Methomyl poisoning presenting with decorticate posture and cortical blindness

Chih-Ming Lin

Abstract

Methomyl is a potent pesticide that is widely used in the field of agriculture. The systemic toxic effects of methomyl have been well described. However, the neurological effects of methomyl intoxication are not well understood. In this study, we report a 61-year-old Taiwanese man who presented with reversible cortical blindness and sustained decorticate posture after consuming a large volume of liquid methomyl in a suicide attempt. We also discuss the correlation between the patient’s clinical symptoms and the neuroimaging observations.

Case Report

A 61-year-old Taiwanese man was admitted to our emergency room because of altered mental status. His wife informed the medical personnel that her husband had quarreled with their son a few days previously, and had remained in a bad mood since the incident. That morning, when she awoke at approximately 6:30 am, she found her husband lying on the bathroom floor. An empty can of liquid methomyl was beside him. She estimated that her husband had swallowed approximately 300 cm³ of methomyl. Further examination revealed depressed consciousness (Glasgow Coma Scale, E1M1V1). The patient’s eyes had pinpoint pupils and his blood pressure and pulse were absent. He was also unable to breathe spontaneously. Cardiac arrest was confirmed and the patient underwent cardiac massage for 11 minutes. He was also intubated to maintain his breathing. After cardiopulmonary resuscitation because of altered mental status, he was extubated after showing general improvement in condition. On the second day of admission, he regained consciousness but exhibited irregular limb and torso posture. On the sixth day, he started to complain of blurred vision. An ophthalmologist was consulted but no obvious abnormalities could be identified. On suspicion of cerebral disease, a neurologist was consulted. Further examination revealed cortical blindness and decorticate posture. Cerebral magnetic resonance imaging (MRI) was arranged, which identified bilateral occipital regions lesions. The patient was administered normal saline and treated with aspirin and piracetam for 3 weeks in hospital. During the treatment period, his symptom of cortical blindness resolved, whereas his decorticate posture was refractory. Follow-up brain MRI results supported our clinical observations by indicating the disappearance of the bilateral occipital lesions and symmetrical putaminal high signal abnormalities. In this article, we briefly discuss the possible mechanisms underlying the cerebral effects of methomyl poisoning. Our study can provide clinicians with information on the manifestations of methomyl intoxication and an appropriate treatment direction.

Discussion

Our patient regained consciousness after aggressive CPR and gastric lavage. Cortical blindness improved after aspirin and piracetam treatment. Our patient had developed decorticate posture and subsequent cortical abnormalities. A neurological examination was also conducted, confirming decorticate posture and cortical blindness. Other neurological findings, including those regarding the patient’s motor and sensory systems, coordination, deep tendon reflexes, and cranial nerves, were all unremarkable. Therefore, we arranged a brain MRI to eliminate possible central visual pathway lesions. The brain MRI revealed lesions in the bilateral tips of the occipital lobe areas (Figure 1A, B). We hydrated the patient with normal saline and administered 75 mg of aspirin once daily and 150 mg of piracetam twice daily. He remained in the hospital for 3 weeks, after which he was discharged for neurology outpatient clinical follow-up. He attended outpatient clinical follow-ups for 2 months after discharge and his vision improved, whereas his decorticate posture remained refractory. A second brain MRI was performed, revealing the disappearance of the bilateral occipital lobe lesions and symmetrical putaminal high signal abnormalities (Figure 2). This patient continues to attend regular follow-ups at the clinic.

blindness after methomyl intoxication. Following treatment, his symptom of cortical blindness subsided, whereas his decorticate posture persisted. Brain MRI studies initially revealed occipital lesions, followed by the resolution of these lesions and symmetrical putaminal high signal abnormalities. The order of clinical symptom presentation contrasted with the patient’s cerebral MRI findings.

Hu et al. reported visual impairment after acute insecticide poisoning following the ingestion of malathion.1 Malathion and methomyl share some chemical characteristics.1,2 Previous studies have suggested that the central visual pathway can be intermittently interrupted because of the indirect effect of decreased blood flow to the occipital regions.1,4,5 A post-CPR state can also cause transient cortical blindness,2,6-8 possibly through the disproportionate allocation of cerebral blood flow. Cortical blindness has been reported in children and adult patients.3,8 However, in these patients, unlike our case, their cortical blindness was permanent. The association between the cerebral effects of methomyl intoxication and the anoxic state after CPR remains under investigation.

According to our research, no previous study has reported permanent decorticate posture after a post-CPR state or methomyl intoxication. Taga et al. reported transient decorticate posture after thoracic epidural injection,9 although the underlying mechanisms of such symptoms have yet to be elucidated. In this study, we report a 61-year-old Taiwanese man who developed decorticate posture and cortical blindness after methomyl poisoning. His symptom of cortical blindness improved after aggressive aspirin and piracetam treatment, whereas the symptom of decorticate posture remained refractory. Our results can provide physicians with information on the symptoms of methomyl intoxication and the appropriate treatment direction.
