Abstract

A possibility of extending the applicability range of non-relativistic calculations of electronuclear response functions in the quasielastic peak region is studied. We show that adopting a particular model for determining the kinematical inputs of the non-relativistic calculations can extend this range considerably, almost eliminating the reference frame dependence of the results. We also show that there exists one reference frame, where essentially the same result can be obtained with no need of adopting the particular kinematical model. The calculation is carried out with the Argonne V18 potential and the Urbana IX three-nucleon interaction. A comparison of these improved calculations with experimental data shows a very good agreement for the quasielastic peak positions at \(q = 500, 600, 700\) MeV/c and for the peak heights at the two lower \(q\)-values, while for the peak height at \(q = 700\) MeV/c one finds differences of about 20%.

In Ref. [1] we have studied the longitudinal response functions for electron scattering from three–nucleon systems in the momentum transfer range between 250 and 500 MeV/c. A non-relativistic (n.r.) formulation of the nuclear three–body problem has been adopted and the full dynamics has been taken into account both in the initial and final state. A related study has been recently presented in Ref. [2]. In order to check the validity of our n.r. calculation we have checked in [1], among other issues, also the reference frame dependence and found that it is not negligible for momentum transfers \( q \geq 400 \) MeV/c. A frame dependence of a similar type had already been observed in deuteron electrodisintegration [3, 4, 5]. In Ref. [1] the hadronic current was evaluated in the Breit frame and the results were compared with experimental data. In the present work we reconsider the frame dependence and present results up to \( q = 700 \) MeV/c.

It is clear that as \( q \) increases the results of purely n.r. calculations must become increasingly questionable. One manifestation of the importance of relativity is the frame dependence that occurs in such n.r. calculations at high \( q \). Of course use of any frame in a genuine relativistic calculation must lead to the same laboratory (LAB) frame result. We will show that certain frames in a n.r. calculation may tend to minimize the error due to lack of a proper relativistic calculation. We also suggest a procedure to reduce the frame dependence in the quasi-elastic peak region.

In the one photon exchange approximation the inclusive electron scattering cross section in the LAB frame is given by

\[
\frac{d^2\sigma}{d\Omega d\omega} = \sigma_M \left[ \frac{(q^2 - \omega^2)^2}{q^4} R_L(q, \omega) + \left( \frac{(q^2 - \omega^2)}{2q^2} + \tan^2 \frac{\theta}{2} \right) R_T(q, \omega) \right],
\]

where \( R_L \) and \( R_T \) are the LAB longitudinal and transverse response functions, respectively. The LAB frame electron variables are denoted by \( \omega \) (energy transfer), \( q \) (momentum transfer), and \( \theta \) (scattering angle).

In addition to \( R_L \) one may define related responses \( R^r_L \) expressed in terms of quantities pertaining to reference frames obtained via boosting the LAB frame along \( q \). In general nuclear states are products of internal and center of mass momentum substates. In the n.r. approximation after integrating over the center of mass momentum one has

\[
R^r_L = \sum_i dF \left| \langle \psi_i | \sum_j \rho_j(q^r, \omega^r)|\psi_f \rangle \right|^2 \delta \left( E_f^r - E_i^r - \omega^r \right).
\]

2
Here $q_{fr}$ and $\omega_{fr}$ are the momentum and energy transfer in a new reference frame, the internal substates are indicated with $\psi_i$ and $\psi_f$, and $\rho_j(q_{fr}, \omega_{fr})$ are the internal single-nucleon charge operators as defined in [1] (the energy dependence is due to the inclusion of the nucleon form factors).

The summation-integration symbol denotes the usual sum/integration over final state variables in addition to averaging over the initial state magnetic quantum numbers. In the relativistic case we have the same formula, but with the substates $\psi_i$ and $\psi_f$ depending, respectively, on the total momenta $P_{fr}^i$ and $P_{fr}^f = P_{fr}^i + q_{fr}$ of the initial and final states in a given reference frame. Thus $\psi_i$ and $\psi_f$ are frame dependent in the relativistic case. We disregard this frame dependence in our calculations and we do not consider the boost corrections of the states.

Energy conservation is explicit in the argument of the $\delta$–function where $E_{fr}^f$ and $E_{fr}^i$ denote the total initial and final energies and can be expressed with relativistic or n.r. kinematics (both cases will be considered in the following). In the n.r. case the center of mass and internal energies can be separated so that:

$$\delta \left( E_{fr}^f - E_{fr}^i - \omega_{fr} \right) \approx \delta \left( e_{fr}^f + \left( P_{fr}^f \right)^2 / (2MT) - e_{fr}^i - \left( P_{fr}^i \right)^2 / (2MT) - \omega_{fr} \right)$$

$$\equiv \delta \left( e_{fr}^f - e_{fr}^i(q_{fr}, \omega_{fr}) \right)$$

(4)

where $e_{fr}^f$, $e_{fr}^i$, are intrinsic energies of the final and initial states.

The response $R_L$ can be expressed in terms of $R_{fr}^L$ with the help of the relationship

$$R_L(q, \omega) = \frac{q^2}{(q_{fr})^2} \frac{E_{fr}^f}{MT} R_{fr}^L(q_{fr}, \omega_{fr}).$$

(5)

The origin of the factor $q^2/(q_{fr})^2$ is shown in Ref. [3], Eqs. (2.13), (2.14) (see also e.g. Refs. [4, 6, 7]). The factor $E_{fr}^f/MT$ arises since we adopt the usual normalization of the target state to unity instead of its covariant normalization. (In [1] this factor was not included).

We will use relation (5) to get the LAB response from calculations referring to frames different from the LAB frame and study the frame dependence of n.r. calculations.

In addition to the LAB frame we consider three other frames. One is the so–called anti–lab (AL) frame, where the total momentum in the final state is zero. Thus the target nucleus has a momentum $-q_{AL}$. If one neglects the internal motion of the nucleons inside the nucleus then one could say that the nucleon momenta in the initial state are about $-q_{AL}/A$
in this reference frame. Absorption of a virtual photon of momentum \( q_{AL} \) by a ground state nucleon (the quasi-elastic process) would result in a final state, where one nucleon has a momentum of about \( q_{AL}(A-1)/A \) and \( A-1 \) slower nucleons each have a momentum of about \(-q_{AL}/A\).

If one chooses to minimize the sum of the center of mass kinetic energies of initial and final states, one is led to the Breit (B) frame. In the Breit frame the target nucleus moves with \(-q_B/2\) and the nucleon momenta are thus about \(-q_B/(2A)\). According to the above picture the final state in the vicinity of the q.e. peak corresponds roughly to one nucleon with momentum \( q_B(2A-1)/(2A) \) and \( A-1 \) nucleons with momenta of about \(-q_B/(2A)\). At fixed \( q \) and \( \omega \) values the anti–lab and Breit responses tend to the LAB response with increasing \( A \).

As a fourth reference frame we introduce what we call the active nucleon Breit frame (ANB). In this frame the target nucleus consisting of \( A \) nucleons has a momentum of \(-Aq_{ANB}/2\) so that the nucleons have momenta about \(-q_{ANB}/2\) in the initial state. The final state in the vicinity of the q.e. peak would correspond to an active nucleon with momentum of about \( q_{ANB}/2 \) while the other nucleons continue moving with the momenta about \(-q_{ANB}/2\). Thus within these approximations the maximum nucleon momentum is limited by \( q_{ANB}/2 \approx q/2 \) in the ANB frame, whereas in other reference frames nucleons with momenta up to \( q \) are present. The momentum of the active nucleon is largest in the LAB frame so that one may expect that this reference frame is the least suitable within a n.r. approach. In particular, the relativistic correction related to the kinetic energy is four times larger in the LAB frame than in the ANB frame. In the following we will calculate \( R_{BL} \), \( R_{AL} \), and \( R_{ANB} \) and then use \( R_{BL} \) to give the predicted \( R_L \) from each of these. These indirectly calculated \( R_L \) are then compared with \( R_L \) as computed directly in the LAB frame at \( q=500, 600 \) and \( 700 \) MeV/c. By comparing our results to experimental data it should become apparent if the ANB frame, for example, is superior to the LAB frame.

The present calculation proceeds in the manner described in [1]. There we found only a weak potential model dependence so that in the present calculation we choose the Argonne V18 (AV18) NN \[8\] plus Urbana IX (UrbIX) NNN \[9\] potentials. As in [1] the n.r. charge operator is supplemented with the first order relativistic corrections (Darwin–Foldy and spin–orbit terms). However while in [1] \( q \) values up to 500 MeV/c were considered, in the present work we calculate the responses at \( q = 500, 600 \) and \( 700 \) MeV/c. The inclusion of these higher \( q \) values requires a larger set of basis states for convergence. For example,
whereas the total angular momentum of the final states was limited to \( J = 21/2 \) in [1] here we include states up to \( J = 31/2 \). As in [1] we use the simple dipole fit for the proton electric form factor, but consider also the proton form factor fit from [10]. For the neutron electric form factor we take the fit from [11].

Fig. 1 shows the \( R_L \) results for the various frames together with experimental data at \( q_{LAB} = 500, 600, \) and 700 MeV/c. It is readily seen that one obtains rather frame dependent results. One finds the following differences in peak positions and peak heights between the two extreme cases (ANB and LAB frame results): 6 MeV and 13% (500 MeV/c), 11 MeV and 19% (600 MeV/c), 20 MeV and 24% (700 MeV/c). As anticipated of all four frames the LAB frame calculation leads to the worst result in comparison with experimental data. Let us recall that these LAB results just represent the conventional n.r. calculation. On the other hand the ANB frame leads to a good description of the data at \( q = 500 \) and 600 MeV/c. This may be related to the fact that nucleons with only moderate momenta are present in this reference frame. Description of the data with the ANB frame would be even better if a contemporary proton form factor in place of the dipole form factor is used. This will be demonstrated below. The above considerations demonstrate the frame dependence inherent in a n.r. calculation of the longitudinal response at high \( q \). Clearly a proper relativistic calculation would remove this frame dependence, but one can still ask whether there is a way to modify the n.r. calculation such that the degree of frame dependence would be reduced.

A clue is evident in the work of Arenhövel and collaborators (see e.g. [12]) in deuteron electrodisintegration, where the relative momentum of outgoing nucleons is determined in a relativistically correct way and the energy that is used as input to the n.r. calculation is obtained from that momentum by the usual n.r. relation. In general in a two–body problem one may either determine the kinetic energy in a relativistically correct way and solve the n.r. Schrödinger equation with it or determine the relative momentum \( p_{12} \) in a relativistically correct way and solve the Schrödinger equation for the "fake" kinetic energy \( E_{12} = p_{12}^2/2\mu_{12} \), where \( \mu_{12} \) is the reduced mass of the two particles. The reason why the latter procedure is chosen in the case of deuteron electrodisintegration is because the construction of NN potential models proceeds that way.

If one is mainly interested in the region of the quasielastic peak then one can adopt an analogous procedure based on a two–body model for the quasi-elastic process. That is, the
final state is assumed to consist of a knocked–out nucleon and an (A-1) particle residual system remaining in its lower energy state. We stress here that the two–body model is adopted only for determining the kinematical input of a calculation where the full three–body dynamics is properly taken into account.

The momenta of the knocked–out nucleon and that of the residual nucleus are denoted by $p_N^{fr}$ and $p_X^{fr}$, respectively. Then the relative and center of mass momenta will be given by $p^{fr} = \mu (p_N^{fr}/M - p_X^{fr}/M_X)$ and $P_f^{fr} = p_N^{fr} + p_X^{fr}$, where $M_X$ is the mass of the residual nucleus and $\mu$ is the $N - X$ reduced mass. (Note that $p^{fr}$ depends on the reference frame in the relativistic case). The value of $p^{fr}$ can be obtained from the following relativistically correct kinematical relation

$$\omega^{fr} = E_f^{fr} - E_i^{fr}$$

where

$$E_f^{fr} = \sqrt{M^2 + [p_f^{fr} + (\mu/M_X)P_f^{fr}]^2} + \sqrt{M_X^2 + [p_f^{fr} - (\mu/M)P_f^{fr}]^2}$$

Then, in accordance with the preceding discussion on the two–body system, the final state relative energy to use in the n.r. calculation is taken to be

$$e_f^{fr} = (p_f^{fr})^2/(2\mu).$$

Here one has to notice that in order to solve Eq. (6) for $p_f^{fr}$ one needs to know its direction. For the class of reference frames we consider the momentum $P_f^{fr}$ is directed along $q$. Again, since we are mainly interested in the region of the quasielastic peak we can safely assume that $p_f^{fr}$ is also directed along $q$. (Indeed, e.g. $p^{LAB} \simeq (\mu/M)q$.)

Proceeding in the way described above is formally equivalent to replace $(E_f^{fr} - E_i^{fr})$ in the delta function of Eq. (2) by a function $F(e_f^{fr}) = (E_f^{fr}(e_f^{fr}) - E_i^{fr})$. Therefore

$$\delta \left( E_f^{fr} - E_i^{fr} - \omega^{fr} \right) = \left( \frac{\partial F^{fr}}{\partial e_f^{fr}} \right)^{-1} \delta \left( e_f^{fr} - e_f^{rel}(q^{fr}, \omega^{fr}) \right),$$

with

$$\left( \frac{\partial F^{fr}}{\partial e_f^{fr}} \right)^{-1} = \frac{p_f^{fr}}{\mu} \left( \frac{\partial E_f}{\partial p^{fr}} \right)^{-1}.$$  

This leads to

$$R_f^{fr}(q^{fr}, \omega^{fr}) = \frac{p}{\mu} \left( \frac{\partial E_f}{\partial p} \right)^{-1} \int df \left| \langle \psi_i | \sum_j \rho_j(q^{fr}, \omega^{fr}) | \psi_f \rangle \right|^2 \delta \left( e_f^{fr} - e_f^{rel}(q^{fr}, \omega^{fr}) \right).$$

(11)
In order to calculate this quantity a new calculation is not required. We have obtained it via interpolation with respect to the momentum transfer of the n.r. response.

This procedure should reduce the frame dependence of $R_L(q,\omega)$ considerably. This is evident in the free case, i.e. when there is no interaction between the fast nucleon and the residual system. In this case the n.r. and relativistic final states would contain the relative motion plane wave with the same momentum $p$, resulting in no frame dependence of the matrix elements due to a difference in relative motion. This situation can be only slightly changed by the nuclear force.

In Fig. 2 we show the various $R_L$ results in comparison with experimental data and in fact we find an enormous reduction of the frame dependence. For the peak positions we even have an essentially frame independent result and also the differences of the peak heights are much reduced, namely to maximally 4, 6 and 9% at $q=500, 600$ and 700 MeV/c, respectively. It is evident that there is a good agreement between theory and experiment for the position of the quasielastic peak at all three momentum transfers. Concerning the peak heights one finds a relatively good agreement at $q=500$ and 600 MeV/c, while at 700 MeV/c the theoretical peak height overestimates the experimental one between about 20 and 30%.

It is interesting to check which of the frame dependent results of Fig. 1 reproduces best the frame independent peak positions of Fig. 2. It turns out that this is the ANB frame. Also the peak heights of the ANB curves in Fig. 1 and Fig. 2 are not much different: 4% ($q = 500$ MeV/c), 5% ($q = 600$ MeV/c), 6% ($q = 700$ MeV/c). This is not surprising since the ANB frame is the only frame where the nucleon has equal initial and final energies (in fact the initial nucleon momentum is about $-q_{ANB}/2$ and its final momentum is $q_{ANB}/2$). Thus the quasi-elastic peak occurs at $\omega_{ANB} = 0$, independent of whether relativistic or n.r. kinematics are employed. Note that in the A=2 case the ANB frame coincides with the anti–lab frame which is often chosen for the deuteron electrodisintegration.

A comparison of Figs. 1 and 2 shows that the n.r. ANB frame calculations not only agree with the relativistic two-body kinematics calculations at the peak but also in the tails. This is illustrated in another way in Fig. 3 where the n.r. ANB frame results are shown together with the relativistic kinematics Breit frame results. The choice of the Breit frame was motivated by the deuteron electrodisintegration work of \[\text{\ref{5}}\] where it was shown that boost corrections are minimal for this frame.

Apart from theoretical uncertainties of the quasielastic $R_L$ response due to frame depen-
of course, probably the greatest remaining theoretical uncertainty is due to the proton electric form factor. As an illustration we show in Fig. 4 the Breit frame results with relativistic two-body kinematics using the two above mentioned different proton electric form factors (dipole fit and fit from [10]). In comparison to the dipole fit the fit of [10] reduces the peak height by about 4, 6 and 7% at \( q = 500, 600 \) and 700 MeV/c leading to an improved agreement with experiment at the lower two \( q \) values and reducing the discrepancy at \( q = 700 \) MeV/c to about 15%. On the other hand, the rather large experimental uncertainties preclude making definitive conclusions.

We summarize our results as follows. We have shown that the usual n.r. calculation of the longitudinal inclusive \((e, e')\) response leads to rather frame dependent results at intermediate momentum transfers of \( q = 500 - 700 \) MeV/c. The frame dependence is drastically reduced if one assumes a two-body break up model with relativistic kinematics to determine the input to the n.r. dynamics calculation. One obtains a nearly frame independent peak position and much smaller deviations for the peak heights. Within n.r. kinematics, of the considered reference frames the ANB frame turns out to be the best, leading to results almost identical to those obtained with the suggested two-body break up model. In comparison with experimental data we find good agreements for the positions of the quasielastic peak and also good agreements of the peak heights at \( q = 500 \) and 600 MeV/c, while at \( q = 700 \) MeV there is a discrepancy between about 15 and 25%.
