}\rangle\), \(c^{(3)}_3\) reduces to the bipartite concurrence of \(|\varphi^{(12)}\rangle\), i.e., \(c^{(3)}_3(|\psi\rangle) = c(|\varphi^{(12)}\rangle)\). Thanks to the above construction [9], as convex roof, these properties also pertain to mixed states. Note, however, that \(c^{(3)}_3(|\psi\rangle)\) for a bi-separable mixed state \(\rho\) is not equivalent to \(c(\Pi_{3} \rho)\): Whereas the latter expression gives the bipartite correlation of \(\rho\) only for a product state \(\rho = \rho^{12} \otimes \sigma^{(3)}\), \(c^{(3)}_3\) is significantly more powerful, and performs the same task for any state with arbitrary classical correlations between \(\mathcal{H}_3\) and the combined system of \(\mathcal{H}_1\) and \(\mathcal{H}_2\), i.e., for states like \(\sum_{i} p_{i} \rho_{1}^{(12)} \otimes \sigma_{i}^{(3)}\), \(p_{i} \geq 0\). Arbitrary quantum correlations can be accounted for by \(C_3\) with \(P_{+} = P_{-} = P_{+} = 4\) and \(P_{+} = 0\) in eq. [9], which vanishes only for completely separable states. For any bi-separable state its value is given by the bipartite concurrence of the remaining entangled part.

Similarly, different degrees of separability are also captured in larger systems. For example, concurrences like \(c^{(4)}_{ij}\), with
\[
A = 16P_{1}^{(1)} \otimes P_{2}^{(2)} \otimes P_{3}^{(3)} \otimes P_{4}^{(4)} \tag{10}
\]
through \(A = 16P_{1}^{(1)} \otimes P_{2}^{(2)} \otimes P_{3}^{(3)} \otimes P_{4}^{(4)}\), that characterizes separability properties independent of any pairing of subsystems: \(C_4\) vanishes for any state where at least one subsystem is uncorrelated with all other system components. In particular, for GHZ-like states \(|\Psi_{GHZ}\rangle = \sum_{i} \sqrt{\lambda_{i}^{(iii)}}\), \(c_4\) yields non-vanishing values, see table II whereas it vanishes for \(W\)-states, as it is in accord with observations that in tri-partite systems \(W\)-states contain only bipartite correlations [10]. For two-level systems, \(c^{(d)}\) can be used as a measure of the usefulness of a given state for multi-particle teleportation [17], and, since \(A\) is of rank one, eq. [10] does not only provide a lower bound, but rather the exact concurrence of arbitrary mixed states.

As a last example, we would like to focus on the \(N\)-partite generalization \(C_N\) of \(C_3\), with \(p_{(s_i)} = 4\) for all \(s_{(i)}\) in eq. [10] except for \(p_{+},+,+= 0\). Defined for systems with an arbitrary number \(N\) of subsystems, \(C_N\) can be shown [13] to be monotonously decreasing under \(\text{loc}\) operations, such that it does not only allow to access separability properties, but also is an entanglement monotone [13]. As already pointed out in [12], \(C_N\) can vanish for any of the concurrences defined in eq. [9] be expressed in terms of all reduced density matrices \(\rho_{i}\)

\[
C_N(\Psi) = 2^{1-\frac{N}{2}} \sqrt{\langle \Theta_{N-2}(\Psi) \rangle^2 - \sum_{i} \text{Tr} \rho_{i}^2}, \tag{11}
\]
where the multi-index \(i\) runs over all \((2^N - 2)\) subsets of the \(N\) subsystems.

Like \(C_3\), \(C_N\) only vanishes for completely separable \(N\)-partite states. Furthermore, it has the particularly nice property that \(C_N(\Psi)\) reduces to \(C_{N-1}(\xi)\) for any state \(|\psi\rangle\) that factorizes into a product state on one subsystem and on the \((N-1)\)-partite remainder \(|\xi\rangle\). This allows to compare the non-classical correlations inscribed in multi-partite systems of variable size \(N\).

In conclusion, we have seen that a discrete subset of the continuous family of concurrences defined by eqs. [9] allows for a selective assessment of the separability properties of mixed multi-partite quantum states. Given the lower bound [14], these quantities can be evaluated efficiently [11, 14, 15], and thus allow us, e.g., to address important questions such as the time evolution and the scaling properties (in terms of the system size) of entanglement in higher dimensional quantum systems [12, 14] – an objective which so far could only be accomplished for the simple \(2 \times 2\) case [20]. Furthermore, our definition reveals a continuously parametrized identifier of multi-partite entanglement, an observation which still awaits its physical/statistical interpretation.

We are indebted to André Ricardo Ribeiro de Carvalho, Rafał Demkowicz-Dobrzański, and Karol Zyczkowski for fruitful discussions, comments and remarks. Financial support of VolkswagenStiftung and the Polish Ministry of Science through the grant No. PBZ-MIN-008/P03/2003 is greatfully acknowledged.
TABLE I: Some exemplary tri- and four-partite concurrences for bi-separable and GHZ-like states. For bi-separable states, the concurrences $c_3(i = 1, 2, 3)$, $c_{12}^3$, and $c_{34}^3$ either vanish or reduce to the bi- resp. tri-partite concurrence of the remaining entangled part ($|\varphi^{(12)}\rangle$, $|\varphi^{(13)}\rangle$, $|\varphi^{(23)}\rangle$, $|\varphi^{(123)}\rangle \otimes |\zeta^{(3)}\rangle$), or $|\zeta^{(1)}\rangle \otimes |\varphi^{(23)}\rangle$ of $|\psi\rangle$, with $\eta(\phi) = \sqrt{1 - c(\phi)^2}/4$. $C_4$ vanishes for all states where at least one particle is uncorrelated with the other system components.

[21] The anti-symmetric (resp. symmetric) subspaces of $\mathcal{H}_i \otimes \mathcal{H}_i$ are spanned by the states that adopt a phase shift of $\pi$ (resp. 0) upon exchange of the two copies of $\mathcal{H}_i$. Expressed in terms of some arbitrary, orthonormal basis $\{|\alpha_i\rangle\}_i$, the projectors onto these spaces read $P_{\pm}^{(i)} = \sum_{j \neq k} (|\alpha_i\rangle \pm |\alpha_k\rangle)$ $\langle \alpha_i \alpha_k \rangle /4$.
[22] Note that $A$ is acting on $\bigotimes_{i=1}^N \mathcal{H}_i \otimes \mathcal{H}_i$, whereas $|\Psi\rangle \otimes |\Psi\rangle \in \bigotimes_{i=1}^N \mathcal{H}_i \otimes \bigotimes_{i=1}^N \mathcal{H}_i$. Though, the two different spaces are isomorphic, and it is obvious how to identify their corresponding elements.
[23] Any choice with an odd number of factors $P_{\pm}^{(i)}$ is anti-symmetric with respect to an exchange of both copies of $\mathcal{H}_i$ (the entire system, and not a single subsystem!), such that the expectation value with respect to the twofold copy $\langle \Psi | \Psi \rangle$ of a state (i.e., a symmetric object) vanishes.
