On coprime percolation, the visibility graphon, and the local limit of the GCD profile*

Sébastien Martineau†

Abstract

Colour an element of $\mathbb{Z}^d$ white if its coordinates are coprime and black otherwise. What does this colouring look like when seen from a “uniformly chosen” random point of $\mathbb{Z}^d$? More generally, label every element of $\mathbb{Z}^d$ by its greatest common divisor: what do the labels look like around a “uniform” random point of $\mathbb{Z}^d$? We answer these questions and generalisations of them, which includes a result a “local/graphon” convergence. We also investigate the percolative properties of the colouring under study.

Keywords: visible/primitive/coprime points; local limits; graphon; arithmetic; percolation.

---

Colour an element of $\mathbb{Z}^d$ white if its coordinates are coprime and black otherwise. What does this colouring look like? For $d = 2$, this question was investigated in [30]. The starting point of the present paper is the following question: what does this colouring look like when seen from a point chosen “uniformly at random” in $\mathbb{Z}^d$? An answer has already been formulated in [27] but, from the perspective adopted in the current paper, our vocabulary, techniques and results are more satisfactory.

More generally, if one labels every element $x = (x_1, \ldots, x_d)$ of $\mathbb{Z}^d$ by the greatest common divisor of $x_1, \ldots, x_d$ (in short, the GCD of $x$), what do the labels look like around a point chosen “uniformly at random” in $\mathbb{Z}^d$? We answer this question and its generalisations, which includes a result a “local-graphon” convergence. By using the previous work of Vardi [30], we can also investigate the percolative properties of the colouring under study.

(1) Essentially, the same vertex-set will at the same time be endowed with some structure of sparse graph and some structure of dense graph.
Local limit of the GCD profile

1 Introduction

In this paper, the set \( \mathbb{N} = \{0, 1, 2, 3, 4, \ldots \} \) is taken to contain 0. The set of positive integers will be denoted by \( \mathbb{N}^* = \{1, 2, 3, 4, \ldots \} \).

Let \( d \) denote a positive integer. It is well-known that the probability that \( d \) random numbers chosen independently and uniformly in \([1, N]\) are globally coprime converges to \( 1/\zeta(d) \) when \( N \) goes to infinity [13, 7, 8, 28]. Recall that on \([1, \infty)\), the Euler-Riemann \( \zeta \) function is defined by

\[
\forall s \in [1, \infty), \quad \zeta(s) := \sum_{n \geq 1} n^{-s} = \prod_{p \in \mathcal{P}} \frac{1}{1 - p^{-s}} \in [1, \infty],
\]

where \( \mathcal{P} = \{2, 3, 5, 7, 11, \ldots \} \) denotes the set of prime numbers. More generally, one has the following result — see [18, Theorem 459] and [29].

Let \( d \geq 2 \). Let \( F \) be a bounded subset of \( \mathbb{R}^d \). For every \( r \in (0, \infty) \), set \( F_r := \{ x \in \mathbb{Z}^d : r^{-1} x \in F \} \). Assume that \( |F_r| \) converges to a nonzero limit when \( r \) tends to infinity. Then, one has

\[
\lim_{r \to \infty} \frac{|\{ x \in F_r : \text{GCD}(x_1, \ldots, x_d) = 1 \}|}{|F_r|} = \frac{1}{\zeta(d)}.
\]

A classical corollary of (A) is the following stronger statement. Recall that the \emph{zeta distribution} of parameter \( s > 1 \) is the probability distribution on \( \mathbb{N}^* \) giving weight \( \frac{n^{-s}}{\zeta(s)} \) to each \( n \in \mathbb{N}^* \).

Let \( d \geq 2 \). Let \( F \) be a bounded subset of \( \mathbb{R}^d \). For every \( r \in (0, \infty) \), set \( F_r := \{ x \in \mathbb{Z}^d : r^{-1} x \in F \} \). Assume that \( |F_r| \) converges to a nonzero limit when \( r \) tends to infinity. Let \( Y_r \) denote a random element of \( F_r \) chosen uniformly at random (for every \( x \in F_r \), we have \( \mathbb{P}(Y_r = x) = 1/|F_r| \)). Then, \( \text{GCD}(Y_r) \) converges in distribution to a zeta distribution of parameter \( d \), as \( r \) goes to infinity.

In this paper, we are interested in the following two moral questions.

\emph{Colour an element of \( \mathbb{Z}^d \) white if its coordinates are coprime and black otherwise. What does this colouring look like when seen from a point of \( \mathbb{Z}^d \) chosen "uniformly at random"?} \hspace{1cm} (Q1)

\emph{Label every element of \( \mathbb{Z}^d \) by its GCD. What do the labels look like around a point of \( \mathbb{Z}^d \) chosen "uniformly at random"?} \hspace{1cm} (Q2)

Even though (Q2) is stronger than (Q1), it is fruitful to study both questions independently (why this is the case will be addressed in Remark 2.13). Let us now make these two questions precise. Let \( X \) be a Polish space. Denote by \( \Omega_X \) the space \( X^\mathbb{Z}^d \) endowed
Local limit of the GCD profile

with the product topology, which is also Polish. Let \( c \) be an element of \( \Omega_X \). In (Q1), we will be interested in \( X = \{0, 1\} \) and \( c = \text{cop} := \text{I}_{\text{coprime}} \). In (Q2), we will be interested in \( X = \mathbb{N} \) and \( c = \text{gcd} : x \mapsto \text{GCD}(x_1, \ldots, x_d) \).

If \( F \) is a nonempty finite subset of \( \mathbb{Z}^d \), one defines the probability measure \( \mu_{F,c} \) as follows — it represents \( c \) seen from a uniform random point in \( F \). For any \( y \in \mathbb{Z}^d \) and \( \omega \in \Omega_X \), define \( \tau_y \omega \in \Omega_X \) by \( (\tau_y \omega)_x = \omega_{x-y} \). Let \( Y \) be a random element of \( F \) chosen uniformly at random (for every \( x \in F \), we have \( P(Y = x) = 1/|F| \)). We denote by \( \mu_{F,c} \) the (probability) distribution of the \( \Omega_X \)-valued random variable \( \tau_{-y} \omega \). In other words, \( \mu_{F,c} \) is the probability measure on \( \Omega_X \) defined by \( \mu_{F,c} = \frac{1}{|F|} \sum_{x \in F} \delta_{\tau_{-y} \omega} \). A third formulation goes as follows: for every Borel subset \( A \) of \( \Omega_X \), we have \( \mu_{F,c}(A) = |\{ x \in F : \tau_{-y} \omega \in A \}|/|F| \).

We want to describe the limit of \( \mu_{F,c} \) when \( c \) is a map of interest and \( (F_n) \) is a reasonable sequence of finite subsets of \( \mathbb{Z}^d \), such as \( ([1, N]^d) \), \(([-N, N]^d) \), or \( \{\{ x \in \mathbb{Z}^d : \|x\|_2 \leq n \}\} \).\(^{2}\) Limits are taken in the following sense: the space of probability measures on \( \Omega_X \) is endowed with the weak topology, namely the smallest topology such that for every bounded continuous map \( f : \Omega_X \to \mathbb{R} \), the map \( \mu \mapsto \int_{\Omega_X} f(\omega) \, d\mu(\omega) \) is continuous.

When \( X \) is discrete, \( \mu_n \) converges to \( \mu \) if and only if for every cylindrical event \( A \), one has \( \mu_n[A] \xrightarrow{n \to \infty} \mu[A] \). Recall that a cylindrical event is an event of the form \( \{ \omega \in \Omega : \omega_f \in A \} \), where \( F \) is a finite subset of \( \mathbb{Z}^d \), \( \omega_f \) stands for the restriction of \( \omega \) to \( F \), and \( A \) is some measurable subset of \( X^F \). When \( X \) is compact, the space of probability measures on \( X \) is compact for the weak topology.

**Theorem 1.** Let \( d \geq 2 \). Let \( F \) be a bounded convex subset of \( \mathbb{R}^d \) with nonempty interior. For every \( r \in (0, \infty) \), set \( F_r := \{ x \in \mathbb{Z}^d : r^{-1}x \in F \} \). Then, \( \mu_{F,\text{gcd}} \) converges to some explicit probability measure \( \mu_{\infty, \text{gcd}} \) when \( r \) goes to infinity.

The probability measure \( \mu_{\infty, \text{gcd}} \) is defined on page 5. It does not depend on \( F \) but only on \( d \). Theorem 1 answers (Q2), hence (Q1). It can be seen as a generalisation of [27, Theorem 1]. Our arguments and those of [27] follow different approaches.

The remaining of the paper is organised as follows. Section 2 investigates (Q1) and (Q2). This section contains the proof of Theorem 1, as well as complementary results. The use of relevant arithmetic/probabilistic notions makes the core of the problem very apparent: see \( \hat{\Omega} \) on pages 5 and 7. Section 3 provides several generalisations of these results.

## 2 Answers to (Q1) and (Q2)

In Section 2.1, we study (Q1). In Section 2.2, we investigate (Q2). Finally, in Section 2.3, we comment on the previous sections and explore some ergodic and percolative properties of \( \mu_{\infty, \text{cop}} \).

### 2.1 The random coprime colouring

In this section, we answer (Q1) by proving Theorem 2. Let us define \( \mu_{\infty, \text{cop}} \), which will turn out to be the limit of \( \mu_{F_n, \text{cop}} \) when \( (F_n) \) is a reasonable sequence of finite subsets of \( \mathbb{Z}^d \). For every prime \( p \), let \( W_p \) denote a uniformly chosen coset of \( p\mathbb{Z}^d \) in \( \mathbb{Z}^d \), i.e. one of the \( p^d \) sets of the form \( x + p\mathbb{Z}^d \). Do all these choices independently. We will be interested in the random set \( \bigcap_{p} (\mathbb{Z}^d \setminus W_p) \). One realisation of this random set has been simulated and depicted in white on page 1. By identifying this set with its indicator function, we can see it as an \( \Omega_{\{0,1\}} \)-valued random variable. It thus makes sense to define \( \mu_{\infty, \text{cop}} \) to be the (probability) distribution of this random variable. In other words, we consider the

---

\(^{2}\) This way of proceeding is closely related to local convergence and local weak convergence (also called Benjamini-Schramm convergence): see [3, 4, 12].
The map $pcop: \mathbb{Z}^d \to X$ is given by $pcop(x)_p = 1_{x \not\equiv p \mathbb{Z}^d}$. Let us now define $\mu_\infty_{pcop}$. For every $p \in P$, pick a uniform coset $W_p$ of $p\mathbb{Z}^d$ among the $p^d$ possible ones. Do this independently for every $p$. Define the random element $W' \in \Omega_{X} \cong \{0,1\}^{\mathbb{Z}^d \times P}$ via $W'(x,p) := 1_{x \not\equiv W_p}$. We denote by $\mu_\infty_{pcop}$ the distribution of the random variable $W'$. Note that the random element $W$ of $\Omega_{\{0,1\}}$ defined by $W(x) := \min_p W'(x,p)$ has distribution $\mu_\infty_{pcop}$.

Lemma 2.5. Let $d \geq 1$ and let $(F_n)$ be a Følner sequence of $\mathbb{Z}^d$. Then, $\mu_{F_n,pcop}$ converges to $\mu_\infty_{pcop}$.

Lemma 2.5 can be deduced from Lemma 2.4. We will instead deduce it from Lemma 2.7: see Remark 2.8. Our task is now to get Proposition 2.3 from Lemma 2.5, and Proposition 2.2 from Proposition 2.3. But before doing so, I would like to explain why Proposition 2.2 does not follow directly from Lemma 2.5.
Local limit of the GCD profile

To deduce directly Proposition 2.2 from Lemma 2.5, one would need the continuity of the map \( f : \Omega_{(0,1)}^\rho \rightarrow \Omega_{(0,1)}^\rho \) defined by \( f(\omega)_x = \min_{y} \omega(x)_y \). Indeed, \( \cop = f \circ \cop \). But this continuity, equivalent to that of the \( \min \) map defined from \( \{0,1\}^\rho \) to \( \{0,1\} \), does not hold. However, the \( \min \) map is upper semicontinuous, which permits the proof of Proposition 2.3. Notice that there can be no way to do “as if” \( f \) was continuous. Indeed, if one makes no other assumption than \( (F_n) \) being Følner (which suffices for Lemma 2.5), then it is possible that \( \mu_{F_n, \cop} \) does not converge to \( \mu_{\infty, \cop} \). The proof of this is deferred to Remark 2.12.

**Proof of Proposition 2.3.** Let us make the assumptions of Proposition 2.3. For \( Y_n \) uniformly chosen in \( F_n \), let us consider \( (\tau - Y_n \cop, \tau - Y_n \cop \! \cop) \in \Omega_{(0,1)}^\rho \times \Omega_{(0,1)}^\rho \). As \( \{0,1\} \times \{0,1\}^\rho \) is compact, up to passing to a subsequence, we may assume that the distribution of \( (\tau - Y_n \cop, \tau - Y_n \cop \!) \) converges to some probability measure \( \rho \) on \( \Omega_{(0,1)} \times \Omega_{(0,1)}^\rho \). Notice that for every \( x \in \mathbb{Z}^d \) and \( p \in \mathcal{P} \), one has

\[
p(\cop(x)_p = 0) \implies \cop(x) = 0.
\]

Besides, for every \( x \) and \( p \) (which range over countable sets), the set

\[
\{ (\omega, \omega') : \omega(x) \leq \omega'(x)_p \}
\]

is open and closed inside \( \Omega_{(0,1)} \times \Omega_{(0,1)}^\rho \). As a result, for \( \rho \)-almost every \( (\omega, \omega') \), for every \( x \in \mathbb{Z}^d \), one has \( \omega(x) \leq \min_{y} \omega'(x)_y \). But recall that if \( (\mathcal{W}, \mathcal{W}') \) denotes a random variable with distribution \( \rho \), then \( \mathcal{W} \) has distribution \( \mu \), \( \mathcal{W}' \) has distribution \( \mu_{\infty, \cop} \) — by Lemma 2.5 —, and thus \( \min_{p} \mathcal{W}'(x, p) \) has distribution \( \mu_{\infty, \cop} \). Proposition 2.3 follows.

**Proof of Proposition 2.2.** Let us make the assumptions of Proposition 2.2. Up to taking a subsequence of \( (F_n) \), we may assume that \( \mu_{F_n, \cop} \) converges to some \( \mu \). We want to prove that \( \mu = \mu_{\infty, \cop} \). By Proposition 2.3, there is a monotone coupling of \( (\mu, \mu_{\infty, \cop}) \), i.e. some coupling \( \rho \) of \( (\mu, \mu_{\infty, \cop}) \) such that for \( \rho \)-almost every \( (\omega, \omega_{\infty}) \), one has \( \forall x, \omega(x) \leq \omega_{\infty}(x) \).

But by the \( 1/\zeta(d) \)-assumption, one has

\[
\mu(\{ \omega : \omega(\vec{0}) = 1 \}) = 1/\zeta(d) = \prod_{p \in \mathcal{P}} (1 - p^{-d}) = \mu_{\infty, \cop}(\{ \omega : \omega(\vec{0}) = 1 \}).
\]

As a result, for \( \rho \)-almost every \( (\omega, \omega_{\infty}) \), one has \( \omega(\vec{0}) = \omega_{\infty}(\vec{0}) \). The same argument applies for any \( x \in \mathbb{Z}^d \) instead of \( \vec{0} \). Indeed, the probability measure \( \mu_{\infty, \cop} \) is translation invariant by construction, and \( \mu \) is translation invariant because \( (F_n) \) is a Følner sequence. Thus, \( \mu \) is equal to \( \mu_{\infty, \cop} \) and Proposition 2.2 is proved.

**2.2 The random GCD labelling**

In this section, we prove Theorem 1. Let us first define \( \mu_{\infty, \gcd} \). For every prime \( p \), perform the following random choices: set \( \mathcal{W}_0^d := \mathbb{Z}^d \), and conditionally on \( (\mathcal{W}_0^d, \ldots, \mathcal{W}_{n-1}^d) \), pick a uniform coset \( \mathcal{W}_n^d \) of \( p^n \mathbb{Z}^d \) among those lying inside \( \mathcal{W}_{n-1}^d \). Do this independently for every \( p \). We set the random \( p \)-adic valuation of a vertex \( x \) in \( \mathbb{Z}^d \) to be \( V_p(x) := \sup \{ n \in \mathbb{N} : x \in \mathcal{W}_n^d \} \in [0, \infty] \). We define the random GCD profile to be the random map \( x \mapsto \prod_{p \in \mathcal{P}} V_p(x) \). (This occurs almost surely nowhere, but one should set \( \prod_{p \in \mathcal{P}} V_p(x) = 0 \) whenever \( \forall p. V_p(x) = \infty \).) The distribution of the random GCD profile is denoted by \( \mu_{\infty, \gcd} \). It is a priori a probability distribution on \( \Omega_{[0, \infty]} \). By the Borel–Cantelli Lemma, for every \( d \geq 2 \), it is also a probability distribution on \( \Omega_{\mathbb{N}} \), and it is as such that it will be considered from now on. We will prove the following proposition.
Local limit of the GCD profile

**Proposition 2.6.** Let \( d \geq 1 \) and let \((F_n)\) be a Følner sequence of \( \mathbb{Z}^d \). For every \( n \), let \( Y_n \) denote a uniformly chosen element of \( F_n \). Assume that the distribution of \( \text{GCD}(Y_n) \) is tight (which implies \( d \geq 2 \)). Then, \( \mu_{F_n \cdot \text{gcd}} \) converges to \( \mu_{\infty \cdot \text{gcd}} \).

With the notation of Theorem 1, for any sequence \((r_n)\) converging to infinity, \((F_{r_n})\) is a Følner sequence. By (B), it is thus sufficient to prove Proposition 2.6 in order to get Theorem 1.

The forthcoming Lemma 2.7 uses the notion of profinite numbers. Define \( \hat{Z} \) as follows: \( \hat{Z} = \lim_{n \to \infty} \mathbb{Z}/n\mathbb{Z} = \{ x \in \prod_{n \geq 1} \mathbb{Z}/n\mathbb{Z} : \forall (m, n), m|n \Rightarrow \pi_{m,n}(x_n) = x_m \} \), where \( \pi_{m,n} \) denotes the morphism of reduction modulo \( m \) from \( \mathbb{Z}/n\mathbb{Z} \) to \( \mathbb{Z}/m\mathbb{Z} \). One can see \( \hat{Z} \) as a dense subgroup of \( \hat{Z} \) via the injection

\[ \Phi : N \mapsto (n \mapsto n + n\mathbb{Z}). \]

Elements of \( \hat{Z} \) are called **profinite numbers**. The topology on \( \hat{Z} \) is defined as follows. Endow \( \prod_{n \geq 1} \mathbb{Z}/n\mathbb{Z} \) with the product topology: this topology induces on the subsets \( \hat{Z} \subset \prod_{n \geq 1} \mathbb{Z}/n\mathbb{Z} \) and \( Z \subset \hat{Z} \) the so-called **profinite topology**. It makes \((\hat{Z}, +)\) to be a metrisable compact topological group.

Recall that when \( p \) is a prime, the set of \( p \)-adic integers is defined by \( \mathbb{Z}_p = \lim_{n \to \infty} \mathbb{Z}/p^n\mathbb{Z} \). The Chinese Remainder Theorem implies that \( \hat{Z} \) and \( \prod_{p} \mathbb{Z}_p \) are isomorphic as topological groups (and even as rings), an isomorphism being given by

\[ \hat{Z} \ni n \mapsto (n \mapsto n_p)_{p \in P} \in \prod_{p} \mathbb{Z}_p. \]

Let \( \text{prof} : \mathbb{Z}^d \to \hat{Z}^d \) be defined by \( \text{prof}(x) = (\Phi(x_1), \ldots, \Phi(x_d)) \in \hat{Z}^d \). In order to define a suitable probability measure \( \mu_{\infty \cdot \text{prof}} \), notice that there is a unique Haar measure on the compact group \( \hat{Z} \cong \prod_{p} \mathbb{Z}_p \) which corresponds to the product of Haar measures on \( \mathbb{Z}_p \).

A Haar-distributed element of \( \mathbb{Z}_p \) is a random \( p \)-adic integer \((X_p)_n \geq 0 \) such that for every \( n \geq 1 \), conditionally on \( X_{n-1} \), the element \( X_n \) is uniform among the \( p \) elements of \( \mathbb{Z}/p^n\mathbb{Z} \) that reduce to \( X_{n-1} \) modulo \( p^{n-1} \).

Pick a Haar-distributed element \( Y \) of \( \hat{Z}^d \), i.e. \( d \) independent Haar-distributed elements of \( \hat{Z} \). We denote by \( \mu_{\infty \cdot \text{prof}} \) the distribution of the following random element of \( \Omega_{\hat{Z}^d} \):

\[ x \mapsto Y + \text{prof}(x). \]

**Lemma 2.7.** Let \( d \geq 1 \) and let \((F_n)\) be a Følner sequence of \( \mathbb{Z}^d \). Then, \( \mu_{F_n \cdot \text{prof}} \) converges to \( \mu_{\infty \cdot \text{prof}} \).

**Proof.** As \( \hat{Z} \) is compact, up to passing to a subsequence, we may assume that \( \mu_{F_n \cdot \text{prof}} \) converges to some probability measure \( \mu \). Let \( Y_n \) denote a uniformly chosen element of \( F_n \), and set \( X_n := \text{prof}(Y_n) \). By Lemma 2.4, for every \( N \), the \((\text{mod } N)\)-component of \( X_n \) converges in distribution to the uniform probability measure on \( (\mathbb{Z}/N\mathbb{Z})^d \). As a result, \( X_n \) converges in distribution to the Haar probability measure on \( \hat{Z}^d \). Therefore, if \( s \) is \( \mu \)-distributed, then \( s(0) \) is Haar-distributed on \( \hat{Z}^d \). It thus suffices to prove that \( \mu \) gives probability 1 to the following set: \( \{ n \in \Omega_{\hat{Z}^d} : \forall x \in \mathbb{Z}^d, \sigma(x) = \sigma(0) + \text{prof}(x) \} \). But this is clear as it is closed and has probability 1 for every \( \mu_{F_n \cdot \text{prof}} \). \( \square \)

**Remark 2.8.** As the map \( f : \hat{Z} \to \{0,1\}^P \) defined by \( f(n)_p := 1_{n_p \neq 0} \) is continuous, Lemma 2.5 follows directly from Lemma 2.7.

As we are interested in the GCD of random elements of \( \mathbb{Z} \), it is useful to recall what the GCD of a profinite number is. While the GCD of an element of \( \mathbb{Z} \) is a natural number (possibly 0), the GCD of a profinite number will be a supernatural number. The set of **supernatural numbers** is \( \mathbb{T} := [0, \infty]^P \). The set \( [0, \infty] \) is endowed with the usual
Local limit of the GCD profile

A set $U$ is open if and only if for $n$ large enough, $n \in U \iff \infty \in U$. The set $\mathbb{N} = [0, \infty]^\mathbb{P}$ is endowed with the product of these topologies. One can see any nonnegative integer $n \in \mathbb{N}$ as a supernatural number via the following injection:

$$\Psi : n \mapsto (p \mapsto p\text{-adic valuation of } n).$$

The $p$-adic valuation of a profinite number $n$ is $v_p(n) := \sup\{k \in \mathbb{N} : n \equiv 0 \text{ mod } p^k\} \in [0, \infty]$. The GCD of $(n_1, \ldots, n_d)$ is the supernatural number $p \mapsto \min(v_p(n_1), \ldots, v_p(n_d))$.

Let $\text{super} : \mathbb{Z}^d \to \mathbb{N}^*$ be defined by $x \mapsto \Psi(\text{GCD}(x))$. Given a Haar-distributed element $Y$ of $\mathbb{Z}^d$, denote by $\mu_{\infty, \text{super}}$, the distribution of the following random element of $\Omega_{\mathbb{N}}$:

$$x \mapsto \text{GCD}(Y + \text{prof}(x)).$$

**Lemma 2.9.** Let $d \geq 1$ and let $(F_n)$ be a Følner sequence of $\mathbb{Z}^d$. Then, $\mu_{F_n, \text{super}}$ converges to $\mu_{\infty, \text{super}}$.

**Proof.** As the GCD-map is continuous from $\mathbb{Z}$ to $\mathbb{N}$, this follows directly from Lemma 2.7.

Notice that the conclusion of Lemma 2.9 is quite close to the one we have been looking for. Assume further that $d \geq 2$. Then, as $\sum_{p \in \mathbb{P}} p^{-d} < \infty$, the Borel–Cantelli Lemma yields that if $X$ is $\mu_{\infty, \text{super}}$-distributed, then almost surely, every $x \in \mathbb{Z}^d$ satisfies $X(x) \in \Psi(\mathbb{N}^*)$. Recall that $\Psi(\mathbb{N}^*)$ consists in finitely supported elements of $\mathbb{N} = [0, \infty]^\mathbb{P}$ all the values of which are finite. If $n \in \Psi(\mathbb{N}^*)$, then $n = \Psi(\prod_{p \in \mathbb{P}} p^{v_p})$ and we write $\chi(n) = \prod_{p \in \mathbb{P}} p^{v_p} \in \mathbb{N}^*$. The random variable $(\chi(X(x)))_{x \in \mathbb{Z}^d}$ thus has distribution $\mu_{\infty, \text{gcd}}$.

If $\chi$ was continuous and defined everywhere on $\mathbb{N}$, one could directly deduce from Lemma 2.9 that $\mu_{F_n, \text{gcd}}$ converges to $\mu_{\infty, \text{gcd}}$; but the actual properties of $\chi$ do not allow to perform this derivation, not even in an indirect manner. Indeed, $(F_n)$ being Følner and $d$ being at least 2 do not suffice to guarantee this convergence: these conditions do not even suffice to guarantee convergence of $\mu_{F_n, \text{cop}}$ to $\mu_{\infty, \text{cop}}$. See Remark 2.12. We need the tightness assumption and this goes through the following easy lemma.

Denote by $f\sharp\rho$ the pushforward by $f$ of a given measure $\rho$.

**Lemma 2.10.** Let $X$ and $Y$ be Polish spaces. Let $f : X \rightarrow Y$ be a continuous injective map that maps every Borel subset of $X$ to a Borel subset of $Y$. Let $(\mu_n)_{n \leq \infty}$ denote a sequence of probability measures on $X$. For every integer $n$, set $\nu_n := f\sharp\mu_n$. Likewise, set $\nu_{\infty} := f\sharp\mu_{\infty}$. Assume that $\nu_n$ converges to $\nu_{\infty}$ and that $\mu_n$ converges to some probability measure $\mu$. Then $\nu$ and $\mu_{\infty}$ are equal.

**Proof.** By continuity of $f$, the sequence $\nu_n = f\sharp\mu_n$ converges to $f\sharp\mu$. As this sequence also converges to $f\sharp\mu_{\infty}$, we have $f\sharp\mu = f\sharp\mu_{\infty}$. By injectivity of $f$, we have $\mu(A) = f\sharp\mu(f(A)) = f\sharp\mu_{\infty}(f(A)) = \mu_{\infty}(A)$, where the assumptions indeed guarantee that $f(A)$ is Borel.

In Lemma 2.10, if one does not assume $\mu_n$ to converge to some probability measure, one cannot deduce that $\mu_n$ converges to $\mu_{\infty}$: Take $X = [0, 1]$, $Y = \mathbb{R}/\mathbb{Z}$, and set $f : X \rightarrow Y$ to be reduction modulo 1; for $n \in \mathbb{N}^*$, set $\mu_n = \delta_{1/n}$, and let $\mu_{\infty} = \delta_1$.

**Proof of Proposition 2.6.** Let $(F_n)$ and $(Y_n)$ be as in Proposition 2.6. By hypothesis, GCD($Y_n$) is tight. Together with the assumption that $(F_n)$ is a Følner sequence, this implies that $d \geq 2$ and that for every $x \in \mathbb{Z}^d$, GCD($Y_n + x$) is tight. Therefore, the (N-indexed) sequence of random variables (GCD($Y_n + x$))$_{x \in \mathbb{Z}^d}$ is tight. Up to passing to a subsequence, we may thus assume that its distribution converges to some probability measure $\mu$ on $\Omega_{\mathbb{N}}$. 

ECP 27 (2022), paper 8. Page 7/14
Let $X := \Omega_N$ and $Y := \Omega_M$. For $n \in \mathbb{N}$, let $\mu_n := \mu_{\text{gcd}},$ which is a well-defined probability measure on $\Omega_N$ because of the Borel–Cantelli Lemma $(\sum_{p \in \mathcal{P}} p^{-d} < \infty)$. Let $f : X \to Y$ be defined by $f(\sigma) = (\Psi(\sigma_x))_{x \in \mathbb{Z}^d}$. This map is injective, continuous, and maps Borel subsets of $X$ to Borel subsets of $Y$. By Lemma 2.9, $f_\sharp \mu_n$ converges to $f_\sharp \mu_\infty$. As $\mu_n$ converges to $\mu$, Lemma 2.10 yields that $\mu_n$ converges to $\mu_\infty$, which is the desired result. 

### 2.3 Remarks

In our results, we do not need any assumption of monotonicity regarding $(F_n)$. Likewise, it may well be the case that $igcup_n F_n \neq \mathbb{Z}^d$. The fact that $|F_n|$ tends to infinity is a consequence of being Følner.

Even though the conclusion of Proposition 2.6 implies that of Proposition 2.2, Proposition 2.2 cannot be derived from Proposition 2.6. Indeed, one has the following fact.

**Fact 2.11.** For every $d \geq 1$, there is a Følner sequence $(F_n)$ of $\mathbb{Z}^d$ such that the following conditions hold: if $Y_n$ denotes a uniform element of $F_n$, the distribution of $\text{GCD}(Y_n)$ is not tight; and the proportion of coprime vectors in $F_n$ converges to $1/\zeta(d)$.

**Proof.** This fact can be derived from the Chinese Remainder Theorem or from the proof of Theorem 1. We will proceed in the second manner.

If $d = 1$, any Følner sequence automatically satisfies the desired properties. Thus, let us assume that $d \geq 2$, so that $\sum_{p \in \mathcal{P}} p^{-d} < \infty$. Let $\varepsilon > 0$ and $K \in \mathbb{N}$. One has

$$\mu_{\infty, \text{super}}(\{\sigma : \forall p, \sigma(0)_p = 0\}) = \prod_{p \in \mathcal{P}} (1 - p^{-d}) = 1/\zeta(d).$$

By translation invariance, one has $\int \frac{|\{x \in [1,N]^d : \forall p, \sigma_x(0)_p = 0\}|}{N^d} d\mu_{\infty, \text{super}}(\sigma) = 1/\zeta(d).$ Either by ergodicity or because of Proposition 2.3, one can pick an arbitrarily large $N$ such that this proportion has a positive probability to be $\varepsilon$-close to $1/\zeta(d)$. Fixing such an $N$, one can thus find a deterministic subset $U$ of $[1,N]^d$ such that $\left| \frac{|U|}{N^d} - \frac{1}{\zeta(d)} \right| \leq \varepsilon$ and $\mu_{\infty, \text{super}}(\{\sigma : \forall x \in U, \forall p \in \mathcal{P}, \sigma_x(p) = 0\}) > 0$.

Let $s$ be a random variable with distribution $\mu_{\infty, \text{super}}$. As $d \geq 2$, one can pick some $P \geq \text{max}(K, N)$ such that with positive probability, the following two conditions hold:

1. $\forall x \in U, \forall p \in \mathcal{P}, s(x)_p = 0$,
2. $\forall x \in [1,N]^d, \forall p \in \mathcal{P}, (p \geq P \implies s(x)_p = 0)$.

Recall that $\mu_{\infty, \text{super}}$ is defined in terms of the cosets $\mathcal{W}_n^\mathcal{P}$. Let $p$ denote an injective map from $[1,N]^d$ to $\{p \in \mathcal{P} : p \geq P\}$. We will use this injection to modify $s$ into a new random variable $s'$. For every $x \in [1,N]^d \setminus U$, resample $\hat{\mathcal{W}}_n^\mathcal{P}(x)$ and condition $\mathcal{W}_n^\mathcal{P}(x)$ to contain $x$: do this independently of $s$ and independently for every $x \in [1,N]^d \setminus U$. The distribution of the ensuing random variable $s'$ has a density relative to $\mu_{\infty, \text{super}}$. As $s'$ almost surely satisfies the following conditions:

$$\forall x \in U, \prod_{p} p^{s'_x(p)} = 1 \quad \text{and} \quad \forall x \in [1,N]^d \setminus U, \prod_{p} p^{s'_x(p)} \geq K,$$

the corresponding conditions are satisfied by $s$ with positive probability. Denote the corresponding event by $E$. By Theorem 1, the proportion of $x \in [1,n]^d$ such that $\tau_{\text{super}}$ satisfies $E$ converges to a positive number, hence is positive for $n$ large enough.

---

(3) Later in this section, we will see that $\mu_{\infty, \text{super}}$ is ergodic, i.e. that any translation invariant event has probability 0 or 1. One can then use an ergodic theorem such as Theorem 1.1 in [21].
Local limit of the GCD profile

In particular, there is some \( y \in \mathbb{Z}^d \) such that \( \tau_{-y} \) super satisfies \( E \). We say that any such \( y \) is a \((K,N,\varepsilon)\)-counterexample. For every \( n \), pick some \( y^n \) that is an \((n,m_n,1/n)\)-counterexample for some \( m_n \geq n \): the sequence \( F_n = \prod_{i=1}^d [y_i^n + 1, y_i^n + m_n] \) satisfies the desired properties.

**Remark 2.12.** Likewise, the \( 1/\zeta(d) \)-condition cannot be removed from Proposition 2.2: it is well-known that the Chinese Remainder Theorem implies that there are arbitrarily large boxes \( F_n = x_n + [0,N]^d \) in \( \mathbb{Z}^d \) devoid of coprime points. This also follows from Theorem 2, as \( \mu_{\infty, \text{cop}} \) has a positive probability to colour black the whole box \( [0,N]^d \) — use one prime per point of the box. Such a sequence \( (F_n) \) is Følner and yet \( \mu_{F_n, \text{cop}} \) converges to 0. The Følner condition cannot be removed from Proposition 2.2 either.

All the results in this paper concerning visibility extend to lattices in \( \mathbb{R}^d \), as any such lattice may be mapped to \( \mathbb{Z}^d \) by a linear automorphism of \( \mathbb{R}^d \), which preserves visibility.

Notice that \( \mu_{\infty, \text{cop}} \) and \( \mu_{\infty, \gcd} \) are not only translation invariant but also \( \text{GL}_d(\mathbb{Z}) \)-invariant. Even though \( \text{cop} \) and \( \gcd \) are indeed \( \text{GL}_d(\mathbb{Z}) \)-invariant, the \( \text{GL}_d(\mathbb{Z}) \)-invariance of these measures does not follow from Theorems 1 and 2. One way to understand why goes as follows. Every orbit of the multiplicative group \( G \) generated by \( \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \) contains a unique point inside \( A \) := \{ \( x \in \mathbb{Z}^2 : 0 \leq x_1 < |x_2| \} \cup (\mathbb{Z} \times \{0\}) \). Consider the colouring of \( \mathbb{Z}^2 \) which is defined as the chessboard colouring on \( A \) (say white if the sum of coordinates is odd and black otherwise), and take its unique \( G \)-invariant extension. For \( F_n = A \cap [-n,n]^2 \), this colouring seen from a uniform point in \( F_n \) converges to the unbiased choice of one of the two chessboard colourings of the plane: this probability measure is not \( G \)-invariant.

**Remark 2.13.** Here are gathered several comments regarding how our theorems fit together, and how they do with the previous work of Pleasants and Huck [27]. The full statement of Theorem 1 of [27], which involves \( k \)-free points, is a particular case of our Theorem 1. It could also be obtained following the same lines as for the proof of our Theorem 2. Our approach to the question is really different from that of [27], in terms of technique and vocabulary. It further yields additional results — namely Propositions 2.2, 2.3, and 2.6. As for the opportunity to lead the investigation of Section 2.1 while Section 2.2 exists and does not rely on Section 2.1, the situation is as follows. Even though Theorem 2 is a particular case of Theorem 1, Proposition 2.2 does not follow from Proposition 2.6 or Theorem 1: see Fact 2.11. A last important point is that, contrary to [27, 30], we are considering \( \mu_{\infty, \text{cop}} \) (resp. \( \mu_{\infty, \gcd} \)) as a fully-fledged probability measure on \( \Omega_{(0,1)} \) (resp. \( \Omega_N \)): it is thus possible for us to make sense of \( \mu_{\infty, \text{cop}}(A) \) for any Borel subset of \( \Omega_{(0,1)} \), where previous works would not go beyond cylindrical events. This opens up further fields of investigation, e.g. connected to ergodic theory or percolation theory. The remaining of this section is devoted to such questions.

Let us now mention a few questions that can be asked only with the formalism of local limits, i.e. with \( \mu_{\infty, \text{cop}} \) or \( \mu_{\infty, \gcd} \) instead of simply one convergence result per cylindrical event. For every \( c \in \{ \text{cop}, \gcd, \text{prof}, \text{super} \} \), we can ask whether the measure \( \mu_{\infty,c} \) is ergodic — i.e. if every translation invariant measurable subset has \( \mu_{\infty,c} \)-probability 0 or 1. These measures are indeed ergodic. For simplicity, we expose the argument for \( \mu_{\infty, \text{cop}} \). The Chinese Remainder Theorem guarantees the following fact: if \( p_1, \ldots, p_n \) denote the first \( n \) primes, and if for every \( i \leq n, C_i \) denotes a coset of \( p_i \mathbb{Z}^d \) in \( \mathbb{Z}^d \), then there is a translation mapping every \( C_i \) to \( p_i \mathbb{Z}^d \). As a result, whenever we consider only finitely many primes, choosing one coset per prime yields a deterministic outcome up to translation. One concludes by noting that if a translation invariant probability measure on \( \{0,1\}^{\mathbb{Z}^d \times \mathbb{P}} \) yields ergodic measures in projection to any \( \{0,1\}^{\mathbb{Z}^d \times \{p_1, \ldots, p_n\}} \), then the measure under study is itself ergodic. This is easily proved by martingale theory, and
similar reasonings are classical in the study of profinite actions.

Considering \( Z^d \) to be endowed with its usual (hypercubic) graph structure, one may also ask questions of percolation theory [17, 22]: how many infinite white (resp. black) connected components does the colouring \( \mu_{\infty, cop} \) yield? By ergodicity, these numbers have to be deterministic outside some event of probability zero. One can derive from Theorem 1 and Theorem 3.3 in [30] that, for \( d = 2 \) hence for any \( d \geq 2 \), there is at least one infinite white connected component almost surely. One can derive from Theorem 1 and Theorem 3.4 in [30] that, for \( d = 2 \), almost surely, every finite set is surrounded by a white cycle. As a result, in dimension 2, there is almost surely at most one infinite white connected component and no infinite black component. The corresponding statement in dimension \( d \geq 2 \) is obtained via the following observation. For \( i \in [2, d] \), let \( \pi_i : Z^d \to Z^2 \) be defined by \( \pi_i(x) = (x_1, x_i) \). Let \( W \) be a random colouring of \( Z^d \) with distribution \( \mu_{\infty, cop} \) — or \( \mu_{\infty, cop}^{(d)} \), if we want to be explicit about the dimension involved. Denote by \( \mathcal{W}_i \) the “\( \pi_i \)-shadow of \( \mathcal{W} \)”, i.e. the colouring of \( Z^2 \) defined as follows: for any \( y \in Z^2 \), one colours \( y \) black if at least one element of \( \pi_i^{-1} \{y\} \) is black for \( \mathcal{W} \), and one colours it white otherwise. Notice that \( \mathcal{W}_i \) is a random colouring of \( Z^2 \) with distribution \( \mu_{\infty, cop}^{(d)} \). As the 2-dimensional case has been treated, we know that for every \( i \) and every finite subset \( F \) of \( Z^d \), there is a finite subset of \( Z^2 \) that contains \( \pi(F) \) and whose boundary is white for \( \mathcal{W}_i \). Choosing such a finite subset with white boundary and naming it \( F_i \), we get that \( F \) is a subset of the finite set \( \bigcap \pi_i^{-1}(F_i) \), whose boundary is white for \( \mathcal{W} \). The desired result follows.

3 Further generalisations of Theorem 1

3.1 Sampling along affine subspaces

Proposition 3.1 is the analog of Proposition 2.6 for an observer picked uniformly in an affine subspace of \( Z^d \) rather than in the whole space \( Z^d \).

Endow \([0, \infty]\) with its usual topology. Define \( \gcd_{\infty} \in \Omega_{[0, \infty]} \) by setting \( \gcd_{\infty}(x) := \gcd(G(x)) \). Let \((\mu_n)_{n \leq \infty} \) be a sequence of probability measures on \( \Omega_{[0, \infty]} \). Let \( V \subset Z^d \) and denote by \( \pi \) the projection from \([0, \infty]^Z \) to \([0, \infty]^V \). We say that \( \mu_n \) converges to \( \mu_{\infty} \) on \( V \) if \( \pi_\# \mu_n \) — the pushforward of \( \mu_n \) by \( \pi \) — converges to \( \pi_\# \mu_{\infty} \) when \( n \) goes to infinity.

Given \( \Gamma \) an infinite subgroup of \( Z^d \), one defines the probability measure \( \mu_{\infty, \gcd_{\infty}} \) by taking the definition of \( \mu_{\infty, \gcd} \) but asking furthermore at every step that \( \mathcal{W}_i \) intersects \( \Gamma \). This corresponds to taking a Haar-distributed element in the closure of \( \Gamma \) in \( Z^d \).

Finally, we say that a sequence \((F_n)\) of nonempty finite subsets of \( \Gamma \) is a Følner sequence for \( \mu \) if for every \( y \in \Gamma \), one has \( |F_n \Delta (F_n + y)| = o(|F_n|) \).

Proposition 3.1. Let \( \Gamma \) denote a subgroup of \( Z^d \) of rank \( k \geq 1 \). Assume that it is maximal among subgroups of rank \( k \), namely that every subgroup of \( Z^d \) that contains \( \Gamma \) is either equal to \( \Gamma \) or has rank at least \( k + 1 \). Let \((F_n)\) be a Følner sequence for \( \mu \). Let \( Y_n \) denote a uniform element of \( F_n \). Then, \( \mu_{F_n, \gcd_{\infty}} \) converges to \( \mu^\Gamma_{\infty, \gcd_{\infty}} \) on \( Z^d \setminus \Gamma \). If furthermore \( k = 1 \) or \( \gcd(Y_n) \) is tight, then \( \mu_{F_n, \gcd_{\infty}} \) converges to \( \mu^\Gamma_{\infty, \gcd_{\infty}} \).

Remark 3.2. The view from a “uniform point” in an affine subspace \( \Gamma + y \) is just the view seen from a “uniform point” in \( \Gamma \) shifted by \( -y \). One may also notice that if one starts with a group \( \Gamma \) that is not maximal given its rank, then it lies in a unique such group, which is the intersection of its (rational or real) linear span with \( Z^d \): denote it by \( \Gamma \). It follows from the proof of Proposition 3.1 that the following holds. Let \((F_n)\) be a Følner sequence for \( \mu \). Let \( Y_n \) denote a uniform element of \( F_n \). Assume that for every \( y \in \Gamma \), \( \gcd(Y_n + y) \) is tight. Then \( \mu_{F_n, \gcd_{\infty}} \) converges to \( \mu^\Gamma_{\infty, \gcd_{\infty}} \). Actually, it suffices to make the assumption for a system of representatives of \( y \in \Gamma \) for the equivalence relation “being equal modulo \( \Gamma \)”, i.e. for finitely many \( y \)'s.
Local limit of the GCD profile

**Corollary 3.3.** Let $\Gamma$ denote a subgroup of $\mathbb{Z}^d$ of rank $k \geq 1$ which is maximal among subgroups of rank $k$. Let $F$ denote a bounded subset of the linear span of $\Gamma$. For every $r \in (0, \infty)$, set $F_r := \{ x \in \Gamma : r^{-1} x \in F \}$. Assume that $\mu_F^\Gamma$, $\mu_F^\Gamma$ converges to $\mu_F^\Gamma$ tends to infinity and that $(F_n)$ is a Følner sequence for $\Gamma$. Then, $\mu_{F_n, \gcd_j}$ converges to $\mu_{\infty, \gcd_j}$ as $n$ goes to infinity.

**Proof of Proposition 3.1.** Exactly as in Section 2.2, one defines $\mu^\Gamma_{\infty, \text{super}}$ and proves that $\mu^\Gamma_{F_n, \text{super}}$ converges to $\mu^\Gamma_{\infty, \text{super}}$. Let $d(\cdot, \Gamma)$ be as in the conclusion of Lemma 3.4. Let $X := \prod_{x \in \mathbb{Z}^d \setminus \Gamma} \psi([1, d(x, \Gamma)])$. As the closed subset $X \subset Y := \mathbb{N}^{\mathbb{Z}^d \setminus \Gamma}$ has probability 1 for every measure $\mu^\Gamma_{F_n, \text{super}}$, it is the case that $\mu^\Gamma_{\infty, \text{super}}(X) = 1$. Therefore, one can also consider these measures as probability measures on $X$: with this point of view, denote them by $\mu_n$, with $n \leq \infty$. One has that $\mu_n$ converges to $\mu_{\infty}$ — that is for the weak topology on probability measures on $X$. One way to see this is to notice that as $X$ is compact, every subsequence of $(\mu_n)$ admits a converging subsequence and then to apply Lemma 2.10 to the restriction of the identity map from $X$ to $Y$. As the map $f : X \to [0, \infty]^{|\mathbb{Z}^d \setminus \Gamma|}$ defined by $f(x) := \prod_{p \in P} F^{\Gamma(x)}_p$ is continuous, one has that $\mu^\Gamma_{F_n, \gcd_j}$ converges to $\mu^\Gamma_{\infty, \gcd_j}$ on $Z^d \setminus \Gamma$.

Let us now assume that $k = 1$. As $\sum_{p \in P} \frac{1}{p} = \infty$, the second Borel–Cantelli Lemma yields that $\mu^\Gamma_{\infty, \text{super}}$-almost every configuration gives the label $\infty$ to every element of $\Gamma$. If $Y_n$ denotes a uniformly chosen element of $F_n$, and $y$ some element of $\Gamma$, one has that GCD($Y_n + y$) converges in probability to $\infty$. Together with convergence on $Z^d \setminus \Gamma$, this implies that $\mu^\Gamma_{F_n, \gcd_j}$ converges to $\mu^\Gamma_{\infty, \gcd_j}$.

Instead of $k = 1$, now assume that GCD($Y_n$) is tight. As $(F_n)$ is a Følner sequence for $\Gamma$, one has that for every $y \in \Gamma$, the random variable GCD($Y_n + y$) is tight. Together with convergence on $Z^d \setminus \Gamma$, this implies that the sequence $(\mu^\Gamma_{F_n, \gcd_j})$ is tight. One then concludes as in the proof of Proposition 2.6.

**Lemma 3.4.** Let $(d, k)$ satisfy $1 \leq k \leq d$. Let $\Gamma$ be a subgroup of $\mathbb{Z}^d$ of rank $k$ and maximal with this property. Then, there is a norm $\| \cdot \|$ on $\mathbb{R}^d$ such that for every $N \geq 1$ and every $x \in N\mathbb{Z}^d$, one has $d(x, \Gamma) > 0 \implies d(x, \Gamma) \geq N$, where $d(x, \Gamma) := \min \{ \|x - y\| : y \in \Gamma \}$.

**Proof.** By a change of coordinates and by maximality of $\Gamma$, one may assume that $\Gamma = \mathbb{Z}^k \times \{0_{d-k}\}$, in which case the lemma is clear (every element of $\text{GL}_d(\mathbb{Z})$ preserves $N\mathbb{Z}^d$).

**Proof of Corollary 3.3.** Let $Y_n$ be a uniform element of $F_n$. By Proposition 3.1, it suffices to assume that $k = 2$ and to show that GCD($Y_n$) is tight. Since GCD’s are unchanged by $\text{GL}_d(\mathbb{Z})$, we may assume that $\Gamma$ is equal to $\mathbb{Z}^2 \times \{0_{d-k}\}$, and tightness results from (B).

**3.2 Local-graphon limits**

If $X_1, \ldots, X_N$ are sampled “uniformly” and independently in $\mathbb{Z}^d$, we can describe the set of $(i, j)$’s such that $X_i$ is visible from $X_j$, i.e. such that GCD($X_i - X_j$) = 1? The techniques of Section 2.1 actually yield the following proposition.

**Proposition 3.5.** Let $d \geq 1$ and let $(F_n)$ be a Følner sequence of $\mathbb{Z}^d$. Assume that the probability that a uniform element of $F_n$ is coprime converges to $1/\zeta(d)$. Let $(X_n)$ denote a sequence of independent Haar-distributed elements of $\prod_{p \in P} (\mathbb{Z}/p\mathbb{Z})^d$. Let $M \geq 1$ and $R \geq 1$. For every $n$, let $(Y_n^m)_{1 \leq m \leq M}$ denote $M$ independent uniform elements in $F_n$. Set:

$$\psi_n : \begin{cases} ([1, M] \times [-R, R]^d)^2 & \mapsto \{0, 1\} \\ (m_0, y_0), (m_1, y_1) & \mapsto 1_{Y_n^{m_0} + y_0 \text{ is visible from } Y_n^{m_1} + y_1} \end{cases}$$
Local limit of the GCD profile

\[\psi_\infty : \left( [1, M] \times [-R, R]^d \right)^2 \rightarrow \{0, 1\} \]
\[\{(m_0, y_0), (m_1, y_1)\} \mapsto \mathbb{1}_{Y_0 + y_0 + Y_1 + y_1 \in V}\]

Then, the distribution of \(\psi_n\) converges to that of \(\psi_\infty\).

**Remark 3.6.** When one takes \(M = 1\) and all \(R \geq 1\), Proposition 3.5 recovers exactly Proposition 2.2. Indeed, the convergence of probability measures on \(\Omega_{\{0,1\}}\) is defined as the convergence of probabilities of cylindrical events, and every cylindrical event \(A\) can be defined by looking only at the \(\{0,1\}\)-colouring inside some \([-R, R]^d\), for some \(R\) depending on \(A\). A convergence as that of Proposition 2.2 is called a local convergence. On the other side, taking \(R = 0\) and all \(M \geq 1\) would provide a graphon convergence \([6, 11]\). More precisely, let \(\mathcal{G}_n\) denote the random graph with vertex-set \(F_n\) and an edge between two distinct vertices if and only if the one is visible from the other. Consider the following standard probability space \(\mathcal{X} := \prod_{p \in \mathcal{P}} (\mathbb{Z}/p\mathbb{Z})^d\), endowed with the product of uniform measures. Consider the measurable function \(\delta : \mathcal{X}^2 \rightarrow [0, 1]\) defined by \(\delta(x_1, x_2) := \mathbb{1}_{y_0, x_1(p) \neq x_2(p)}\). Then, \(\mathcal{G}_n\) converges to the graphon represented by \((\mathcal{X}, \delta)\). As Proposition 3.5 captures as particular cases some local convergence and some graphon convergence, we refer to such a statement as a “local-graphon convergence”.

This proposition can be readily adapted to the whole GCD profile (one assumes tightness, considers maps to \([0, \infty)\) rather than to \(\{0, 1\}\), and predicts the GCD of \((Y_{m_n} + y_0) - (Y_{m_n} + y_1))\) and the case of affine subspaces.

One might also be interested in other arithmetic conditions than coprimality: for example, saying that a number is \(k\)-free if no \(p^k\) divides it, one may colour in white the \(k\)-free points of \(\mathbb{Z}\), or the points in \(\mathbb{Z}^d\) with \(k\)-free GCD. See \([2, 9, 25, 26, 27]\). One can generalise Proposition 3.5 to such contexts as follows. Recall that \(\mathbb{Z}\) and \(\hat{\mathbb{Z}}\) can be endowed with the profinite topology. Likewise, \(\mathbb{Z}^d\) and \(\hat{\mathbb{Z}}^d\) can be endowed with the product of profinite topologies, which we also refer to as the profinite topology.

**Example 3.7.** For every \(k \geq 0\), the set \(\{x \in \mathbb{Z}^d : \text{GCD}(x)\text{ is } k\text{-free}\}\) is profinitely closed in \(\hat{\mathbb{Z}}^d\). For \(k = 1\), this coincides with the set \(\{x \in \mathbb{Z}^d : \text{GCD}(x) = 1\}\).

Let \(V \subset \mathbb{Z}^d\), and let \(\text{col}_V := I_V\). Let \(\mu_{\infty, \text{col}_V}\) denote the distribution of \(x \mapsto I_{V + x \in \mathbb{V}}\), where \(Y\) is Haar-distributed in \(\hat{\mathbb{Z}}^d\) and \(\mathbb{V}\) denotes the closure of the set \(V\) in \(\hat{\mathbb{Z}}^d\).

**Proposition 3.8.** Let \(d \geq 1\) and let \((F_n)\) be a Følner sequence of \(\mathbb{Z}^d\). Let \(V\) denote a subset of \(\mathbb{Z}^d\). Assume that \(V\) is profinitely closed in \(\hat{\mathbb{Z}}^d\). Assume that \(\frac{\nu \cap V}{\nu}\) converges to \(\mu_{\infty, \text{col}_V}\) \((\nu : 0 \in \omega)\). Let \((X_n)\) denote a sequence of independent Haar-distributed elements of \(\hat{\mathbb{Z}}^d\). Let \(M \geq 1\) and \(R \geq 1\). For every \(n\), let \((Y_{m_n}^{(m_n)} : m_n \leq M\) denote \(M\) independent uniform elements in \(F_n\). Consider the following random maps:

\[\psi_n : \left( [1, M] \times [-R, R]^d \right)^2 \rightarrow \{0, 1\} \]
\[\{(m_0, y_0), (m_1, y_1)\} \mapsto \mathbb{1}_{Y_{m_n} + y_0 + Y_{m_n} + y_1 \in V}\]

\[\psi_\infty : \left( [1, M] \times [-R, R]^d \right)^2 \rightarrow \{0, 1\} \]
\[\{(m_0, y_0), (m_1, y_1)\} \mapsto \mathbb{1}_{X_{m_n} - X_{m_n + \text{prof}(y_0 - y_1)} \in \mathbb{V}}\]

Then, the distribution of \(\psi_n\) converges to that of \(\psi_\infty\).

Acknowledgments. At the end of a talk given by Nathanaël Enriquez, Bálint Virág asked him about the local limit of visible lattice points: I would like to thank Bálint Virág for asking this question and Nathanaël Enriquez for letting me know of it. I am also grateful to Nathanaël Enriquez for many enthusiastic discussions about this project. I am thankful to Subhajit Goswami and Aran Raoufi for comments on an earlier version of this paper, to Samuel Le Fourn for bibliographical help, and to the anonymous referees for their feedback. I am grateful to my former postdoctoral advisors Nicolas Curien and Jean-François Le Gall, as well as the Université Paris-Sud, for having provided me with an excellent working environment.

Addendum. After this paper got fully finalised, I became aware of the existence of [20]. In this article, Kubota and Sugita use profinite techniques to prove a particular case of (A).
