Transducin mediates signal transduction in a classical G protein-coupled receptor (GPCR) phototransduction cascade. Interactions of transducin with the receptor and the effector molecules had been extensively investigated and are currently defined at the atomic level. However, partners and functions of rod transducin a (Gαt1) and βγ (Gβ1γ1) outside the visual pathway are not well-understood. In particular, light-induced redistribution of rod transducin from the outer segment to the inner segment and synaptic terminal (IS/ST) allows Gαt1 and/or Gβ1γ1 to modulate synaptic transmission from rods to rod bipolar cells (RBCs). Protein-protein interactions underlying this modulation are largely unknown. We discuss known interactors of transducin in the rod IS/ST compartment and potential pathways leading to the synaptic effects of light-dispersed Gαt1 and Gβ1γ1. Furthermore, we show that a prominent non-GPCR guanine nucleotide exchange factor (GEF) and a chaperone of Gα subunits, resistance to inhibitors of cholinesterase 8A (Ric-8A) protein, is expressed throughout the retina including photoreceptor cells. Recent structures of Ric-8A alone and in complexes with Gα subunits have illuminated the structural underpinnings of the Ric-8A activities. We generated a mouse model with conditional knockout of Ric-8A in rods in order to begin defining the functional roles of the protein in rod photoreceptors and the retina. Our analysis suggests that Ric-8A is not an obligate chaperone of Gαt1. Further research is needed to investigate probable roles of Ric-8A as a GEF, trafficking chaperone, or a mediator of the synaptic effects of Gαt1.

Keywords: retina, G protein, GPCR, transducin, Ric-8A, GEF, chaperone

INTRODUCTION

A prototypical heterotrimeric G protein, transducin (Gαβγ), is a key signaling mediator in the visual transduction cascade in vertebrate rod and cone photoreceptors. Traditionally, studies of transducin focused on its structure and mechanisms underlying this signaling cascade. Phototransduction takes place in a specialized ciliary compartment of photoreceptor cells called the outer segment (OS). Absorption of light by rhodopsin allows the photoexcited receptor (R*) to stimulate GDP/GTP exchange on Gαβγ, thus releasing GαGTP from Gβγ and R*. Subsequent activation of cGMP phosphodiesterase 6 (PDE6) by Gα,GTP causes concentration of cytoplasmic cGMP to drop, halting conductance of cGMP-gated channels in the plasma membrane.
(Arshavsky et al., 2002; Fu and Yau, 2007). Besides rhodopsin and PDE6, an essential partner of transducin in the visual cascade is a photoreceptor-specific member of the RGS (regulators of G protein signaling) family, RGS9-1. RGS9-1 in complex with Gβδ1 acts as a GTPase-activating protein for Gαt, and thus is a major regulator of the turn-off of the visual signal (He et al., 1998, 2000; Makino et al., 1999; Cowan et al., 2001; Martemyanov and Arshavsky, 2009; Arshavsky and Burns, 2012). Together, the interactions of transducin with R*, PDE6, and RGS9-1/Gβδ1 control the signal amplification, sensitivity, and speed of photoresponses. The remarkable molecular level of insight into these interactions has been recently elevated with solutions of the cryo-EM structures of transducin complexed with rhodopsin and PDE6 (Gao et al., 2019, 2020). Nevertheless, several important aspects of transducin biology, including its folding, trafficking, and roles outside the phototransduction cascade remain largely obscure. Rod transducin subunits Gαt1 and Gβ1γ1 are known to undergo bi-directional translocation between the OS and inner compartments of rod photoreceptors in a light-dependent manner, but its partners in the inner photoreceptor compartments, the inner segment and synaptic terminal (IS/ST), and the significance of these interactions are not well understood (Sokolov et al., 2002; Calvert et al., 2006; Artemyev, 2008; Slepak and Hurley, 2008). Light-induced translocation of Gαt1 and Gβ1γ1 was shown to reduce phototransduction gain, and thus it contributes to light adaptation of photoreceptor cells (Sokolov et al., 2002). Analyses of mouse models with impaired transducin translocation also support an important role of the phenomenon in neuroprotection of rods, presumably by reducing the metabolic stress associated with the constitutive phototransduction reactions under light conditions saturating responsiveness of rods (Fain, 2006; Peng et al., 2011; Majumder et al., 2013; Tian et al., 2014). Arguably, the most intriguing and poorly understood consequence of Gαt1 and Gβ1γ1 translocation is its modulation of the synaptic transmission from rods to rod bipolar cells (RBCs). Block of transducin translocation via additional lipid anchoring of the Gαt1 A3C mutant in a mouse model desensitized signal transmission to RBC, suggesting that transducin translocation enhances signalning to RBC in wild type mice (Majumder et al., 2013). Ultimately, the mechanism underlying the synaptic effect of transducin may involve its interactions with the synaptic machinery and/or modulation of the voltage-gated Ca2+ channels, Ca1.4. Analysis of known and identification of novel partners of transducin in the IS/ST may provide clues to this mechanism.

**TRANSDUCIN PARTNERS IN THE INNER PHOTORECEPTOR COMPARTMENTS: UNC119 AND LGN/GPSM2**

One well-known partner of Gαt1 outside the phototransduction cascade is Uncoordinated 119 (UNC119). UNC119 is a mammalian ortholog of C. elegans unc-119 (Maduro and Pilgrim, 1995), also known as Retina Gene 4 protein (RG4; Higashide et al., 1996). UNC119 is uniquely abundant in photoreceptor cells, specifically the rod IS/ST, and its levels in other tissues are significantly lower (Higashide et al., 1998; Swanson et al., 1998; Karim et al., 2010). Truncation mutation in UNC119 is linked to cone-rod dystrophy in human patients (Kobayashi et al., 2000), whereas knockout of UNC119 in mice causes slow retinal degeneration (Ishiba et al., 2007). UNC119 shares sequence and structural homology with the prenyl-binding protein PDE6δ (or PDE6d), both featuring immunoglobulin-like β-sandwich fold serving as a lipid-binding module (Zhang et al., 2011). Unlike PDE6δ, which is a prenyl-binding protein, UNC119 selectively binds myristoyl moiety (Zhang et al., 2004, 2011; Gopalakrishna et al., 2011). Owing its lipid-binding specificity, UNC119 is generally viewed as a carrier protein for myristoylated cargo, with a preference for cargo proteins targeted to primary cilia via an ARL3-dependent mechanism (Ismail et al., 2012; Fansa and Wittinghofer, 2016; Frederick et al., 2020). Consistent with the role of UNC119 as a trafficking chaperone of transducin, the anterograde transport of translocated Gαt1 to the OS during dark adaptation is impaired in UNC119 knockout mice (Zhang et al., 2011). Quantification of UNC119 in rods suggests that the light-dispersed Gαt1 is a major partner of UNC119 (Sinha et al., 2013). However, the function of UNC119 in the retina appears to extend beyond that of a trafficking chaperone across the connecting cilium. Besides Gαt1, UNC119 interacts in a lipid modification-independent manner with CaBP4 (Haeseeler, 2008). Notably, the levels of UNC119 are reduced in mice lacking Gαt1 or CaBP4, suggesting that UNC119 functionally interacts with both of these proteins (Haeseeler, 2008; Sinha et al., 2013). CaBP4 is an EF-hand Ca2+ binding protein that binds to and modulates the voltage-dependence of Ca1.4 channels thereby enhancing RBC responses (Haeseeler et al., 2004). Rod and cone synaptic function is markedly diminished in CaBP4 knockout mice (Haeseeler et al., 2004), and loss-of-function mutations in CaBP4 cause congenital stationary night blindness and other visual disorders in humans (Littink et al., 2010; Bijveld et al., 2013). Potentially, light-dispersed Gαt1 may relieve UNC119-dependent constraint on the CaBP4 regulation of Ca1.4 channels. Another lipid-independent interactor of UNC119 is RIBEYE, a major component of synaptic ribbons (Schmitz et al., 2000; Alpadi et al., 2008). This interaction recruits UNC119 to synaptic ribbons, and it may be essential for synaptic transmission at the rod ribbon synapse (Alpadi et al., 2008). It is not known if and how transducin modulates the binding of UNC119 to RIBEYE, but this may represent a potential pathway contributing to the synaptic effects of transducin translocation.

An interesting and possibly critical property of UNC119 is its ability to interact with heterotrimeric Gαt1Gβ1γ1, promote dissociation of Gαt1 from Gβ1γ1, and release them from the membrane (Gopalakrishna et al., 2011). Analysis of the complex between UNC119 and the full-length Gαt1 by Small Angle X-ray Scattering (SAXS) and chemical crosslinking suggested an additional interface between the proteins involving the switch II region Gαt1, which overlaps with the Gβ1γ1 binding site (Cheguru et al., 2015). Thus, UNC119 apparently dissociates transducin subunits by disrupting and sterically occluding the Gβ1γ1-binding sites on Gαt1 (Cheguru et al., 2015). As a result, two species are produced, Gαt1 GDP (or Gαt1GDP-UNC119 complex) and Gβ1γ1. Each of these species may now interact with...
new partners. In particular, Go13 GDP is primed for interaction with Leu-Gly-Asn repeat-enriched (LGN) protein LGN/GPSM2 (Mochizuki et al., 1996). LGN/GPSM2 belongs to the class of G-protein modulators containing G-protein regulatory (GPR) or GoLoco motifs. GoLoco/GPR-proteins interact with and stabilize Go subunits in a GDP-bound form, hence serving as guanine nucleotide dissociation inhibitors (GDI; Natochin et al., 2000; Bernard et al., 2001; Blumer et al., 2007). LGN/GPSM2 is best known for its role in Ga-regulated positioning of a mitotic spindle during cell division (Lancaster and Knoblich, 2012; di Pietro et al., 2016). However, LGN/GPSM2 is also expressed in terminally differentiated photoreceptor cells, where it is localized to the IS/ST (Kerov et al., 2005; Nair et al., 2005). LGN/GPSM2 was shown to interact with endogenous Go11, and its role as a potential modulator of transducin trafficking has been proposed (Kerov et al., 2005). Evidence supporting this notion is starting to emerge (Bocchero et al., 2020). Interestingly, disruption of planar polarity mechanisms involving Go13 and LGN/GPSM2 collapsed the gradients of ribbon size and maximal synaptic Ca2+ influx in the inner hair cells (Jean et al., 2019), suggesting that Go11-LGN/GPSM2 signaling may also be involved in regulation of ribbon synapses in photoreceptors.

The synaptic regulation by translocated Go11 may be due to sequestration of Gβγ. In a well-characterized mechanism, the release of neurotransmitters at synapses of the central nervous system triggers negative feedback by activating presynaptic Go protein-coupled receptors (GPCRs) and thereby generating free Gβγ. Gβγ in turn inhibits Ca2+ influx by binding directly to the a-subunits of presynaptic Cav2.1 and CaV2.1 channels (Catterall, 2011; Khan et al., 2013; Zamponi and Currie, 2013). In contrast, CaV1.4 is not known to be regulated directly by Gβγ. A distinct mechanism of synaptic inhibition involves interactions between Gβγ subunits and the SNARE complex, specifically SNAP25 (Blackmer et al., 2001, 2005; Yoon et al., 2007). In cone photoreceptors, activation of presynaptic metabotropic glutamate receptor reduced synaptic transmission to horizontal cells via Gβγ/SNARE interactions (Van Hook et al., 2017). Furthermore, phosducin, an abundant Gβγ-binding protein in photoreceptors, was also implicated in regulation of synaptic transmission to RBCs, as the protein knockout resulted in a reduced sensitivity of ERG responses from RBCs in dark-adapted mice (Herrmann et al., 2010). These findings though were not confirmed in recordings from retinal slices, indicating that such experimental conditions may have abolished the phenotype (Long et al., 2013). It is possible that Go11 and/or phosducin sequester Gβγ liberated by activation of presynaptic GPCRs and thus enhance sensitivity of the rod-RBC synaptic transmission.

RIC-8A IN PHOTORECEPTORS: A GEF OR A CHAPERONE?

In considering novel potential partners of Go11 in photoreceptor cells, one candidate, Ric-8A, was conspicuous. Resistance to inhibitors of cholinesterase 8 (Ric-8) were originally discovered as positive regulators of G-protein signaling pathways (Miller et al., 1996, 2000). Subsequent studies demonstrated that Ric-8 proteins interact directly with the monomeric GDP-bound Go subunits and act as non-GPCR guanine nucleotide exchange factors (GEFs; Tall et al., 2003). Two isoforms, Ric-8A and Ric-8B are encoded in vertebrate genomes. Each isoform regulates a particular subset of Go subunits: Ric-8A interacts with Go21α, Go22α, and Go12/13, whereas Ric-8B is selective for Go1 (Klattemhoff et al., 2003; Tall et al., 2003; Von Dannecker et al., 2005; Nagai et al., 2019). The interaction of Ric-8 with GDP-bound Go stimulates release of GDP, leading to the formation of a stable intermediate complex of Ric-8 and nucleotide-free Go. Once Go binds GTP, it dissociates from Ric-8, and thus the nucleotide-exchange cycle on Go is completed (Tall et al., 2003). The GEF activity of Ric-8A opposing the GDI-activity of LGN/GPSM2 might be important to the role of Ric-8A in Ga-regulated positioning of mitotic spindle (Afshar et al., 2004; David et al., 2005; Tall and Gilman, 2005). Still, the interplay between Ric-8A and LGN/GPSM2 proteins in this process is poorly understood. More recently, Ric-8A attracted attention as a chaperone of Go subunits (Papaserghi et al., 2015).

In cell-free translation systems, Ric-8A was required for the expression of properly folded Ga subunits, and co-expression of Ric-8 with Ga subunits in HEK293 cells and insect cells led to significant elevations in the expression levels of Ga subunits (Chan et al., 2011, 2013; Gabay et al., 2011). Although compelling evidence has been accumulated for both the GEF and chaperone function of Ric-8A in vitro and in cell cultures, little is known about specific pathways and systems regulated by Ric-8A in vivo, and it is often unclear which of the two Ric-8A functions dominates its biological effects. This is in part due to embryonic lethality of the Ric-8A knockout mice (Tonissoo et al., 2010; Gabay et al., 2011). Conditional knockouts of Ric-8A in differentiated neuronal populations and glial cells reveal apparent and severe phenotypes, yet the exact mechanisms of the Ric-8A deficiency underlying these phenotypes could not be discerned (Ma et al., 2012; Ruisu et al., 2013). Targeted disruption of Ric-8A expression in mouse B-cells led to a loss of Go1 and Go2 and caused severe humoral immunodeficiency, a phenotype consistent with the chaperone function of the protein (Boularan et al., 2015).

Growing evidence for the important biological roles of Ric-8 spurred the interest in understanding the molecular and structural basis underlying its activities. This work culminated in solution of the atomic structures initially of Ric-8A in complex with a Go11 mimetic, and subsequently in complex with the full-length Ga subunits (Srivistava and Artemyev, 2019; Srivistava et al., 2019; Zeng et al., 2019; McClelland et al., 2020; Seven et al., 2020). The structure of the active nearly full length Ric-8A1-492 revealed two main domains of Ric-8A: an armadillo-like core (residues about 1-426) and an unstructured C-terminal tail (residues 427-492; Srivistava et al., 2019). The armadillo-like core of Ric-8A is a mixture of canonical ARM repeats and ARM-related HEAT repeats folded into a ribbon-like superhelix featuring a concave surface (Srivistava et al., 2019; Zeng et al., 2019). The concave surface of Ric-8A forms an extensive interface with the Go11 C-terminus (Figure 1A). Critical contacts between Ric-8A and the Ga C-terminus are made by the very C-terminal residue F350 of Go11 (Figure 1A;
Mutations interfering with the interaction network of the C-terminal residue of Goa ablate the binding of Ric-8A to folded GoaGDP (Srivastava et al., 2019), as well as disrupt the chaperone activity of Ric-8A (Seven et al., 2020). As a GEF, Ric-8A interacts with the folded GoaGDP and induces partial unfolding of the latter accompanied by the large dislocation of the Goa C-terminal α5-helix from the β-sheet core of the Ras-like domain, disorganization of the nucleotide-binding site and release of GDP (Srivastava and Artemyev, 2019; McClelland et al., 2020; Seven et al., 2020; Figure 1B). As a chaperone of nascent Goa, Ric-8A would interact with a partially folded intermediate of Goa in which the α5-helix has not yet assumed its position with the β-sheet cradle (Seven et al., 2020). The Goa1 C-terminal region is unstructured as a part of MBP-fusion protein, but it forms the α5-helix upon binding to Ric-8A (Srivastava et al., 2019). Therefore, the chaperone activity of Ric-8A may involve folding of the Goa C-terminal region into an α5-helix and stabilization of the β-sheet core of the Ras-like domain thereby preparing Goa for the first time GTP-binding event (Srivastava et al., 2019; McClelland et al., 2020; Seven et al., 2020). Upon binding of GTP, Goa is released from Ric-8A and the α5-helix replaces Ric-8A in stabilizing the β-sheet core of Goa. The GTP-binding site in the Ric-8A/Goa complex is disorganized to a greater extent compared to that in the GPCR/Goαβγ complexes (McClelland et al., 2020; Seven et al., 2020; Srivastava and Artemyev, 2020). Remarkably, the distal portion of the C-terminal tail of Ric-8A forms a unique smaller secondary interface with the switch II/α3-helix region of Goa, which appears to assist GTP-binding (Srivastava and Artemyev, 2019; McClelland et al., 2020; Seven et al., 2020; Figure 1C). Altogether, the structures of the Ric-8A/Goa complex are consistent with both proposed functions of Ric-8A, as a GEF and a chaperone. Specific function of Ric-8A would have to be determined in the context of a cellular activity under investigation.

Given the high rate of transducin synthesis and transport in photoreceptors (Frederick et al., 2020), and the likely existence of the quality control chaperone mechanism, we first investigated expression of Ric-8A in retina and photoreceptor cells. In homogenates of C57Bl/6 mouse retina specific monoclonal Ric-8A antibody 3E1 recognized a single band of the predicted MW of 60 kDa (Figure 2A; Gabay et al., 2011). Immunofluorescence staining of cryosections of the C57Bl/6 retina with 3E1 antibody revealed that Ric-8A is distributed throughout the retina, including in the IS, OPL, INL, and IPL (Figure 2B). Expression of Ric-8A in the photoreceptor IS/ST was also confirmed by Western blot analysis of tangential retina sections (Figure 2C; Sokolov et al., 2002). The retinal distribution of Ric-8A suggested that it can serve as a chaperone for newly synthesized Goa1 and/or a GEF for light-translocated Goa in rods, as well as chaperone/GEF for Goa in RBCs. Goa is abundant in RBCs, where it mediates signaling via the mGlur6 cascade, which couples a decrease in glutamate levels in the synaptic cleft with opening of the TRPM1 cation channels in the dendritic tips of RBCs (Dhingra et al., 2000, 2002). To test the former hypothesis, we generated a mouse model with conditional knockout of Ric-8A in rods. To achieve specific deletion of Ric-8A in rods, Ric-8AΔF/F mice in which exons 2–4 of the gene are floxed (Ma et al., 2012) were crossed to iCre-75+/+ mice, in which expression of Cre is driven by a 4-κb mouse rod opsin promoter (Li et al., 2005). The iCre-75+/− driver strain is commonly used for RP-specific conditional KO, as it provides for robust and uniform expression of Cre in rods (Li et al., 2005; Lai et al., 2013; Sundermeier et al., 2014; He et al., 2016). Immunofluorescence staining of retina cryosections from Ric-8AΔF/F Cre+ mice confirmed robust expression of Cre (Supplementary Figure 1) and deletion of Ric-8A in mutant rods.
FIGURE 2 | Expression of Ric-8A in the retina and conditional knockout of the protein in mouse rods. (A) Western blot with anti-Ric-8A monoclonal antibody 3E1; lane 1 – recombinant human Ric-8A (50 ng), lane 2 – C57Bl retina homogenate (50 µg). (B) Immunofluorescence (IF) staining of mouse retina cryosections with 3E1 monoclonal antibody. Ric-8A is present throughout the retina in 2-month old WT mice and absent in the inner segment (IS), outer nuclear layer (ONL), and outer plexiform layer (OPL) in 2-month old Ric-8A<sup>F/F</sup>Cre<sup>+</sup> mice. INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer; and blue, To-Pro3 nuclear stain. (C) Western blot analysis of tangential sections of WT retina indicates the presence of Ric-8A in the IS (approx. lanes 5–6), the inner compartments of rods (approx. lanes 7–11), and the bipolar cell layer (approx. lanes 12–15). Ric-8A is largely excluded from the outer segment (OS; approx. lanes 2–4). Lane 0 – recombinant Ric-8A. (D, E) Western blot analyses of equal fractions of total retina extract from control 2-month old Ric-8A<sup>F/F</sup> mice (lane 1) and littermate Ric-8A<sup>F/F</sup>Cre<sup>+</sup> mice (lane 2) with anti-Ric-8A antibody 3E1 (D) and anti-G<sub>α</sub><sub>t1</sub>K-20 antibody (SCBT; E). PDE6 – loading control. The bands were quantified with ImageJ. From three similar experiments, the average reductions of Ric-8A and G<sub>α</sub><sub>t1</sub> in the Ric-8A<sup>F/F</sup>Cre<sup>+</sup> retina were 36 ± 3% and 22 ± 4%, respectively. (F) IF staining of retina cryosections from dark-adapted mice with anti-G<sub>α</sub><sub>t1</sub> antibody. G<sub>α</sub><sub>t1</sub> is localized mainly to the rod OS in 2-month old Ric-8A<sup>F/F</sup>Cre<sup>+</sup> mice. (G, H) a-wave amplitudes and b-wave amplitudes measured from recordings of dark-adapted mice. Points represent the mean ± SEM (n = 6, left and right eyes from 3 mice of each genotype). Curves represent fits from single (G) or double (H) sigmoidal functions. For each flash strength, there were no statistically significant differences (adjusted P value > 0.05) between Ric-8A<sup>F/F</sup>Cre<sup>+</sup> and control mice. (I) Kinetics of GTPγS binding to chimeric G<sub>α</sub><sub>t1</sub> alone (1 µM) and in the presence of Ric-8A (3 µM). Representative experiment. For n = 3 experiments, the k<sub>app</sub> values are: G<sub>α</sub><sub>t1</sub> 0.005 ± 0.001 min<sup>-1</sup> and G<sub>α</sub><sub>t1</sub>+Ric-8A 0.025 ± 0.002 min<sup>-1</sup>; unpaired t-test.
(Figure 2B and Supplementary Figure 2). Western blot analysis of Ric-8A in dark-adapted Ric-8A<sup>+</sup>/Cre<sup>+</sup> retinas indicated that the protein level is reduced by ~36% (Figure 2D). The extent of reduction in the protein level of Ric-8A in the entire retina is consistent with the localization of a major fraction of the protein to the inner retina. Surprisingly, the ablation of Ric-8A expression in rods caused only a modest ~22% reduction in the protein level of Ga<sub>11</sub> (Figure 2E). Furthermore, the majority of Ga<sub>11</sub> was properly targeted to the OS in the absence of Ric-8A (Figure 2F). Supporting the functional folding of transducin in rods lacking Ric-8A, the a- and b-wave ERG responses of mutant mice were comparable to those from control mice (Figures 2G,H). Thus, our results indicate that although Ric-8A may slightly increase the abundance of Ga<sub>11</sub> in rods, the proper folding of Ga<sub>11</sub> in the absence of Ric-8A proceeds efficiently enough to support the photoreceptor function. Although mouse rods lacking Ric-8A may express Ric-8B, the latter isoform does not interact with Ga<sub>11</sub> (Papasergi et al., 2015; Srivastava et al., 2019). One caveat to this conclusion needs to be noted. It cannot be excluded that Ric-8A is a catalytic chaperone that can efficiently assist folding of Ga<sub>11</sub> even when present in trace amounts. Trace amounts of Ric-8A in mutant rods may result if the Ric-8A protein expressed prior to the gene excision persists for a long time or if the gene excision is incomplete.

Nevertheless, it is possible that the main function of Ric-8A in rods is linked to its GEF activity. We confirmed that Ric-8A is a GEF for the Ga<sub>11</sub> similarly as it is for other members of the Ga<sub>11</sub> family by measuring the kinetics of GTP<sub>γ</sub>S-binding to a transducin-like chimeric Ga<sub>11</sub> GDP in the presence or absence of Ric-8A. The apparent rate of the nucleotide exchange was increased by ~5-fold in the presence of Ric-8A (Figure 2I). Future studies are needed to investigate functional significance of the Ric-8A GEF activity toward Ga<sub>11</sub>.

DISCUSSION

The structures of the Ric-8A complexes with Ga subunits reveal the molecular underpinnings of its chaperone and GEF activities (Srivastava and Artemyev, 2019; Srivastava et al., 2019; McClelland et al., 2020; Seven et al., 2020). Depending on the Ric-8A function in a given system, the structures can represent either the GEF complex intermediate with an empty-pocket for nucleotide binding or the folding intermediate of Ga during its biosynthesis. The Ric-8A/Ga complex reveals two remarkable features: a large displacement of the a5-helix of Ga from the β-sheet cradle of the Ras-like domain, and a unique interaction of the C-terminal helix of Ric-8A with the switch II/a3-helix region of Ga (Srivastava and Artemyev, 2019, 2020; McClelland et al., 2020; Seven et al., 2020). The interaction of Ric-8A with the C-terminus/a5-helix of Ga is central to both the GEF and the chaperone activity. When Ric-8A acts as a GEF, this interaction initiates GDP-release, just like GPCRs cause GDP-release during activation of heterotrimeric G-proteins. When Ric-8A acts as a chaperone, this interaction induces the folding of the a5-helix outside the β-sheet cradle of partially folded Ga (Srivastava et al., 2019; McClelland et al., 2020). The interaction of the C-terminal helix of Ric-8A with the switch II/a3-helix region of Ga likely promotes GTP-binding to Ga thereby concluding either the GEF or the chaperone cycle of Ric-8A (Srivastava and Artemyev, 2019, 2020; McClelland et al., 2020; Seven et al., 2020). We demonstrated that Ric-8A is expressed throughout the retina. Thus, retina represents an excellent opportunity to dissect the roles of Ric-8A. The conditional knockout of Ric-8A in mouse rods argues against its role as an essential chaperone of Ga<sub>11</sub>. Yet, as a GEF, Ric-8A may play roles in transducin trafficking and/or modulation of the rod-RBC synaptic transmission. The role of Ric-8A in RBCs and its potential influence on the abundance of Ga<sub>11</sub> and the mGluR6-mediated cascade remains to be investigated. Ga<sub>q/11</sub> is the Ga subfamily that is most stringently dependent on Ric-8A as a chaperone (Gabay et al., 2011). Therefore, defining role of Ric-8A in intrinsically photosensitive retinal ganglion cells and the Ga<sub>q</sub>-mediated melanopsin signaling cascade is of particular interest (Do and Yau, 2010; Schmidt et al., 2011).
