Optical Spectroscopy of the Central Regions of Bright Barred Spiral Galaxies

J.A. García-Barreto¹, H. Aceves², O. Kuhn³, G. Canalizo⁴, R. Carrillo¹ and J. Franco¹

Abstract

Se presentan espectros ópticos en la banda roja de 18 galaxias espirales con barra. El estudio se enfoca a la determinación de la cinemática local y condiciones del gas ionizado en el núcleo compacto (dentro de un diámetro de 5") y en las regiones circunnucleares (dentro de un diámetro de 20"). Sólo 8 galaxias presentan emisión brillante al Este y Oeste del núcleo compacto. En otras 10, las líneas de emisión son débiles y solo pudimos obtener un espectro promedio de la emisión central. No se detectaron líneas de emisión en las otras 8 galaxias. Se presenta una estimación de la masa dinámica en la región central de cada galaxia en base a las velocidades observadas en regiones circunnucleares. En NGC 4314 y NGC 6951, que presentan emisión de Hα distribuida en estructuras de anillo alrededor del núcleo compacto, se determinan los cocientes [NII]/Hα y [SII]/Hα para ambos lados del anillo. La diferencia de velocidades en uno y otro lado se usa como indicativo de la velocidad de rotación del gas alrededor del núcleo de la galaxia. Las velocidades encontradas en las regiones circunnucleares en NGC 4314 y NGC 6951 explican naturalmente la discrepancia que existe en la literatura sobre las velocidades de recepción reportadas. Se encuentra que los cocientes [NII]/Hα y [SII]/Hα son diferentes en cada lado del anillo (un factor de ~ 2 mayor en el lado oeste) y se infiere que las condiciones físicas son diferentes. El cociente [NII]/Hα en el núcleo de NGC 6951 es un factor de 2 mayor comparado con el valor de la región oeste. Las densidades electrónicas se han estimado de los cocientes de líneas de azufre [SII].

Optical red spectra of a set of 18 bright barred spiral galaxies are presented. The study is aimed at determining the local kinematics, and physical conditions of ionized gas in the compact nucleus (inside a diameter of 5") and in the circumnuclear regions (inside a diameter of 20"). Only 8 galaxies showed bright emission from their east and west side of the nucleus. The spectrum of each region was analyzed separately. In other 10 galaxies the line emission was so weak that we were only able to obtain an average spectrum of the central emission. No emission was detected in the remaining 8 galaxies. An estimate of the dynamical mass is presented based on the observed velocities in the circumnuclear regions. In NGC 4314 and NGC 6951, that show Hα emission distributed in circumnuclear ring structures, we determine the [NII]/Hα and [SII]/Hα ratios for the eastern and western regions of the rings. The velocity difference for the two sides is used to derive the rotation velocity of the gas around the compact nucleus. The ratio, [NII]6583/Hα, is a factor of 2 larger in the compact nucleus of NGC 6951 than in its western side. The electron gas densities have been estimated from the [SII] lines ratio.

1. Introduction

The study of emission lines in spiral galaxies has proven to be very useful in determining the distribution of ionized gas, and the physical conditions at the central regions (Burbidge & Burbidge 1960a, 1960b, 1962, 1964, 1965; Burbidge, Burbidge & Pendergast 1960; Keel 1983a,b; Kennicutt & Kent 1983; Heckman, Balick & Crane 1980; Stauffer 1982a,b; Kennicutt 1992a,b; Appenzeller & Ostericher 1988; Filippenko & Sargent 1985; Ho, Filippenko & Sargent 1995, 1997a,b; Vaceli et al. 1997).

Optical observations of barred spiral galaxies usually show the presence of symmetric structures around their center (presumably in the plane of the disk) which are referred to as rings (e.g. Buta 1986, Buta & Croker 1991, Buta 1995). These symmetric structures are observed at different radii in their host galaxy; some are seen as extended structures at ~ 10 – 15 kpc from the center, but some others are located about 4 – 5 kpc, and there are circumnuclear rings at 300 – 900 pc from the compact nucleus (e.g. Arsenault et al., 1988; Pogge 1989a, 1989b; García-Barreto et al., 1991a,b, 1996; Barth et al., 1997; Genzel et al.,...
A dynamical explanation for the origin of the structures has been sought in terms of non-symmetric perturbations to the ‘normal’ gravitational potential of spiral galaxies (Binney & Tremaine 1987). The standard model to explain the formation of circumnuclear structures requires knowledge of the angular velocity of the gas and stars ($\Omega_g$), the epicyclic frequencies ($\kappa$), and an estimate of the angular velocity of the bar ($\Omega_b$). In this model, it is generally assumed that the gravitational potential of the bar and $\Omega_b$ are independent of time (Binney & Tremaine 1987). Some of these galaxies have neighbors and many numerical models have been carried out to examine the possible role of tidal interactions in the formation of bars and symmetric structures (e.g. Noguchi 1988; Friedli & Benz 1993).

Previous spectra of Shapley Ames Galaxies (Filippenko & Sargent 1985; Ho, Filippenko & Sargent 1993, 1996), and they were chosen using the following criteria: 1) bright barred galaxies in the Shapley Ames Catalog (first or second edition Sandage & Tammann 1987), 2) with declinations within a range accessible from San Pedro Mártir, $41^\circ \leq \delta \leq 70^\circ$, and 3) with IRAS colors characteristic of star-forming galaxies according to Helou (1986: with $\log(f(12)/f(25)) \leq -0.15$ and $\log(f(60)/f(100)) \leq -0.1$) or equivalently, an IRAS dust temperature $T_d \geq 25$ K. The characteristics of each galaxy such as distance, IRAS fluxes, radio continuum fluxes, dust temperature, blue luminosity, HI mass, X-Ray luminosity and inclination, are summarized in García-Barreto et al. (1993, 1996).

The purpose of the observations was to determine the physical conditions (velocities and line ratios) from the innermost central regions (circumnuclear structure and compact nucleus). The slit length and width were selected accordingly. Table 1 lists the systemic velocities from optical, HI and CO observations taken from the literature, as well as whether a given galaxy shows H$\alpha$ emission from either the compact nuclear region (innermost 5$''$ in diameter) and or circumnuclear regions (innermost 20$''$ in diameter) (ie. Fugger 1989a, Fugger 1989b, García-Barreto et al., 1996).

The optical observations were performed at the Observatorio Astronómico Nacional in San Pedro Mártir, Baja California, México, on 1993, May 28, 29, 30 and June 1, using the 2.12m telescope f/7.5 equipped with a 1024 × 1024 Thompson CCD detector coupled to a Boller & Chivens spectrograph with 600 grooves per mm at a grating angle of 13°. The central wavelength was chosen in the red part of the

### Notes:

a) Pixels added in slits for each region to produce the final spectra.

b) Observed heliocentric velocity centroids in km s⁻¹. The velocity centroid uncertainties amount to about 25 km s⁻¹ as a result of wavelength calibration and Gaussian fitting. Columns 4 and 5 correspond to [NII] λ6584.1 Å, columns 9 and 10 to [NII] λ6583.4 Å, columns 11 and 12 to [SII] λ6716.4 Å, and columns 13 and 14 to [SII] λ6730.8 Å.

c) Hα full width at half maximum, in km s⁻¹, after deconvolution with an instrumental response (FWHM₁/₂ ≈ 23 ± 0.1 Å = 145±5 km s⁻¹).

d) Hα flux in units of 10^{-14} erg s⁻¹ cm⁻².

### Table 4

**Broadline from a western spectrum 12° away from the spectrum of narrow lines.**

Garcia-Barreto et al., 1992.
spectrum in order to include the [N II], Hα and [S II] lines. The detector scale gives a 1.6 Å pixel\(^{-1}\) spectral resolution and a spatial resolution of 0\(''\).73 pixel\(^{-1}\) in the spectroscopic mode. The original slit length was 80 pixels long (or 58\(''\)) by 10 pixels (or 7.3\(''\)) wide positioned at P.A. \(\sim\)90\(^\circ\) (E of N), that is, East – West. In order to avoid edge effects, we discarded in the final analysis altogether the outer 21 pixels from the slit length and thus the final slit length was only 59 pixels or 43\(''\). Only emission from about 19\(''\) on each side of a central region of a galaxy was observed assuming that the compact nucleus was positioned in the middle of the slit covering the innermost 7 pixels.

The slit was positioned on the brightest optical region of each galaxy, at the declination corresponding to the compact nucleus. Figure 1 shows a sketch of the relative position of the slit with respect to a circumnuclear structure in the innermost central region of a galaxy. Our final analysis showed that in some galaxies the slit was off nucleus by a few arcseconds.

The on source time was 1200s for all the galaxies in the list (except for NGC 5915 which was observed for only 900s). Each galaxy observation was followed by a 1 second exposure of a tungsten lamp. Dome flats taken with the same instrumental setup were used to flatten each galaxy spectrum. The data were bias-subtracted and flat-fielded using the NOAO IRAF software. The sky was subtracted with the IRAF task background using for each galaxy the apertures without any line emission (usually on the edges of the slit).

Not all the galaxies had emission away from the central pixels which correspond to the nucleus. Our original list of galaxies was 26, but we only detected emission lines in the spectra of 18 of them. Eight out of 18 showed emission from the east and west side of the central regions, and 6 out of 8 showed emission from their compact nuclear region as well. In the end we extracted three different final spectra from each of the eight galaxies. In order to extract the final spectra we used the IRAF task apall where we co-added the pixels that correspond to each region. The numbers of pixels that were co-added to create each spectrum are given in the third column of Table 2. In none of the galaxies did we detect emission from the complete disk and thus no rotation curve could have been produced. Figures 2, 3, 4, 5, 6, 7, 8, 9 shows the spectra of the eight galaxies from their eastern and western circumnuclear regions. Ten galaxies did not show any bright emission away from their central pixels and a final spectrum for each of them was obtained after adding the central 5 to 20 pixels.

The task “splot” was used to measure the strengths, central wavelengths, widths, and fluxes of the emission lines. The central wavelengths, widths and fluxes of emission lines were estimated by fitting gaussian curves with the IRAF task splot. For this purpose we fitted multiple curves in order to account for blended broad lines and when possible corroborated the values by fitting individual lines. The uncertainty for the velocity centroids of the emission lines amounts...

\(^a\)in Mpc from Tully (1988).

\(^b\)True velocity difference, in km s\(^{-1}\), between the nucleus and the west (east) side in (NGC 4691), NGC 5135, NGC 5383, NGC 5915 and NGC 6951. True velocity half difference between the east and west sides in NGC 4314 and in NGC 5534, for which we assumed an inclination of 30\(^\circ\).

\(^c\)Dynamical mass of each galaxy inside a radius R, in units of solar masses: \( M_{\text{dyn}} = 233.7 R(\text{pc}) V^2(\text{km s}^{-1})^2 \) to about 25 km s\(^{-1}\) as a result of wavelength calibration and gaussian fitting. The instrumental spectral resolution was estimated by calculating the full width at half maximum of emission lines of a lamp at different wavelengths across the band. Our estimated value is \( \text{FWHM}_{\text{inst}} \sim 3.23 \pm 0.1 \text{ Å} \) or about 145\pm5 km s\(^{-1}\). The tabulated line widths were corrected for instrumental resolution by subtracting the instrumental width in quadratures from the observed width: \( \text{FWHM}_{\text{real}}^2 = \text{FWHM}_{\text{obs}}^2 - \text{FWHM}_{\text{inst}}^2 \).

3. Results and Discussion

In this section we present the results of our observations: first, we provide the estimates of central masses calculated from the observed velocities, assuming that the ionized gas rotates on circular orbits around the compact nucleus and lies on the plane of each galaxy’s disk. The velocities may also be useful in deriving the properties of resonances using density wave theory and theory of orbits in order to associate circumnuclear structures with Inner Lindblad Resonances (see Binney & Tremaine 1987 and Contopoulos & Grosbøl 1989). The spatial distribution of H\(\alpha\)+[NII] of these barred galaxies, except for NGC 5383, has been reported by Pogge 1989a, Pogge 1989b and Garcia-Barreto et al., 1996. Then, the line ratios and electron densities can be derived.

3.1. Velocities and Inner Masses

Table 2 lists the heliocentric velocities, in km s\(^{-1}\), for [NII]\(\lambda6548, 1\), H\(\alpha\) \(\lambda6562, 8\), [NII]\(\lambda6583, 4\) and [SII]\(\lambda6716, 4\) and \(\lambda6730, 8\) lines from the 8 galaxies we were able to isolate the emission from the eastern and western sides. Table 3 lists the heliocentric velocities for other 10 galaxies with no emission away from the central pixels in our slit.

Our observations indicate that the different systemic velocities reported in the literature for NGC 4314 (\(v_{\text{sys}} = 883 \text{ km s}^{-1}\) [Sandage & Tammann 1987]; \(v_{\text{sys}} = 1004 \text{ km s}^{-1}\) [Smith et al. 1987; Strauss et al. 1992]) are most likely the result of their position of the slit relative to the circumnuclear structure. The velocities agree with the observed velocities for the eastern and western regions of the circumnuclear structure (see Table 2). Our optical velocities are somewhat smaller then the velocities obtained from CO lines. In particular, the eastern CO emission peaks at around \(v_{\text{east}} \approx 920 \text{ km s}^{-1}\) and the western CO emission peaks at around \(v_{\text{west}} \approx 1030 \text{ km s}^{-1}\) (Benedict, Smith & Kenney 1996). The differences between optical and CO lines may be the result of hydrodynamic processes at play, e.g. molecular outflows, supernovae events, etc., that may produce a different velocity for the molecular and atomic components.

In NGC 5430, we only detected a velocity of \(v \approx 3065 \text{ km s}^{-1}\), which is quite different from the re-
ported systemic optical velocity of $v_{sys} = 2875 \text{ km s}^{-1}$. On the other hand, the CO lines have $v_{NE} \approx 2893 \text{ km s}^{-1}$ and $v_{SW} \approx 3069 \text{ km s}^{-1}$ (Contini et al., 1997). This leads us to conclude that our spectrum only showed the emission from the southwestern (SW) blob, and that the reported systemic velocity is probably better associated to the NE blob.

Our velocities for NGC 4691 and NGC 6951 are in agreement with the velocities reported by Wiklind, Henkel & Sage (1993) and by Boer & Schulz (1993). The optical velocities for NGC 3504 differ by $\approx 100 \text{ km s}^{-1}$ from the CO velocities. This discrepancy is likely the result of positioning the slit off the nucleus (e.g., Kenney et al., 1992). Table 4 lists the velocity differences for the galaxies observed.

We estimate the dynamical mass interior to the rings of ionized matter. Assuming that most of the mass interior to these rings is homogeneously distributed inside a radius R, the dynamical mass may be estimated from $M_{dyn}(M_\odot) = 233.7 R(\text{pc}) V_{true}^2 (\text{km s}^{-1})^2$, where $V_{true} = V_{obs}/\sin(i)$, with $V_{obs}$ the observed velocity and $i$ is the inclination angle of the circumnuclear structure with respect to the plane of the sky. We are assuming, not necessarily being correct, that the circumnuclear structure is on the plane of a given galaxy and its inclination is the same as the inclination of the galaxy disk. This assumption is based primarily on the idea that circumnuclear structures are at distances of about 300 pc up to 1 kpc from
the compact nucleus and such a large structure would be unstable if being inclined with respect to the plane of the disk. In addition, we are implicitly assuming circular orbits for the gas in the rings, which might not be true especially in the presence of a pronounced bar.

Table 6 gives the estimated dynamical masses, $M_{\text{dyn}}$, assuming as we said before that the ionized gas in circumnuclear regions lies in the plane of the galaxy’s disk and that they follow circular orbits as a response to a central axisymmetric gravitational potential. As mentioned earlier if circumnuclear structures (i.e. rings) are to be explained as Inner Lindblad Resonances, more observations are needed in order to have the complete radial velocity field (rotation curves) and to compute epicyclic frequencies, $\kappa(r)$. We estimate an error of about a factor of two on the masses presented in Table 6.

3.2. Line Ratios and Electron Densities

3.2.1. [NII]/H$\alpha$ ratio

Burbidge & Burbidge (1962) showed that the regions in external galaxies with H$\alpha$ and [NII] emission lines, and a line intensity ratio of $[\text{NII}]\lambda 6583/\text{H}\alpha \sim 0.33$, have a degree of excitation that is similar to the extended HII regions in our own galaxy. They also pointed out that the observed ratio is larger than 1
in the nucleus of some galaxies. More recent observations of several emission lines, with better sensitivity and spectral coverage, have been used to determine the excitation mechanisms in different objects. [Baldwin, Phillips & Terlevich 1981, Osterbrock 1989]. In particular, the emission lines used are: [NeV] λ 3426 Å, [OII] λ 3727 Å, Hβ λ 4861 Å, HeII λ 4686 Å, [OIII] λ 5007 Å, [OI] λ 6300 Å, Hαλ 6563 Å, [NII] λ 6584 Å. Depending on the line ratios, the excitation mechanisms for the line-emitting gas could be: a) photoionization by OB stars, b) photoionization by a power-law continuum source, c) collisional ionization from shock waves, and d) a combination of the above.

Actually, the nuclear regions are usually excited by a power-law source but the circumnuclear rings are excited by UV radiation from recently formed stars. Recent spectroscopic surveys of spiral galaxies show low-ionization emission, suggesting that a flat-spectrum (power law) radiation field photoionizes the nuclear gas (Keel 1983a,b,c; Kennicutt & Kent 1983, Filippenko & Sargent 1985, Ho, Filippenko & Sargent 1995, 1997a,b; Ho et al. 1997). In the nucleus of Seyfert galaxies the same mechanism seems to operate and high-ionization emission iron lines are found from the central regions, such as: [Fe VII] λ 5721 Å, [Fe VII] λ 6087 Å, Fe X λ 6374 Å and Fe XIV λ 5303 Å (Appenzeller & Ostreicher 1988). In contrast, several observations support the idea that circumnuclear rings are regions of massive OB star formation: e.g., those with bright Hα emission, 10µ
emission, radio continuum emission, and CO mm line emission (e.g. Hummel, van der Hulst & Keel 1987; Garcia-Barreto et al., 1991a; Garcia-Barreto et al., 1991b; Kenney et al., 1992; Telesco, Dressel & Westencroft 1993; Vila-Vilaró et al., 1993; Benedict, Smith & Kenney 1996; Contini et al., 1997). This is in line with the expectations from galactic dynamics, where large accumulations of material can occur at regions near Lindblad resonances, hence, providing suitable conditions for triggering the formation of stars. Our results corroborate these views, and we find that the photonizing agents for the nuclear gas and the circumnuclear rings are of different nature.

The line ratios [NII]/Hα and [SII]/Hα were computed separately for the eastern and western regions for all galaxies with circumnuclear structures. The [NII]λ 6548/Hα ratio is on average ∼ 0.12 in the eastern side, ∼ 0.16 in the western side (Table 2). The ratio is ∼ 0.25 for galaxies without extranuclear emission (Table 3). The [NII]λ 6583/Hα ratio is on the average ∼ 0.43 in the eastern side and ∼ 0.58 in the western side. The average ratio is ∼ 0.78 for galaxies presenting spectra from their central regions without circumnuclear structures. The values found are in agreement with the values found in other barred galaxies like NGC 1097 (Phillips et al., 1984).

In the case of NGC 4314 and NGC 6951, with clear circumnuclear rings, the line ratio was found different from each side of the ring. The [NII]λ 6583/Hα ratios in NGC 4314 are 0.45 and 0.85 while in NGC 6951 they are 0.48 and 0.93 from their eastern and western circumnuclear regions, respectively. These values suggest different intrinsic physical conditions as a result of local star formation and evolution in each side of the ring. We believe that the ratio of [NII]λ6583/Hα of 1.01 quoted by Ho, Filippenko & Sargent 1997b for NGC 4314 represents the ratio from the western side of the circumnuclear ring and not necessarily from the compact nucleus since images suggest that there is no Hα emission from the compact nucleus (Pogge 1989a; Garcia-Barreto et al., 1996). Additionally, the ratio [NII]λ6583/Hα from the compact
nucleus of NGC 6951 is about 2, in agreement with previous values reported \citep{Ho1997}. Figure 10 shows the spectrum corresponding to the compact nucleus of NGC 6951. NGC 4477 and NGC 5728 also show a ratio of [NII]λ 6583/Hα of \sim 2.4 and \sim 1.4 respectively, in accord to values found previously \citep{Phillips1984, Schommer1988, Ho1997}. These galaxies are classified as Seyfert 2 galaxies with physical characteristics that account for the ratio observed in the nucleus \citep{Kennicutt1988}. Ho, Filippenko & Sargent 1997].

3.2.2. [SII]/Hα and [SII]λ6716/[SII]λ6731

The ratio of [SII]/Hα is found in the range from 0.07 to 0.2 with no obvious difference in either side of circumnuclear regions. It is in the range from 0.1 to 0.3 from the compact nucleus in galaxies with circumnuclear structures and it is 0.1 to 0.4 in central regions of galaxies without circumnuclear regions (see Tables 2 and 3). The lower values seem to be from the eastern and western side of the nuclei, but further observations with longer integration times and wider slits are needed to confirm this. Ratios with larger values from nuclei and low values from circumnuclear regions have been found in NGC 1097 \citep{Phillips1984} and NGC 5728 \citep{Schommer1988}.

The [SII]λ6716/[SII]λ6731 ratio was found to be in the interval from 0.6 to 1.4, suggesting electron densities of a few hundred particles per cm$^3$ (see Tables 4 and 5; e.g. \cite{Osterbrock1989}).

4. Summary

We have presented new long slit spectroscopic observations with [NII], Hα, and [SII] emission lines from 18 RSA barred spiral galaxies, eight of which have structures around the nucleus. The main results are the following: a) We were able to determine the heliocentric optical velocities for the ionized gas from the compact nucleus, and the eastern and western regions, in eight galaxies. With these velocities we have estimated the inner dynamical mass of each galaxy assuming that the gas move in circular orbits on the plane of the galaxy. b) We were able to estimate the line ratios [NII]λ6548/Hα, [NII]λ6583/Hα, [SII]λ6716/Hα and [SII]λ6730/Hα for the eastern, western, and compact nuclear regions, separately, of eight galaxies. In particular, we found that in galaxies with clear circumnuclear rings, as in NGC 4314 and NGC 6951, the ratio [NII]λ6583/Hα is lower in the eastern region than in the western region of the ring suggesting different local physical conditions as a result of star formation and evolution. c) In NGC 4477, NGC 5728 and NGC 6951 we found that the ratio [NII]λ6583/Hα is larger than unity in the central nuclear regions, in agreement with values reported.

Acknowledgments

We acknowledge useful comments from the referee that helped us to improve the final version of this paper. J.A.G-B acknowledges partial financial support from DGAPA (UNAM) and CONACYT (971010), México, that allowed him to spend his sabbatical year at the Astronomy Department of the University of Minnesota and he would like to thank the Astronomy Department of the University of Minnesota for their hospitality where part of the original article was written. H.A. thanks the Spanish Ministry of Foreign Affairs for financial support. J.F. acknowledges the support given to this project by DGAPA-UNAM grant, CONACyT grants 400354-5-4843E and 400354-5-0639PE, and a R&D Cray research grant. This research has made use of the NASA/IPAC extragalactic database (NED) which is operated by the Jet Propulsion Laboratory, Caltech, under contract with the National Aeronautics and Space Administration.
