Abstract

Experiments on the motion of a particle on an inclined rough plane have yielded some surprising results. For example, it was found that the frictional force acting on the ball is viscous, i.e. proportional to the velocity rather than the expected square of the velocity. It was also found that, for a given inclination of the plane, the velocity of the ball scales as a power of its radius. We present here a one dimensional stochastic model based on the microscopic equations of motion of the ball, which exhibits the same behaviour as the experiments. This model yields a mechanism for the origins of the viscous friction force and the scaling of the velocity with the radius. It also reproduces other aspects of the phase diagram of the motion which we will discuss.
I. INTRODUCTION

A mixture of particles with different sizes can segregate under a wide range of conditions and due to various mechanisms (usually a combination) such as the “Brazil nut effect” \[1\], shear \[2\], percolation \[3\], convection \[4\], or surface flow \[5\]. Clearly the problems of mixing and segregation have important consequences for many industries. To understand this complicated phenomenon, it is easiest to study the effects of the various mechanisms separately, if possible.

In this paper we are interested in segregation due to flow which can be seen, for example, in sand piles. When grains with various sizes flow on the surface, one observes that the largest grains find their way to the bottom of the pile while the smaller ones are stopped farther uphill. This segregation is caused by the roughness of the underlying surface on which the grains are flowing. In a much simplified picture, one can consider the bulk of the sand pile as providing a rough substrate on which the surface grains are flowing and segregating. For experimental purposes, one can carry the simplification farther and consider an inclined plane made rough by sticking beads of a given radius, \(r\), for example glass or sifted sand, on contact paper and attaching it to the plane. This was done in a series of experiments \[6–9\] where various properties of the motion of balls down this plane were studied. We refer the reader to the references for details of the experiments and results. Here we will review some of the results before proceeding to our theoretical model.

Three regimes were found \[6–9\] for the motion of the ball down the plane: A) A sticking or pinning regime where the ball comes to a sudden stop after travelling some distance, B) a regime where the ball attains a steady state with a constant (on average) velocity independent of the initial release velocity, and C) a jumping regime where the ball experiences big bounces and does not achieve a steady state on the 2 meter long plane used in the experiments. One expects that for a long enough plane, the ball will always reach a steady state, but even so, the nature of the motion in this regime appears to be different from that of region B. However, because of experimental difficulties, this regime remains mostly
unstudied.

In region B, it was found that the constant (average) velocity satisfies $\langle v \rangle \propto R^\alpha \sin(\theta)$. This is a surprising result because it means that the force of friction acting on the ball is viscous, i.e. proportional to the velocity. A straightforward argument suggests that the friction force should be quadratic in the velocity leading to a $\sqrt{\sin(\theta)}$ behaviour: It is clear that the deceleration due to collisions is proportional to the number of collisions per second times the velocity loss per collision. The velocity loss per collision is proportional to the velocity itself, and one can argue that the average number of collisions/second is the velocity of the ball divided by the average distance between surface beads. This gives a friction force which is quadratic in the velocity, contrary to what is seen experimentally. Two assumptions that would lead to viscous friction are 1) the velocity loss per collision is a constant independent of the velocity, or 2) the number of collisions per second is a constant independent of the velocity. However, neither of these assumptions can be justified physically and the explanation should be sought elsewhere.

It is tempting to draw an analogy between the motion of a ball down a rough plane with peaks and troughs and the motion of particles in random potentials using a Langevin equation to describe the dynamics. However, such an approach cannot explain the viscous dissipation because the viscous friction term is put in as an assumption from the start. In addition, even if one does assume the viscous force and pursues this approach, the scaling of the velocity with $R$, i.e. with the roughness which in this approach characterizes the random potential, is not correctly reproduced. The missing ingredient will be discussed in section III. A different approach was taken in where a Langevin equation, with the viscous dissipation and the velocity scaling with $R$ built in, was used to study other aspects of the motion such as the stopping distance and its dependence on various parameters.

The approach we will take here is different still. We will consider the one dimensional case, i.e. discs of radius $r$ are randomly stuck on a line inclined at an angle $\theta$ with the horizontal, and on which is released a disc of radius $R$. We then consider the equations of motion of the disc, $R$, as it moves down the line, and make as many simplifying assumptions
as is reasonable, eventually turning the deterministic equations into stochastic ones. Our goal in this is not to have a detailed microscopic agreement with experiments: That would be an unrealistic hope with a very simple model and is more the domain of detailed numerical simulations. Rather, our goal is to have a bare-bones stochastic model that agrees with experiments and reproduces various properties of the motion such as the viscous friction and the scaling of the velocity with $R$. With this model, we succeeded in finding a simple mechanism for the viscous force and the various scaling laws. In all this geometry plays a crucial role.

In section II we will construct the model clearly stating all our assumptions, and in section III we will compare our results with the experiments and make some comments. Section IV contains our conclusions.

II. THE MODEL

Figure 1 shows the geometry of the system. Discs of radius $r$ are put in a straight line, the distance between the surfaces of two neighboring discs being $2\epsilon$, where $\epsilon$ is a random number between 0 and a maximum value, $\epsilon_M$. This line is inclined an angle $\theta$ with respect to the horizontal, and we will take the direction parallel (perpendicular) to it as the $x$ ($y$) direction. Therefore, the gravitational acceleration in the $x$ ($y$) direction is $g\sin(\theta)$ ($-g\cos(\theta)$). The big disc, radius $R$, moves from right to left with a velocity $\vec{v}$ and $x$ and $y$ components $v_x$ and $v_y$, making an angle $\phi$ with the line of discs, $\sin(\phi) = |v_y|/|\vec{v}|$. As shown in Fig. 1, $\gamma$ is the angle between the line perpendicular to the line of discs, and the line connecting the centers of the big and small discs at the point of contact. We will call this the angle of contact which, it should be emphasized, is different from the angle of incidence. Our sign convention is that when the collision is on that side of the small disc which faces the approaching big disc (as in the figure) $\gamma < 0$, and when it is on the other side, $\gamma > 0$.

Our first assumption is that we can ignore the rotation of the big disc as it moves down
the line. Clearly this assumption is not justified if we are aiming at detailed microscopic comparison with experiments. For example, neglecting rotation means that $v_t$, the tangential velocity of the point of contact during a collision is due entirely to the translational velocity of the disc. This is important quantitatively because $\mu_t$, the tangential coefficient of restitution, depends on $v_t$ (see below). However, molecular dynamics (MD) simulations have shown that if we prevent the disc from rotating as it bounces down the line and have only dynamic friction acting as the tangential force, the qualitative features of the motion, like the $\theta$ dependence of the velocity, do not change. Since we are interested here in the scaling properties of the motion, we will neglect the rotation. Therefore, with this assumption, the only effect of the size of the disc is to contribute geometrical constraints as we will see below.

Our second assumption is that after a collision, the velocity components normal and tangential to the small disc at the point of impact are related to the corresponding velocities before the collision by

$$|v'_n| = \mu_n|v_n|,$$  \hspace{1cm}  (1a)

$$v'_t = \mu_tv_t,$$  \hspace{1cm}  (1b)

where $\mu_n(\mu_t)$ is the normal (tangential) coefficient of restitution. There are absolute value signs in eq.(1a) but not eq.(1b) because the coefficient of normal restitution is always positive while that for tangential restitution can be negative (see eq.(9a,b)). The angle of incidence, $a_i$ (not shown in the figure), is of course given by $\cos(a_i) = |v_n|/|\vec{v}|$, and $\sin(a_i) = |v_t|/|\vec{v}|$, while the angle of reflection, $a_r$, is given by $\cos(a_r) = |v'_n|/|\vec{v}'|$, and $\sin(a_r) = |v'_t|/|\vec{v}'|$, where the primes denote values just after the collision. Now consider the big disc going down the inclined line colliding with the small discs, and let us examine the $k$th collision. Let the $x$ and $y$ velocities just before (after) the $k$th collision be $v_x(k)$ ($v'_x(k)$) and $v_y(k)$ ($v'_y(k)$). It is easy to see from these definitions and the simple plane geometry that

$$v_n(k) = |v_y(k)|\cos(\gamma) - v_x(k)\sin(\gamma),$$  \hspace{1cm}  (2a)

$$v_t(k) = |v_y(k)|\sin(\gamma) + v_x(k)\cos(\gamma),$$  \hspace{1cm}  (2b)
keeping in mind our convention for the sign of $\gamma$. The $x$ velocity after the $k$th collision is $v'_x(k) = |\vec{v}'|\sin(a_r + \gamma)$ which, after expanding the sine and using the above definitions of the angle of reflection, gives

$$v'_x(k) = \mu_tv_t\cos(\gamma) + \mu_nv_n\sin(\gamma).$$

(3)

Combining this with eqs.(2a,b) allows us to express the $x$ velocity just after the $k$th collision in terms of the $x$ and $y$ velocities just before the collision as

$$v'_x(k) = v_x(k)\left(\mu_t\cos^2(\gamma) - \mu_n\sin^2(\gamma)\right) + |v_y(k)|\left(\mu_t + \mu_n\right)\sin(\gamma)\cos(\gamma). \quad (4a)$$

A similar argument for $v_y(k)$ gives

$$v'_y(k) = -v_x(k)\left(\mu_t + \mu_n\right)\sin(\gamma)\cos(\gamma) + |v_y(k)|\left(\mu_n\cos^2(\gamma) - \mu_t\sin^2(\gamma)\right). \quad (4b)$$

Our next assumption, which is supported by MD simulations [12,13], is that the motion of the disc is composed mainly of a series of small bounces with very little or no rolling which we will, therefore, ignore. This means that the $k$th collision will cause the disc to bounce and spend a time $\delta\tau(k)$ in the air during which it will experience $x$ acceleration $g\sin(\theta)$. Therefore, its $x$ velocity just before the $(k+1)$th collision is $v_x(k+1) = \delta\tau(k)g\sin(\theta) + v'_x(k)$, which, combined with eq.(4a), gives

$$v_x(k+1) = \delta\tau(k)g\sin(\theta) + v_x(k)\left(\mu_t\cos^2(\gamma) - \mu_n\sin^2(\gamma)\right) + |v_y(k)|\left(\mu_t + \mu_n\right)\sin(\gamma)\cos(\gamma). \quad (5a)$$

What happens to the perpendicular velocity, $v_y$? If the disc, after the collision shown in fig. 1, bounces up and lands on another small disc but at the same $y$ value, its $v_y$ just before the new collision is identical to that just after the previous collision. In general, however, the $y$ value will be different because the big disc will land on various different points of the small discs. However, since we are typically interested in $R/r \geq 3$, we see that the variations in $y$ are very small. We can, therefore, make the simplifying assumption that $v_y(k+1)$, the $y$ velocity just before collision $(k+1)$ equals $v'_y(k)$, the $y$ velocity just after collision $k$ [14]. We then have

$$v_y(k+1) = -v_x(k)\left(\mu_t + \mu_n\right)\sin(\gamma)\cos(\gamma) + |v_y(k)|\left(\mu_n\cos^2(\gamma) - \mu_t\sin^2(\gamma)\right). \quad (5b)$$
So, eqs.(5a,b) express the $x$ and $y$ velocities just before the $(k+1)$th collision in terms of those just before the $k$th collision. Although not written explicitly, to simplify the notation, it should not be forgotten that the contact angle $\gamma$ appearing on the right hand side of these equations is actually $\gamma(k)$, the angle for the $k$th collision. These equations are deterministic since, given the initial conditions, one can, in principle, calculate for all subsequent collisions the two terms that have not yet been specified, $\delta\tau(k)$ and $\gamma(k)$. Such a detailed microscopic approach is not our goal in this paper. Instead, we want to transform eqs.(5a,b) into stochastic processes by making $\gamma$ a stochastic variable. To do that we need its distribution which must be based on the underlying microscopics of the collisions. To simplify the calculation of this distribution, we assume that the disc, $R$, collides with a given small disc only once. It is clear from fig. 1 that, for a given incident velocity, $\vec{v}$, or equivalently, for a given angle $\phi$, the largest (positive) contact angle, $\gamma_{\text{max}}(k)$, is obtained when the big disc collides with the small disc while tangent to the line $L_2$. For this case, $\gamma_{\text{max}}(k) = \phi(k)$. On the other hand, the smallest (i.e. the largest negative) $\gamma_{\text{min}}(k)$ is obtained for the case shown in the figure, with the big disc tangent to line $L_1$. Notice that $L_1$ is tangent to the disc just to the right of the disc involved in the collision. This shows how discs cast velocity dependent “shadows” on their neighbors thus restricting the area available for a collision with a given bead. It is straightforward to show that

$$\sin(\gamma_{\text{min}}(k)) = \sin(\phi(k))\cos(\alpha(k)) - \cos(\phi(k))\sin(\alpha(k)), \quad (6a)$$

where

$$\cos(\alpha(k)) = 1 - \frac{2r + \epsilon}{r + R}\sin(\phi(k)), \quad (6b)$$

and where $2(r + \epsilon)$ is the distance between the center of the disc under collision and that to its immediate right. Recall that $\epsilon$ is a uniformly distributed random number between 0 and some maximum value $\epsilon_M$. This gives the range of the stochastic variable, $\gamma(k)$, to be between a maximum value, $\phi(k)$ (where $\sin(\phi(k)) = v_y(k)/|\vec{v}(k)|$), and a minimum value given by eqs(6a,b). But we still need its distribution. To this end, we assume that for a given collision, the point of disc $R$ that is closest to line $L_1$ (in fig. 1 it actually touches it) is equally likely
to be anywhere between $L_1$ and $L_2$. The position of this point determines the value of the contact angle $\gamma$, and therefore knowing its probability distribution (which we assume to be uniform) gives the probability distribution for $\gamma$. Using this, it is straightforward to show from the geometry that $\gamma$ is given by

$$\sin(\gamma(k)) = \sin(\phi(k)) \left( \frac{R + y\sin(\phi(k))}{r + R} \right) - \cos(\phi(k)) \left( 1 - \left( \frac{R + y\sin(\phi(k))}{r + R} \right)^2 \right)^{1/2}, \quad (7a)$$

where

$$y = \text{uniform random number } \in \left[ \frac{r}{\sin(\theta)} - 2(r + \epsilon), \frac{r}{\sin(\theta)} \right]. \quad (7b)$$

One sees that the distribution for $\gamma$ is a function of the geometry ($R$, $r$, and $\epsilon$) and the incoming velocities ($v_x$ and $v_y$) which determine how much of the surface disc area is available for collision. The distribution given by eqs. (7a,b) is shown in fig. 2.

Equations (5a,b) and (7a,b) define most of the stochastic model. We still need to specify $\delta\tau(k)$, the time between collisions, when energy is fed into the system. Perhaps a temptingly simple hypothesis is that $\delta\tau(k) = \bar{d}/v_x(k)$ where $\bar{d}$ is the average distance between the centers of the line discs. However, as explained in section I, it is easy to see that this gives a friction force proportional to $v_x^2$, and not $v_x$. An alternative argument is to say that for a perfectly smooth surface, the time between bounces is given only by $v_y \delta\tau(k) = 2v_y(k)/g\cos(\theta)$, and assume the same holds for the rough plane. Integrating the stochastic equations of motion with this assumption produces two types of solution depending on the parameters used: Either the ball energy is continuously dissipated until it comes to a complete stop, or the ball makes bigger and bigger jumps accelerating all the time and never reaching a stationary state. Clearly neither of these two possibilities for $\delta\tau(k)$ is realistic. Since the surface is rough, both $v_x$ and $v_y$ play a role in determining $\delta\tau(k)$. As we shall see below, the balance between $v_x$ and $v_y$ plays a crucial role in determining the properties of motion.

To motivate our choice for $\delta\tau(k)$ note, from eqs. (4a,b), that a collision with a negative $\gamma$ transfers velocity from the $x$ to the $y$ direction, while the opposite happens for a positive $\gamma$. Furthermore, for a negative $\gamma$ collision, the big disc has to jump over the small disc in order to continue its motion, while for a positive $\gamma$ collision the big disc can always continue its
motion. For these reasons, we assume that for a collision with $\gamma$ negative (positive), $\delta\tau(k)$ is determined only by $v_y$ ($v_x$). In other words, for $\gamma(k) < 0$

$$\delta\tau(k) = \frac{2v_y'(k)}{g\cos(\theta)}, \quad (8a)$$

and for $\gamma(k) \geq 0$

$$\delta\tau(k) = \frac{2(r + \epsilon)}{v_x'(k)}. \quad (8b)$$

Note that in eq.(8b) we are assuming that the distance travelled to the next collision is well approximated (on average) by $2(r + \epsilon)$. Of course in reality, $v_x$ and $v_y$ together determine the time between collisions. This can be calculated but would not reveal the underlying reasons for the viscous force which we are trying to explain. Equations (8a,b) give a simplification that attempts to understand the separate roles of the parallel and perpendicular velocities.

The last ingredient in our model is the experimental observation that the tangential coefficient of restitution is strongly dependent on the angle of incidence [15], given by the normal (tangential) components of the velocity, $v_n$ ($v_t$) (see eqs.(2a,b)). It was found in reference [17] that the tangential coefficient of restitution is well parameterized by

$$\mu_t(k) = 1 - 3.5(1 + \mu_n)\frac{v_n(k)}{v_t(k)}, \quad (9a)$$

in collisions that involve gross sliding, whereas in collisions that do not

$$\mu_t(k) = -\beta. \quad (9b)$$

In these equations, $\mu$ is the coefficient of friction, and $\beta$ is the tangential coefficient of restitution in the absence of sliding. The normal and tangential velocities are given by eqs.(2a,b). We mention here that one consequence of our ignoring the rotation of the big disc is that the tangential velocity is given only in terms of the translational velocities $v_x$ and $v_y$. However, rotation modifies the tangential (but not the normal) velocity and therefore the effective $\mu_t$ for each collision. This effective change in $\mu_t$ will lead to a different average velocity, but not to a qualitatively different behaviour. This is one justification for ignoring rotation.
Now, our stochastic process is completely defined by eqs. (5a,b), (7a,b), (8a,b) and (9a,b). This stochastic process is nonlinear and cannot be solved exactly. However, the equations can be easily iterated numerically, and the statistical properties of the motion of the disc down the line studied in detail. The initial conditions are random choices for \( v_x(1), v_y(1) \) and \( \gamma(1) \) from which everything else follows simply by generating the random number \( y \). If a collision results in a negative value for \( v_x \) we consider the disc to have been pinned.

The equations defining our model can be further simplified by noting that all the angles are very small allowing us to expand all trigonometric functions to second order in \( \gamma \). However, the resulting equations will still be nonlinear and require a numerical integration. The utility of such an expansion would be for approximate solutions, e.g. mean field.

III. RESULTS

In this section we compare the results of our model with the experiments. The first test of the model is whether it can reproduce the three experimentally found phases \([6–9]\), the pinning phase A, the constant velocity phase, B, where \( \langle v_x \rangle \propto \sin(\theta) \), and the “jumping” phase, C. Figure (3a) shows \( \langle v_x \rangle \) as a function of \( \sin(\theta) \) for three values of \( R \), the radius of the big disc. We clearly see regions that are linear in \( \sin(\theta) \) through which we have fitted straight lines. Although we will not attempt to match our results exactly with experimental values, it is beneficial to see if the theoretical results are in reasonable general agreement with experiments. The linear regions stretch from about 4.5 to 14.5 degrees (the precise values depend on \( R \), and for a given \( R \) they depend on the coefficients of friction and normal restitution), and the values of \( \langle v_x \rangle \) are of the order of 5 to 15 cm/sec, all in very good general agreement with the experiments. Also in agreement with experiments, we found that the average velocity in region B does not depend on the initial velocity with which the ball was released. This is an important property of the motion in this region and does not apply in region C. When we scale the curves in fig. (3a) by a factor of \( R^{-0.49} \) we get fig. (3b) which shows excellent scaling in the linear region, again in agreement with the experiments. The
exponent we found, $-0.49$ differs from the experimental value $-1.4$. Changing the parameters of the calculation, i.e. the values of the coefficients of restitution and friction, changes the exponents only a little and does not bring it close enough to the experimental value. We think that this difference could be due to the fact that the calculation is done in one dimension while the experiments are two dimensional. It might also be that our approximations, while maintaining the qualitative features of the physics, have changed this exponent. This insensitivity of the exponent to the values of the coefficients of restitution and friction explains the experimental result that for a given value of $\theta$, $R$, and $r$, the average velocity is practically independent of the material of the plane or the ball. In other words, having fixed $\theta$, $R$, and $r$, balls of plastic, glass and steel, whose coefficients of restitution and friction are not very different, were found to have the same terminal velocity. Furthermore, this terminal velocity did not change when the surface of the plane was changed from glass beads, radius $r$, to sand with average grain radius $r$.

To check how linear these plots are, we show in fig. (4) $\langle v_x \rangle - v_{fit}$ where $v_{fit}$ is the value of the velocity given by the straight line fit to each of the curves. We see that for $\sin(\theta)$ between about $0.1$ and $0.25$ the deviation is extremely small and the linear fit is excellent. For $\sin(\theta)$ larger than about $0.25$ we see that the $\langle v_x \rangle$ increases faster than linearly. We take this as the definition of region C, which for brevity we will call the “jumping” regime because, as mentioned in the introduction, the motion is dominated by large jumps as compared with the small bounces in region B. We see from fig. (4) that the largest disc, dashed line, enters the jumping regime earlier and faster than the smaller ones. This is in agreement with experimental phase diagrams and with numerical simulations. Experiments have also shown that as the ball approaches the jumping regime, C, it exhibits intermittent behaviour where it still has a constant average velocity but it shows bursts of acceleration and deceleration. Figure (5) shows a plot of distance travelled as a function of time for $\sin(\theta) = 0.53$ from our model. Bursts of acceleration and deceleration are clearly seen. This intermittency gets much more dramatic as one gets closer to the jumping regime (increasing $\theta$) before the motion gets completely destabilized. The origin of a burst of acceleration is
a particularly big bounce, due to high speed and a large negative $\gamma$, where the disc spends a long time in the air, gaining a lot of energy which it has difficulty losing. Then comes another big shock that dissipates a lot of the energy, and the disc regains its former slower velocity. This mechanism can be inferred from the sharpness of slope changes (i.e. velocity changes) in fig. (5).

Figure (4) also shows that as $\theta$ is decreased, the average velocity decreases and eventually exhibits a sublinear dependence before it enters the pinning regime. To study the transition between the pinning regime, A, and the constant velocity regime, B, we release several discs for each value of $\theta$ and $R$ (keeping $r$ fixed) one after the other and with slightly different initial velocities. We consider the system in the pinning regime when at least half the discs are stopped. As is clear from fig. (6), the pinning regime quickly shrinks (i.e. moves towards smaller $\theta$), and then disappears as $R$ is increased. This agrees with the experiments, although in our calculation region A disappears faster.

Experiments have indicated [8,19] that $\langle v_x \rangle$ does not depend on the ratio $R/r$ alone. For example, Jan et al [19] showed that changing $R$ while keeping the ratio $R/r$ fixed (they kept $R = r$), $\langle v_x \rangle$ grows like $\sqrt{R}$. Figure (7) shows $\langle v_x \rangle R^{-0.5}$ as a function of $\sin(\theta)$ for $R = 3, 4.5, 6, 7.5, 9$mm and $R/r$ fixed at 6. The figure exhibits excellent data collapse with an exponent that agrees with the experimental value. The same scaling is observed in MD simulations [12].

So, we see that the simplified stochastic model presented here has reproduced remarkably well all the features of the experimental results. But what is the mechanism behind the linear dependence on $\sin(\theta)$ and the scaling with $R$? As mentioned in section II, if one argues that the time between collisions, $\delta \tau$, is set by the parallel velocity, $v_x$, one gets a very stable dependence of the velocity on $\sqrt{\sin(\theta)}$ implying a friction force that is proportional to the square of the velocity. The faster the disc moves, the shorter the time interval during which energy is fed into the system. If, on the other hand, one assumes, as in ballistic flight, that $\delta \tau$ is determined only by the perpendicular velocity, $v_y$, then one gets very unstable motion. The faster the disc, the longer the time interval during which energy is fed into the system.
and the more difficult it is to dissipate it. This drives the instability. In our simple model, the time of flight is given by both $v_x$ and $v_y$ depending on the side of the line beads that is impacted.

For small inclination angles, our model gives $\delta \tau$ that is dominated \cite{20} by $v_x$ as shown in fig. (8a) for $\sin(\theta) = 0.03$. This gives a dependence on $\sin(\theta)$ that is very close to a square root, as is seen for the same angle in fig. (3a,b). The reason for this is that at such small angles, $v_y$ is so small that the motion is mostly parallel to the line, \textit{i.e.} in the $x$ direction, which as mentioned above, gives a $\sqrt{\sin(\theta)}$ dependence. For large values of $\theta$, the motion is very bumpy, $v_y$ is quite large and it dominates the contribution to $\delta \tau$, as is seen in fig. (8c) for $\sin(\theta) = 0.4$. At this value, we see that $\langle v_x \rangle$ increases faster than linearly with $\sin(\theta)$, fig. (3a,b), as the system is headed for the jumping regime, C. In between the two regions of sublinear and superlinear dependence on $\sin(\theta)$, there is a region of competition between the $v_x$ and $v_y$ contributions to $\delta \tau$ as is seen in fig. (8b) for $\sin(\theta) = 0.2$, which is in the heart of the linear regime. It is this competition between the destabilizing influence of $v_y$ and the strong stabilizing influence of $v_x$ that gives rise to the effective viscous friction and linear dependence on $\sin(\theta)$.

What about the scaling observed in figs. (3b) and (7)? We found that if we use a tangential coefficient of restitution, $\mu_t$, that is constant instead of as in eq. (9a,b), the scaling exponent for fig. (3a) is 0, \textit{i.e.} all the curves always overlap completely in the linear regime. Furthermore, we found that with this assumption, it is the smaller discs that enter the jumping regime, C, first, in clear contradiction with the experiments and intuition. Therefore the experimentally based eqs. (9a,b) are crucial to obtaining the correct behaviour. On the other hand, we found that taking $\mu_t$ to be constant does not change the behaviour in fig. (7) \textit{(i.e.} when $R/r =$constant) by much: the exponent is changed from 0.5 to 0.43 and the scaling is still clearly visible. This interesting result indicates that although, in our model, the exponents for figs. (3b) and (7) are very similar, the two scaling effects appear to have different origins!

It is worth emphasizing that geometry is playing a dominant role in this model. The
distribution of the stochastic variable, \( \gamma \), given by eqs. (7a,b), is dominated by the velocity dependent shadows cast by discs on their neighbors, constraining the cross section available for collisions. In addition, this distribution is clearly crucial in deciding which of eqs. (8a) or (8b) determines the time of flight whose role is discussed above. Because of all this, we see that the allowed collisions and the velocities are strongly dependent on the geometry which also means that, because of eq. (9a), \( \mu_t \) is also dependent on the geometry.

**IV. CONCLUSIONS**

We have presented in this paper a stochastic model for the motion of a disc down an inclined line of smaller discs, separated by random distances. The stochastic equations are based on the original deterministic equations of motion to which we have added some simplifying assumptions. Our two main assumptions are that we can neglect rotation (supported by MD [12]), and that the motion of the disc is a series of small bounces, with one bounce per line disc (supported by recent experimental results on the two dimensional plane [21] and by MD simulations [12]). This simple model, where geometry plays a very important role, accurately reproduces the features of the experimental data, and explains the origin of the viscous friction force. This is seen to be the result of competition between ballistic motion (with large \( v_y \) determining the the time of flight) and motion parallel to the plane (where \( v_x \) determines the time of flight). We also emphasized the importance of the dependence of the tangential coefficient of restitution on the angle of incidence.

The next phase is to compare the results from this model with experiments currently being done on the stopping distance of the balls in regions A and B. The properties of the stopping distance in region B have very important industrial applications in the segregation of grains with different sizes. We will also compare with experiments the results of our model for the longitudinal dispersion of the velocity and its dependence on the sizes of the balls and the inclination angle. For the longer term, we would like to generalize the model to a two dimensional plane, where we can make more quantitative comparisons with experiments.
including results for the transverse motion which is absent on a one dimensional line.

ACKNOWLEDGMENTS

We wish to thank D. Bideau, Ph. de Forcrand, A. Hansen, C. Henrique, I. Ippolito, J. Schäfer, K. Taylor, and D. Wolf for very valuable discussions. G.G.B. and L.S. acknowledge support from the GdR CNRS “Physique des Milieux Hétérogènes Complexes”.
FIGURE CAPTIONS

FIG. 1 Shows the geometry of the inclined line of discs, $r$, on which we release a disc $R$. The collision depicted is that for the largest negative value of $\gamma$, the contact angle.

FIG. 2 A histogram showing the distribution of the stochastic variable $\gamma$ (in radians) given by eqs. (7a,b). Recall that in our convention, $\gamma < 0$ if the collision is as shown in fig. 1, and $\gamma > 0$ if it is on the other side of the perpendicular. $\sin(\theta) = 0.3$, $R = 0.3$cm, $r = 0.05$cm, $\epsilon = 0.01$cm, $\mu_n = 0.9$, $\mu = 0.142$ and $\beta = 0.45$. See eqs. (5a,b), (7a,b), (8a,b) and (9a,b) for definitions of the parameters.

FIG. 3a Shows the dependence of $\langle v_x \rangle$ (in cm/sec) on $\sin(\theta)$. There is a clear linear region in agreement with experiments. $R = 3, 4, 5$mm for $\Box, \triangle, \triangledown$, $\mu = 0.142$, $\mu_n = 0.9$, $\beta = 0.45$, $r = 0.5$mm.

FIG. 3b Same as fig. (3a) but with the vertical axis scaled by $R^{-0.49}$.

FIG. 4 Deviations of $\langle v_x \rangle$ from the straight line fits of fig. (3a). $R = 3, 4, 5$mm for the dot-dash, solid, and dashed lines.

FIG. 5 Distance travelled (in meters) as a function of time (in seconds) for a disc of radius $R = 4$mm and an inclination angle $\sin(\theta) = 0.53$. All the other parameters are as in fig(3a,b). The slope gives the velocity parallel to the inclined line and exhibits bursts of acceleration and deceleration.

FIG. 6 Fraction of pinned discs as a function of the inclination angle. $R = 2, 2.2, 2.4, 2.6, 2.7$mm for $\Box, \diamondsuit, \triangle, \triangledown, +$. The other parameters are as in fig (3a,b). For each data point 500 discs were released.

FIG. 7 Scaling of $\langle v_x \rangle$ with $R$ when $R/r$ is kept constant. The data collapse is for $R = 3, 4.5, 6, 7.5, 9$mm and the same parameters as in fig(3a,b).
FIG. 8a Histogram of times between bounces. The shaded histogram shows $\delta \tau$ for collisions at positive $\gamma$, i.e. where the time of flight is determined by $v_x$. The other histogram shows the case for negative $\gamma$, i.e. $\delta \tau$ is determined by $v_y$. $\sin(\theta) = 0.03$, the other parameters are as in fig. (3a,b).

FIG. 8b As in fig. (8a) but with $\sin(\theta) = 0.2$.

FIG. 8c As in fig. (8a) but with $\sin(\theta) = 0.4$.

[10] In references [3–8] the scaling is expressed as $(R/r)^\alpha$, but since the radius, $r$, of the beads on the plane is kept fixed, we will not use the ratio of the radii. Another reason for not doing that is that even with $R/r$ fixed, changing $R$ will change $\langle v \rangle$, as we will see later.

[20] By “dominate” we mean that most of the energy fed into the system is done during bounces whose duration is determined by one of the velocities, $v_x$ or $v_y$.
