ABSTRACT

The spectral energy distributions (SEDs), spanning the mid-infrared to millimeter wavelengths, of a sample of 13 high-mass protostellar objects (HMPOs) were studied using a large archive of 2D axisymmetric radiative transfer models. Measurements from the Spitzer GLIMPSE and MIPS\textsuperscript{GAL} surveys and the MSX survey were used in addition to our own surveys at millimeter and submillimeter wavelengths to construct the SEDs, which were then fit to the archive of models. These models assumed that stars of all masses form via accretion and allowed us to make estimates for the masses, luminosities, and envelope accretion rates for the HMPOs. The models fit the observed SEDs well. The implied envelope accretion rates are high, \( \approx 10^{-2.5} M_\odot \text{ yr}^{-1} \), consistent with the accretion-based scenario of massive star formation. With the fitted accretion rates and with mass estimates of up to \( \approx 20 M_\odot \) for these objects, it appears plausible that stars with stellar masses \( M_\star > 20 M_\odot \) can form via accretion.

Subject headings: infrared: stars — methods: data analysis — stars: evolution — stars: formation — radiative transfer

1. INTRODUCTION

The process of massive star formation is a subject of current debate (McKee & Ostriker 2007; Zinnecker 2007). While scaled-up versions of the standard accretion model and competing accretion models require high accretion rates (\( \approx 10^{-3} M_\odot \text{ yr}^{-1} \)), competing coalescence models need high stellar densities (\( \approx 10^4 \text{ pc}^{-3} \)). Presumably, the models are applicable in different regimes, but it is unclear if there is a limit to the stellar mass in the accretion models. The ubiquitous detection of outflows with derived high accretion rates supports an accretion picture (Churchwell 1999; Henning et al. 2000; Beuther et al. 2002b; Zhang et al. 2005). Observations of spectral line infall signatures also indicate high infall rates (Zhang & Ho 1997; Keto 2002; Fuller et al. 2005; Beltran et al. 2006; Keto & Wood 2006; Zapata et al. 2008). However, these results are subject to assumptions and questions. Therefore, other independent methods of deducing accretion and determining the accretion rates are important. In this Letter, we model the SEDs of a subset of 13 HMPOs and find results that are consistent with the accretion scenario for massive star formation. The study takes advantage of (1) the legacy surveys GLIMPSE and MIPS\textsuperscript{GAL} to enhance wavelength coverage for the SEDs at high spatial resolutions compared to previous data from IRAS and MSX surveys and (2) new modeling capabilities. Thus, the current work is a significant improvement over previous 1D modeling of the same objects (Williams et al. 2004).

2. SAMPLE AND DATA ANALYSIS

The starting point is the full sample of 69 objects presented in Sridharan et al. (2002) which was chosen by combining the Wood & Churchwell IRAS colors, lack of or weak cm-wavelength continuum emission, high luminosities, and CS detections. Images of the sample at 1.3 mm and 450 and 850 \( \mu m \) wavelengths showed strong emission (Beuther et al. 2002a; Williams et al. 2004). Of the 69 fields, 52 had MIPS\textsuperscript{GAL} data at both 24 and 70 \( \mu m \) of which 41 and 4 were saturated in the two bands, respectively. Attempts to overcome saturation using simple PSF fitting were abandoned due to poor fits. Presence of multiple objects also often prevented reliable photometry. We finally chose a subset of 13 objects, listed in Table 1, for which (1) reliable fluxes could be obtained at 70 \( \mu m \) and at least 2 IRAC bands from the GLIMPSE survey catalog (spring 2005, highly reliable), and (2) the GLIMPSE catalog position and the 1.2 mm image peak were coincident. The kinematic distances listed, from Sridharan et al. (2002), used CS velocities. For cases where distance ambiguity is resolved here, the discarded distance is listed in parentheses.

The fluxes at 24 and 70 \( \mu m \) were obtained by aperture photometry after background subtraction using the MOPEX/\textsc{apex} package from the Spitzer Science Center (SSC). Fluxes for the IRAC and MSX bands were obtained from the GLIMPSE Catalog and the MSXC\textsc{6} Source Catalog, respectively. Aperture correction factors recommended by the SSC were used for MIPS data. The 2MASS data are not included due to uncertainties in the absolute flux calibrations. A lower limit of error was imposed on the 25\%–20\% to the flux.

Combining the Spitzer data with measurements at 1.3 mm and 450 and 850 \( \mu m \) and with MSX data (wherever GLIMPSE data were not available) allowed us to construct SEDs for the 13 objects over a wide wavelength range. We then searched for models that were best fits to the SEDs in a large archive...
of two-dimensional (2D) axisymmetric radiative transfer models of protostars calculated for a large range of protostellar masses, accretion rates, disk masses, and disk orientations. (Robitaille et al. 2006, 2007). This archive has a linear regression tool that can select all model SEDs that fit the observed SED better than a specified χ². Each well-fit SED has a set of parameters and their variances. For the near distance case of IRAS 18264 and IRAS 18553, ΔN = 1 was adopted to restrict the number of models to 200.

3. RESULTS AND DISCUSSION

From the fits shown in Figure 1 it is apparent that the best-fitting models match the SED data quite well. The poorest fit is for IRAS 18264−1152 where higher resolution observations show the presence of multiple objects (Qiu et al. 2007). Unresolved multiplicity is a limitation of the study and we take the quality of the fits for the other sources as an indication that the SED and envelope structure are likely primarily affected by the most massive star in the system. Our primary conclusion from these fits is that the models provide a good description of the SEDs of the HMPOs.

The parameters obtained from the SED fitting, viz., the stellar mass, luminosity, and temperature, M∗, L∗, and T∗, the envelope inner radius Renv, and the envelope accretion rate ṁenv, are listed in Table 2. While a formal confidence interval measure would be desirable, the model grid sampling a 14-dimensional space makes it difficult to do so. Nonetheless average values and variances for the parameters were obtained by taking a

![Figure 1](http://www.astro.wisc.edu/protostars)

**Figure 1.** SEDs for the sources outlined in Table 1. The three panels show representative (IRAS 18440−0148 and IRAS 19217+1651) and the worst (IRAS 18264−1152−far) fits. The triangles denote upper limits. The solid black line shows the best-fitting model while the gray lines show all models that also fit the data reasonably well (χ² − χbest < ΔN where ΔN = 1, 3, or 5). Since the apertures used varied between wavelengths, the fits plotted are synthetic SEDs obtained by interpolating between the different apertures. The dashed line shows the SED of the stellar photosphere in the best-fitting model.
weighted average of all the models within a $\chi^2 - \chi^2_{min} < \Delta N$, following Simon et al. (2007). For a majority of the sources $M_*$ was found to be constrained to within 3 $M_\odot$ and $L_*$, $T_*$, and $M_{env}$ to within 0.5, 0.7, and 0.5 orders of magnitude. For the envelope inner radius $R_{env}$ which did not seem to be well constrained, a range of values is listed.

We restrict further discussion to nine sources with no or resolved distance ambiguity, IRAS 18440−0148, IRAS 18035+0641, IRAS 19074+0752, and IRAS 19217+1651 have unambiguous kinematic distances. For IRAS 18553+0414 and IRAS 19266+1745, the near distance was discarded by Williams et al. (2004) because of incompatible dust mass and luminosity estimates, which we confirmed by the SED fits. For IRAS 18247−1147, IRAS 18372−0541, and IRAS 18431−0312, we compared spectral type estimates by two different methods and picked the distance that resulted in better match. Lyman continuum photon rate estimates using 3.6 cm continuum data from Sridharan et al. (2002) yielded a spectral type (De Buizer et al. 2005b; Panagia 1973; strictly, a lower limit). The second estimate came from SED fits. IRAS 18372−0541 and IRAS 18472−0022 were placed at the far distance with confidence, whereas for IRAS 18247−1147 the choice of near distance was favored, although less certain. This analysis could not be extended to IRAS 18090−1832, IRAS 18264−1152, and IRAS 18521+0134 because the corresponding 3.6 cm continuum flux was either undetected or was $< 1$ mJy (Sridharan et al. 2002). For IRAS 18431−0312, the near and far distances, which are within $\pm 10\%$, led to the same best-fit model mass, envelope accretion rate, luminosity, and the temperature within the uncertainties. Hence these parameters were averaged together.

The model masses, luminosities, and temperatures are found to be spread over the ranges $\sim 10^{-1}$ to $10^0$ $M_\odot$, $10^{3.5}$ to $10^5$ $L_\odot$, and $10^4$ to $10^{4.5}$ K, respectively. Figure 2 shows the fitted accretion rates as a function of the stellar masses, with the main conclusion that we have high accretion rates: $\approx 10^{-2.5} M_\odot$ yr$^{-1}$. Current evidence for high accretion rates come from estimates based on high molecular outflow rates and infall studies (see references in § 1). These estimates are subject to a number of uncertainties—the velocities of the underlying jets, the projection angles, the fraction of the accreting material ejected in the jets, the size of the infall region and densities. Our result is an independent confirmation of high accretion rates using a different approach, and lends important credence to the accretion based massive star formation scenario. We note that in our models, turbulence and magnetic fields are not included which affects the density profiles in the outer regions leading to uncertainties in the accretion rates.

Since all the objects show high accretion rates, this phase is not transient. With model masses up to $\sim 20 M_\odot$, and assuming the high accretion rates derived to continue for $\sim 10^4$ years, it appears plausible that stars of masses $> 20 M_\odot$ could form by accretion.

In comparison, the outflow and infall studies mentioned above arrived at $\dot{M}_{\text{disk}}$ of $10^{-1}$ to $10^3 M_\odot$ yr$^{-1}$ and a similar range for the infall rate $\dot{M}_{\text{env}}$. Here $\dot{M}_{\text{env}}$ and $\dot{M}_{\text{disk}}$ are the rates of material falling on to the disk from the envelope and the accretion rate from the circumstellar disk to the protostar, respectively, a distinction often not carefully made in the literature. In the absence of episodic phenomena, the difference between the two represents the rate of flow in the outflow jets.

**Table 2**

| Source       | Far/Near | $\Delta N$ | No. of Models | $M_*$ ($M_\odot$) | $M_{env}$ ($M_\odot$ yr$^{-1}$) | $L_*$ (log $L_\odot$) | $T_*$ (log K) | $R_{env}$ (AU) | Min | Max |

![Fig. 2](image_url)—Plot of envelope accretion rate $\dot{M}_{\text{env}}$ vs. stellar mass $M_*$ for the sources. The solid line is the best-fit power law to the data. This result is not biased by the model grid distribution, also shown, with the dashed line being its best fit.
While our accretion rates appear to be consistent with being independent of mass, there may be a weak trend of increasing $\dot{M}_{\text{env}}$ with stellar mass $M_*$ (Fig. 2). Although uncertain, we carry out a formal power-law fit to allow comparison with evolutionary tracks, and obtain the best fit of $\dot{M}_{\text{env}} = 10^{-4.2 \pm 1.1} \times M_*^{1.4 \pm 0.8} M_\odot \text{ yr}^{-1}$. Heeding Robitaille (2007), who pointed out several caveats to SED modeling using this archive, we conducted checks to convince ourselves that the trend suggested is not due to biases from the model grid. The distribution of all the grid points within the relevant range in the model archive and its best fit, both presented in Figure 2, demonstrate this. Guided by outflow results, Norberg & Maeder (2000) included mass-dependent $\dot{M}_{\text{disk}}$ for massive stars in their models of evolutionary tracks and found that a power law $\dot{M}_{\text{disk}} = 10^{-7.0} \times M_*^{1.5} M_\odot \text{ yr}^{-1}$ best agreed with observations of pre-main-sequence (PMS) stars in the H-R diagram. Our tentative result is similar to this. Since the evolutionary tracks of Bernasconi & Maeder (1996) used in the SED modeling do not incorporate accretion (the so-called canonical models) and our accretion rates come from collapse models and density profiles, the agreement with the later Norberg & Maeder (2000) work on evolutionary tracks with accretion points to the potential of SED modeling to provide inputs to theoretical work on evolutionary tracks. The power law-indices for disk and envelope accretion rates are about the same, which implies the fraction of the infalling material lost to the outflow is independent of mass.

Combining evolutionary track results and our SED model results, and taking the indices to be the same in the above two power laws, we can obtain a value for $f$, the fraction of the $\dot{M}_{\text{env}}$ eventually arriving on the star to be $f \approx 10^{-7}/10^{-4.2} = 0.16$. Conversely, the fraction lost to the outflow is $f' = 1 - f = 0.84$. This is to be compared with a value of 15% for $f$ suggested by Churchwell (1999) for massive star formation and the theoretically indicated value of $f' \approx 1/3$ (or $f = 2/3$) for low-mass star formation (Tomisaka 1998; Shu et al. 1999).

4. SUMMARY AND CONCLUSIONS

Combining a large archive of 2D radiative transfer models (Robitaille et al. 2006, 2007) and SEDs with wide wavelength coverage using the Spitzer GLIMPSE and MIPS GAL surveys, and the MSX and our published millimeter and submillimeter surveys, a carefully chosen subset of 13 HMPO candidates was modeled. The main findings are that (1) the models fit the data well with high implied envelope accretion rates $\dot{M}_{\text{env}} \approx 10^{-2.5} M_\odot \text{ yr}^{-1}$ required for massive star formation, lending credence to accretion based massive star formation; (2) stars of masses $>20 M_\odot$ may form by accretion. We also find a possible mass dependence of the accretion rates as a power law and determine the fraction of the envelope accretion lost to the outflow jets, both of which are subject to large uncertainties. These results can be improved by extension to larger samples using archival data and better PSF fitting to overcome saturation.
