Vitamin D dependent rickets type I

Chan Jong Kim, M.D.

Department of Pediatrics, Chonnam National University Medical School, Gwangju, Korea

Vitamin D is present in two forms, ergocalciferol (vitamin D₃) produced by plants and cholecalciferol (vitamin D₂) produced by animal tissues or by the action of ultraviolet light on 7-dehydrocholesterol in human skin. Both forms of vitamin D are biologically inactive pro-hormones that must undergo sequential hydroxylations in the liver and the kidney before they can bind to and activate the vitamin D receptor. The hormonally active form of vitamin D, 1,25-dihydroxyvitamin D₃ [1,25(OH)₂D], plays an essential role in calcium and phosphate metabolism, bone growth, and cellular differentiation. Renal synthesis of 1,25(OH)₂D from its endogenous precursor, 25-hydroxyvitamin D (25OHD), is the rate-limiting and is catalyzed by the 1α-hydroxylase. Vitamin D dependent rickets type I (VDDR-I), also referred to as vitamin D 1α-hydroxylase deficiency or pseudovitamin D deficiency rickets, is an autosomal recessive disorder characterized clinically by hypotonia, muscle weakness, growth failure, hypocalcemic seizures in early infancy, and radiographic findings of rickets. Characteristic laboratory features are hypocalcemia, increased serum concentrations of parathyroid hormone (PTH), and low or undetectable serum concentrations of 1,25(OH)₂D despite normal or increased concentrations of 25OHD. Recent advances have showed in the cloning of the human 1α-hydroxylase and revealed mutations in its gene that cause VDDR-I. This review presents the biology of vitamin D, and 1α-hydroxylase mutations with clinical findings.

Key words: Vitamin D, Rickets, 1α-hydroxylase

Introduction

1,25-dihydroxyvitamin D₃ [1,25(OH)₂D] is one of the principle hormonal regulators of calcium and phosphorus metabolism in the body and is critically important for normal growth and mineralization of bone. Renal synthesis of 1,25(OH)₂D from its endogenous precursor, 25-hydroxyvitamin D (25OHD), is the rate-limiting, hormonally regulated step in the bioactivation of vitamin D and is catalyzed by the mitochondrial cytochrome P450 enzyme, 25OHD-1α-hydroxylase (1α-hydroxylase, P450c1α)₁. Vitamin D dependent rickets type I (VDDR-I), also referred to as vitamin D 1α-hydroxylase deficiency or pseudovitamin D deficiency rickets, is an autosomal recessive disorder caused by mutations of the 1α-hydroxylase gene. Characteristic laboratory features are hypocalcemia, increased serum concentrations of parathyroid hormone (PTH), and low or undetectable serum concentrations of 1,25(OH)₂D despite normal
or increased concentrations of 25OHD. Physiological doses of 1α (OH) vitamin D3 (1α-OHD) or 1,25(OH)2D3 induce remission of the clinical and laboratory abnormalities. This review presents the biology of vitamin D, and 1α-hydroxylase mutations with clinical findings.

**Biosynthesis of vitamin D**

Vitamin D exists as either ergocalciferol (vitamin D2) produced by plants, or cholecalciferol (vitamin D3) produced by animal tissues and by the action of ultraviolet radiation (290-310 nm) on 7-dehydrocholesterol in human skin. Vitamin D3 differs from D2 only in having a 22, 23 double bond and having an additional methyl group attached to carbon 24. Both forms of vitamin D are biologically inactive pro-hormones that must undergo successive hydroxylations at carbons 25 and 1 before they can bind to and activate the vitamin D receptor. The 25-hydroxylation of vitamin D occurs primarily in the liver, catalyzed by the mitochondrial cytochrome P450 enzyme, P450c27. The activity of the hepatic 25-hydroxylase is not under tight physiologic regulation, and thus the circulating concentration of 25OHD is determined primarily by one’s dietary intake of vitamin D and amount of sunlight exposure. Although 25OHD is the most abundant form of vitamin D in the blood, it has minimal capacity to bind to the vitamin D receptor and elicit a biological response. The active form of vitamin D, 1,25(OH)2D, is produced in the proximal renal tubule by the 1α-hydroxylation of 25OHD. The circulating concentration of 1,25(OH)2D primarily reflects its synthesis in the kidney. The 1α-hydroxylase is the rate-limiting step in the bioactivation of vitamin D, and enzyme activity in the kidney is tightly regulated by PTH, calcium, phosphorus, and 1,25(OH)2D itself.

**Vitamin D 1α-hydroxylase**

The human 1α-hydroxylase gene has been cloned and mapped to the chromosome 12q13.1-q13.3 at the same locus as the autosomal recessive VDDR-I. It is approximately 5 Kb and is composed of nine exons. Furthermore, several laboratories have characterized mutations in the 1α-hydroxylase gene in patients with VDDR-I. VDDR-I is characterized by failure to thrive, muscle weakness, hypocalcemia, secondary hyperparathyroidism, and the bony changes of rickets. The hallmarks of the diseases are greatly reduced serum concentration of 1,25(OH)2D despite normal or increased concentrations of 25OHD, and the reversal of clinical and laboratory abnormalities by administration of physiologic amounts of 1,25(OH)2D. To date, a total of 36 mutations in the 1α-hydroxylase gene have been identified in patients with VDDR-I. All but one of the frameshift and premature translation-arrest mutations described eliminated the heme-binding site of P450c1α, hence the resultant protein cannot have 1α-hydroxylase activity. Two mutations described in 1α-hydroxylase gene are relatively more common than the others. Deletion of guanine 958 (958delG), as numbered from the gene’s transcriptional start site, was found on 20 French Canadian alleles; microsatellite haplotype analysis showed that these arose from a single founder. A 7 nucleotide insertion in exon 8 was found in 14 affected alleles; these arose from various ethnic groups with different microsatellite haplotypes.

So far, 5 Korean patients with VDDR-I have been studied at a molecular genetic level and 3 distinct mutations have been identified. The clinical data for these patients were summarized in Table 1. Patient 1 presented with bowing of the legs at 12 months of age. He had a prominent forehead with craniotabes, rachitic rosary, and genu varus. Laboratory data revealed hypocalcemia, high serum alkaline phosphatase and PTH concentrations, and low 1,25(OH)2D concentration. She developed recurrent seizures at 5 months of age. At 15 months of age she was found to have kyphosis, prominent rachitic rosary, a widely open anterior fontanel, varus deformity of the elbow, and x-ray findings of severe rickets with fractures of both fibulae. Laboratory data revealed hypocalcemia, high serum alkaline phosphatase and PTH concentrations, and low 1,25(OH)2D concentration. She

### Table 1. Clinical and Biochemical Features in Four Patients with Vitamin D Dependent Rickets Type I

| Patient no. | Age at diagnosis (months) | Presentation         | Serum Ca (mg/dL) | Serum P (mg/dL) | Serum ALP (IU/L) | Serum PTH (pg/mL) | Serum 25OHD (ng/mL) | Serum 1,25-(OH)2D (pg/mL) |
|-------------|---------------------------|----------------------|------------------|----------------|-----------------|------------------|-------------------|--------------------------|
| 1           | 12                        | bowed legs           | 6.0              | 3.8            | 1,050           | 560              | 336               | <7                       |
| 2           | 5                         | rachitic rosary      | 6.4              | 4.0            | 2,043           | 1,320            | 27                | 9.2                      |
| 3           | 7                         | seizure              | 5.2              | 6.2            | 665             | 750              | 38                | <5                       |
| 4           | 14                        | femur fracture       | 7.3              | 5.0            | 1,437           | N/A              | 16                | <5                       |
| 5           | 5                         | rachitic rosary      | 5.9              | 3.6            | 1,326           | 750              | 77                | <4                       |

Abbreviations; ALP, alkaline phosphatase; N/A, not available.
was successfully treated with 1α-OHD. Patient 3 presented with a hypocalcemic seizure at 5 months of age. At 25 months of age he was found to have a prominent forehead, rachitic rosary, and bowing of the legs. Laboratory evaluation showed hypocalcemia, high serum alkaline phosphatase activity, and low 1,25(OH)2D concentration. Radiographs revealed features of severe rickets. She responded well to 1α-OHD. Patient 4 presented with a femur fracture after minor trauma at the age of 14 months. He had hypocalcemia, high alkaline phosphatase activity, low 1,25(OH)2D concentration, and rachitic changes on x-ray. Administration of 1α-OHD resulted in normalization of clinical, radiographic, and laboratory abnormalities. Patient 5 presented with a hypocalcemic seizure at 5 months of age and was treated with calcium and vitamin D. At 17 months of age he was noted to have rachitic rosary, prominent forehead, and enlargement of wrists and ankles. Laboratory data revealed hypocalcemia, high serum alkaline phosphatase concentration, and rachitic changes on x-ray. Serum concentration of 25OHD was above the normal range whereas that of 1, 25-(OH)2D was not detectable. He responded well to administration of 1α-OHD.

On molecular genetic studies, patient 1 was homozygous for a splice site mutation, substitution of an adenine for a guanine in the first nucleotide of intron 3 (IVS3+1 G>A). This mutation disrupts the splice donor site resulting in retention of intron 3. The retained intron would create a frameshift after codon 196 and a translational termination signal 63 bp downstream from the end of exon 3, resulting in a severely truncated protein that cannot have enzymatic activity. Patient 2 was homozygous for a 7 nucleotide insertion in exon 8; this mutation alters the reading frame downstream of codon 442 and creates a premature TGA stop signal; this is upstream from the heme-binding domain, hence the resulting truncated protein is devoid of activity. Patient 3 and 4 were compound heterozygous for the two mutations detected in patients 1 and 2. Patient 5 was compound heterozygous for the mutation detected in patient 1, IVS3+1 G>A, and for a novel nonsense mutation, 2561G>A in exon 6. The mother and brother of patient 2 were heterozygous for the 7 nucleotide insertion in exon 8; DNA from the father was not available for study. The mother of patient 3 was heterozygous for IVS3+1 G>A, and the father and sister were heterozygous for the 7 nucleotide insertion in exon 8. The mother of the patient 4 was heterozygous for the 7 nucleotide insertion in exon 8; the father was not studied. The mother and brother of patient 5 were heterozygous for the IVS3+1 G>A, and the father was heterozygous for the 2651G>A mutation in exon 6.

There are two common mutation sites in 5 Korean patients with VDDR-I (Table 2). The splice site mutation, IVS3+1 G>A, occurred in 5 of 10 alleles. Guanine to adenine substitution in the first nucleotide of an intron is a common mutation in many genes and usually results in skipping of the 5'-exon or activation of potential splice sites25). However, in short introns, retention of the intron may also occur as has been demonstrated for IVS3+1 G>A in the 1α-hydroxylase19.25). The retention of intron 3 causes altered translation and a premature stop codon 63 bp downstream from the end of exon 3. The resulting truncated 1α-hydroxylase would have only 197 of 508 amino acids, would lack the heme-binding domain, and hence would have no enzyme activity: The 1α-hydroxylase gene contains the normally duplicated sequence 5'-CCCCACCC CCCACCC-3' in exon 8, which encodes residues 438-442 (Pro-Thr-Pro-His-Pro). Korean patients showed triplication rather than duplication of this 7 nucleotide sequence on 4 alleles. This 7 nucleotide insertion alters the reading frame downstream of codon 442 and creates a premature TGA stop signal at codon 446; this is upstream from the heme-binding domain, hence the resulting truncated protein is devoid of activity17. Wang et al.17 previously reported that six families of widely divergent ethnic backgrounds (Filipino, Polish, Chinese, Caucasian American, African American, and Hispanic) carried this 7 nucleotide insertion in association with four different microsatellite haplotypes. Thus, the ethnic and haplotype diversity associated with the 7 nucleotide insertion suggests that it has risen by several independent de novo events, probably as the result of a slipped-strand mispairing mechanism during meiosis26. Kitanaka et al.19 found 10 different 1α-hydroxylase gene mutations in 20 Japanese alleles, suggesting that there is no founder effect in that ethnic group. By contrast, Korean patients revealed only three different mutations in ten alleles, suggesting that in Korean ethnic group, the genetic defect in the 1α-hydroxylase gene is more homogeneous.

### Conclusion

The main hormonal regulator of bone mineralization is vitamin D. Dietary deficiency of vitamin D and genetic disorders of vitamin D biosynthesis and action can cause rickets. The patients with VDDR-I...
have mutations in the gene encoding renal 1α-hydroxylase. A total of 36 mutations in the 1α-hydroxylase gene have been identified. Two mutations (958delG, 7 nucleotide insertion in exon 8) described in 1α-hydroxylase gene are relatively more common than the others. Until now, 5 Korean patients with VDDR-I have been studied and 3 distinct mutations have been identified. There are two common mutation sites; IVS3+1 G>A and 7 nucleotide insertion in exon 8. Japanese patients with VDDR-I revealed 10 different 1α-hydroxylase gene mutations in 20 alleles. By contrast, Korean patients showed only three different mutations in ten alleles, suggesting that the genetic defect in the 1α-hydroxylase gene is more homogeneous in Korean ethnic group.
