Abstract

Background
Two individuals with a first-degree relationship share about 50 percent of their alleles. Parent-offspring relationships cannot be homozygotes for alternative alleles (genetic exclusion).

Methods
Applying the concept of genetic exclusion to HD arrays typed in animals for experimental purposes or genomic selection allows estimation of the rate of rejection of first-degree relationships as the rate at which two individuals typed for a large number of SNPs do not share at least one allele. An Expectation–Maximization algorithm is applied to estimate parentage. In addition, genotyping errors are estimated in true parent-offspring relationships due to the large number of SNPs. Nine candidate Duroc sires and 55 Iberian dams producing 214 Duroc × Iberian barrows were typed for the HD porcine Affymetrix array.

Results
We were able to establish paternity and maternity of 75 and 86 piglets, respectively. A lower bound of the genotyping error of 0.003345 was estimated based on the rate of rejection of true parent-offspring relationships among autosomal SNPs. The true genotyping error is estimated to be between twice and three times the average of the rate of rejection observed in true relationships, i.e., between approximately 0.0067 and 0.0100. A total of 8,558 SNPs were rejected in six or more true parent-offspring relationships facilitating identification of “problematic” SNPs with inconsistent inheritance.

Conclusions
This study shows that animal experiments and routine genotyping in genomic selection allow to establish or to verify first-degree relationships as well as to estimate genotyping errors for each batch of animals or experiment.
Background

Next Generation Sequencing (NGS), a term used for massive parallel sequencing of several hundred thousand to millions of DNA fragments simultaneously, has enabled massive discovery of novel SNP genetic markers (1). Today, high density (HD) SNP arrays allow interrogating a genome for hundreds of thousands of SNPs at a time. Subsequently, HD SNP arrays have been used to interrogate human, animal and plant genomes for SNPs associated to disease and production traits (2, 3).

In livestock production, genotyped individuals in a population are often much more related than in human research. In most cases, individuals with first-degree relationships, i.e., parent-offspring or full-sib relationships, are part of the same selection candidates in genomic selection or crossbreeding programs. For optimum contribution selection (OCS), restricting the relationship between selected parents is crucial to restrict inbreeding in the progeny and maximize genetic gain (4). Therefore, for genomic breeding value estimation, the genetic relationships between individuals based on markers densely distributed across the genome need to be accurately established across individuals (5). In practice, this requirement may be hindered by instances of incorrect labelling, or registration of individuals with their DNA samples. In addition, virtually every genetic study includes genotyping errors, quantified by the Quality scores probability of error provided by genomics companies, resulting from calling algorithms that misidentify and misclassify the individual’s genotype (6). It is likely that genotyping errors vary between experiments due to variation in DNA quality or lab sample handling. Genotyping errors are usually not reported in scientific studies.

The objective of this study is to investigate the rate of rejection of first-degree relationships of individuals in a population using an HD SNP array. A second objective of this study is to demonstrate the use of HD SNP arrays in detecting genotyping errors after parent-offspring relationships are resolved. A third objective is to identify SNPs that repeatedly result in genotyping errors in multiple true parent-offspring relationships.

Methods

Genome-wide rate of rejection of first-degree relationships among all individuals

A first-degree relative is an individual who shares approximately 50 percent of their alleles with a particular other individual. There are two first-degree relationships: parent-progeny, and full-sibs. Under strict Mendelian
inheritance, individuals with a first-degree parent-offspring relationship cannot be homozygous for alternative alleles at a given locus. For example, an individual offspring cannot be homozygous CC at a locus, when a parent is GG at the same locus. Applying this concept to a population in which individuals are genotyped with an HD SNP array allows the rejection of parent-offspring first-degree relationships based on this rule. Full-sibs, on the other hand, can be homozygous for alternative alleles when both parents are heterozygous, but this probability is small, at 0.125.

We define genome-wide rate of rejection of first-degree relationships as the rate at which two individuals genotyped for a large number of SNPs have alternatives alleles, i.e., the number of markers for which two individuals are homozygous for alternative alleles divided by the total number of SNPs genotyped with an HD SNP array. The rate of rejection of a first-degree relationship between two individuals i and j is thus defined as:

\[
\tau_{ij} = \frac{\sum_{i=1}^{N_{snp}} s_i}{N_{snp}}
\]

where \( N_{snp} \) is the total number of SNPs in the array; for each SNP, \( s_i \) is a dummy variable with value 1 if the first-degree relationship is rejected for the \( i \)-th marker (i.e., individuals are homozygous for alternative alleles at that locus); it is 0 otherwise.

Estimates of \( \tau_{ij} \) corresponding to each relationship can be used to detect or confirm first-degree relationships and genotyping errors. In equation (1), \( \tau_{ij} = 0 \) implies that individuals i and j are not homozygous for alternative alleles at any of the SNP markers in the array, therefore, they have a parent-offspring first-degree relationship; \( \tau_{ij} > 0 \) implies there is not a parent-offspring first-degree relationship. However, full-sibs with a true first-degree relationship can be homozygous for alternative alleles when both parents are heterozygous, therefore \( \tau_{ij} > 0 \). In addition, when genotyping errors occur, individuals i and j may appear to be homozygous for alternative alleles at some of the SNP markers in the HD SNP array when in reality they are not, such that \( \tau_{ij} \approx 0 \). In that case, it would mean a rejection of a true parent-offspring first-degree relationship. Because genotyping errors do occur, a method needs to be developed that can distinguish values of \( \tau_{ij} \approx 0 \) that result from genotyping errors only from values of \( \tau_{ij} > 0 \) resulting from a true rejection of a parent-offspring first-degree relationship.
Values of $\tau_{ij}$ can be calculated for all possible relationships between all pairs of individuals in the population; in a population with $n_i$ individuals, the total number of relationships is $(n_i^2 - n_i)/2$. The binomial density models the probability of each outcome according to:

$$p(\tau) = \binom{N_{\text{SNP}}}{\delta} (\tau)^{\delta} (1 - \tau)^{N_{\text{SNP}} - \delta}$$

where $p(\tau)$ is the probability of the rate of rejection, $\tau$, at the number of SNPs rejecting first-degree relationships, $\delta = \sum_{i=1}^{N_{\text{SNP}}} s_i$.

**Expectation-Maximization to estimate first-degree relationships**

Given the distribution of the rate of rejection of first-degree relationships in a population, $\tau$, when $\tau_{ij} > 0$, mixing of several distinct distributions can be identified: one corresponding to binomial probabilities $\tau_g$ resulting from genotyping errors, and others corresponding to binomial probabilities $\tau$, resulting from rejections of first-degree relationships. Here, the rate of genotyping errors is a lower bound of the true rate of genotyping errors, since genotyping errors are only identified in SNP markers for which the individuals are homozygous for alternative alleles; genotyping errors in individuals that do not lead to a rejection of a first-degree relationship will remain undetected. In the dataset it is assumed that estimates of rates of rejection following equation (1) when $\tau_{ij} > 0$ should belong either to the distribution of $\tau_g$ or to the distribution of $\tau$, i.e., a true first-degree relationship is rejected because of genotyping errors (the values are close to zero, $\tau_{ij} \approx 0$) vs. a first-degree relationship is rejected because it does not exist (the values are farther away from zero, $\tau_{ij} > 0$). In order to determine to which of the two distributions a relationship belongs, the dataset has to be first subdivided into known relationship groups.

In our example, we consider a crossbreeding experiment with candidate sires, dams and offspring. The data can now be subdivided into the following relationship groups: dam-offspring, sire-offspring, offspring-offspring, dam-dam, sire-sire, and sire-dam. First, we are interested in identifying dam-offspring, or sire-offspring relationships to establish maternities and paternities of our experimental crossbred population. A given pair of individuals from the dam-offspring or the sire-offspring group has a probability $\gamma$ of belonging to the distribution of $\tau_g$ of true parent-offspring relationships. The likelihood function of the $i$-th relationship is:
\[ L_i(y, \tau_g, \tau_r) = y L_i(\tau_g) + (1 - y) L_i(\tau_r) \]
\[ = y \left[ \left( \frac{N_{\text{snp}}}{\delta_i} \right)^{\delta_i} (1 - \tau_g)^{N_{\text{snp}} - \delta_i} \right] + (1 - y) \left[ \left( \frac{N_{\text{snp}}}{\delta_i} \right)^{\delta_i} (1 - \tau_r)^{N_{\text{snp}} - \delta_i} \right] \]  
\[ (2) \]

where \( \delta_i \) is the number of SNPs rejecting the first-degree relationship. The joint likelihood function for all the relationships between all pairs of individuals within the dam-offspring or within the sire-offspring group is:

\[ L(y, \tau_g, \tau_r) = \prod_{i=1}^{nr} L_i \]  
\[ (3) \]

This likelihood has three unknowns: \( y, \tau_g, \) and \( \tau_r \). Maximizing this equation is not straightforward because equation (2) has an addition term, which makes using logarithms impractical. We can solve equation (3) by applying an Expectation-Maximization algorithm. This method requires starting values for \( \tau_g \) and \( \tau_r \). The expectation for the \( i-th \) relationship is:

\[ E[t_{gi}] = \frac{L_i(\tau_g)}{L_i(\tau_g) + L_i(\tau_r)} \delta_i \]  
\[ (4) \]

\[ E[t_{ri}] = \frac{L_i(\tau_r)}{L_i(\tau_g) + L_i(\tau_r)} \delta_i \]

The binomial probabilities are extremely small when the total number of SNPs is very large, therefore, it is convenient to manipulate these equations to:

\[ E[t_{gi}] = \frac{1}{1 + \frac{L_i(\tau_r)}{L_i(\tau_g)}} \delta_i \]
\[ = \frac{1}{1 + e^{(\ln L_i(\tau_r) - \ln L_i(\tau_g))}} \delta_i \]
\[ E[t_{r,i}] = \frac{1}{1 + \frac{L_i(\tau_g)}{L_i(\tau_r)}} \frac{\delta_i}{\sum_{i=1}^{nr} E[t_{g,i}]} \frac{\delta_i}{N_{snp}} \]

\[ \tau'_g = \frac{\sum_{i=1}^{nr} E[t_{g,i}] \frac{\delta_i}{\sum_{i=1}^{nr} E[t_{g,i}]} \frac{\delta_i}{N_{snp}}}{\sum_{i=1}^{nr} E[t_{r,i}]} \frac{\delta_i}{N_{snp}} \]

\[ \tau'_r = \frac{\sum_{i=1}^{nr} E[t_{r,i}]}{\sum_{i=1}^{nr} E[t_{r,i}]} \frac{\delta_i}{N_{snp}} \]

The maximization step is:

Parameter \( \gamma \), i.e., the probability that \( \tau_{ij} \) belongs to the distribution of \( \tau_g \) of true parent-offspring relationships is estimated following:

\[ \gamma' = \frac{\sum_{i=1}^{nr} E[t_{g,i}]}{nr} \]

The process is iterative and parameters \( \tau'_g \) and \( \tau'_r \) estimated in one iteration are used for the next iteration as \( \tau_g \) and \( \tau_r \), respectively. Once convergence is reached, the \( i-th \) parent-offspring relationships are assigned as true when

\[ \frac{L_i(\tau_g)}{L_i(\tau_g) + L_i(\tau_r)} > 0.5. \]

When this method is applied to the offspring-offspring relationship group, also full-sibs can be detected. In that case, the procedure does not attempt to estimate genotyping errors but will assign relationships according to two distributions with binomial parameter \( \tau \): one distribution with full-sibs and another distribution with any other
relationships. The EM follows the same steps as for parent-offspring relationships as described above. Once, true parent-offspring relationships are identified, a lower bound of the estimate of the genotyping error is simply, $\tau_g$.

**Dataset of Duroc × Iberian Pigs**

The animal material from this study came from an experiment investigating production parameters in a commercial Duroc × Iberian pig cross (7). In Spain, purebred Iberian pig meat (in particular dry-cured products) from pigs kept extensively in a production system called ‘montanera’ where they roam the Mediterranean forest and eat acorns is the most valuable meat product (8). However, because of limited land availability and low production levels, Iberian pigs are regularly crossed with Duroc producing either 50% or 75% Iberian fattening pigs. In 2019, 50% crossbred Iberian pigs constituted 80% of the total Spanish Iberian pig production; 72% of those constituted Duroc × Iberian pigs fed intensively on concentrate (9). The dataset consisted of nine candidate Duroc sires, 55 Iberian dams, and 214 Duroc × Iberian barrows.

**Genotyping with the Porcine Affymetrix HD array**

A total of 288 samples were genotyped with the HD porcine Affymetrix array (658,692 SNPs). One of the samples failed. Best Practices Workflow was applied with the following conditions in the Axiom Analysis Suite version 5.1.1.1: DQC: ≥ 0.82; QC call rate: ≥ 97; Average call rate for passing samples: ≥ 98.5; Percent of passing samples: ≥ 95. Of the 287 samples only 281 passed the QC-Call rate. There were 603,809 SNPs that passed the condition for the call rate. From those, only 546,220 autosomal SNPs mapped to SScroffa_v11.1 were used for estimating rate of rejection of first-degree relationships. The genotyping was carried out at Centro Nacional de Genotipado (CeGen) at the University of Santiago de Compostela.

**Estimation of paternities, maternities and genotyping errors**

The methods to estimate paternities, maternities, genotyping errors were as described in the section Methods. Source code in R language (http://www.r-project.org/) is provided as SUPLEMENTAL MATERIAL 1.
**Results**

**Estimation and distribution of the rate of rejection of first-degree relationships**

In our dataset of Duroc × Iberian crossbreds, no relationship resulted in $\tau_{ij} = 0$. Since we were aware that the dataset included some true dams and sires together with their offspring, these results indicate that all true first-degree relationships were rejected because of genotyping errors; indeed, there were relationships with $\tau_{ij} \approx 0$. The distribution of the rate of rejection of first-degree relationships $\tau_{ij}$, corresponding to all individuals and each relationship, in all relationship groups, is given in Figure 1. Because several peaks can be distinguished, this figure suggests mixture of different underlying distributions corresponding to the distribution of the rate of rejection due to genotype errors $\tau_g$, and to the distribution of $\tau_{ij}$ corresponding to true rejection of first-degree relationships $\tau_r$, in the different relationship groups (Figure 1).

The distinction between the distributions of $\tau_g$ and $\tau_r$ becomes clearer when data is separated by relationship group: dam-offspring, sire-offspring, offspring-offspring, dam-dam, sire-sire, and sire-dam relationships (Figure 2). The distribution of $\tau_{ij}$ within the dam-offspring and within the sire-offspring groups shows a clear separation between rates of rejection of parent-offspring first-degree relationships $\tau_{ij}$ very close to zero ($\tau_{ij} \approx 0$), and between rates of rejection of first-degree relationships $\tau_{ij}$ with higher values ($\tau_{ij} > 0$) belonging to another type of relationships. In the parent-offspring groups, because the probability that two individuals are homozygous for alternative alleles at a given locus is very close to zero, their values correspond to genotyping errors (i.e., the distribution of $\tau_g$), while higher $\tau_{ij}$ values correspond to true rejection of first-degree relationships (i.e., the distribution of $\tau_r$). The distributions of $\tau_g$ and $\tau_r$ are more overlapping in the offspring-offspring group. This is expected from the observation that true full-sibs can be homozygous for alternative alleles when both parents are heterozygous, albeit at a low probability of 0.125. A clear distinction between values of $\tau_{ij}$ very close to zero and those farther away from zero can also be seen in the distribution of $\tau_{ij}$ in the dam-dam and sire-sire groups (Figure 2). These values indicate the presence of one first degree relationship in sire-sire and a number of them in the dam-dam relationships. In further analyses, we realized that some samples of dams were repeated, which
also explains the observed dam-dam first degree relationships. In the sire-dam group, no first degree relationship are detected, which is expected in parents from a cross-breeding experiment since dams and sires belong to two different breeds. The rate of rejection is very large showing the differences in genetics between the breeds.

Figure 2 about here

**Expectation-Maximization to establish first-degree relationships**

Because due to the existence of genotyping errors $\tau_{ij} = 0$ cannot be used as the only criterion on which to accept first-degree relationships, an Expectation-Maximization method was developed to establish whether values of $\tau_{ij}$ belong either to distribution $\tau_g$ (genotyping errors) or to distribution $\tau_r$ (true rejection of first-degree relationships). Relationships with values of $\tau_{ij}$ that belong to distribution $\tau_g$ are true first-degree relationships.

Figure 3 illustrates the convergence of the E-M algorithm for A) Dam-Offspring, B) Sire-Offspring, and C) Offspring-Offspring relationships. Convergence for all parameters took place in just two to three iterations. Initial values for $\tau_g$ and $\tau_r$ were chosen such that they were close to the peak of the corresponding distributions in Figure 2. When the chosen initial values for $\tau_g$ and $\tau_r$ were not close to the corresponding peak of the distribution, parameters were not converging.

Figure 3 about here

Applying the Expectation-Maximization algorithm, we were able to establish paternity of 75 and maternity of 100 piglets. In the latter case, we identified that 14 offspring out of 100 appeared to have two mothers. We could establish that the two mothers were indeed the same individuals, and blood for DNA extraction had been sent twice and with different identification to our lab. Therefore, we established 86 mother-offspring relationships. This also explain the first degree dam-dam relations observed and mentioned earlier. In addition, we established 3462 full-sib relationships among the offspring-offspring relationship group. We verified that 18 offspring that had the same father and mother assigned in the sire-offspring and dam-offspring groups, respectively, were also detected as full-sib relationships in the offspring-offspring group.

**Estimation of genotyping errors**
After establishing relationships with $\tau_{ij} \approx 0$ that belong to distribution $\tau_{ij}$, we established that the genotyping error estimated jointly in sire-offspring and dams-offspring relationship groups was 0.003345. This is a lower bound of the true number of genotyping errors since genotyping errors are only identified for SNP markers in parent-offspring relationships for which individuals are homozygous for alternative alleles; other genotyping errors involving heterozygous animals in either parent or offspring remain undetected. The true genotyping error should be between two and three times the average of the rate of rejection observed in true relationships, i.e., between approximately 0.0067 and 0.0100.

Detection of SNPs with a high rate of rejection of first-degree relationships in true parent-offspring relationships

In our dataset, a total of 1,025,490,522 different SNP markers were involved in the rejection of first-degree relationships in the parent-offspring groups. The genome-wide distribution of those SNPs is given in Figure 4. We can now identify those SNPs that repeatedly rejected first-degree relationships in true parent-offspring pairs. The majority of them rejected first-degree relationships in true parent-offspring only a few times, however, some of the SNPs rejected first-degree relationships particularly often (Figure 5). We identified 8,558 SNPs rejecting six or more true parent-offspring relationships (Figure 5); these SNPs were considered ‘failing’ and are reported in SUPPLEMENTAL MATERIAL 2. For example, SNP with Affymetrix identification Affx-115017537 and mapped to position 3021252 on SSC18 rejected 126 true parent-offspring relationships. Figure 6 shows the cluster provided by the Axiom suite analysis of the genotypes of all parents and offspring for this SNP; only one individual is heterozygous. This is an indication that this SNP does not follow autosomal Mendelian rules of inheritance since most animals are crossbreds (i.e., the majority of animals are ‘offspring’) and the observed homozygous genotypes could only come about when both their sire and dam are homozygous for the same allele. These results could be attributed to genotyping errors, but also to wrong (not autosomal) mapping locations, structural variations, etc.

Discussion

The present study shows the successful application of an Expectation-Maximization (EM) algorithm to establish or to verify first-degree relationships, including parent-offspring and full-sib relationships, when relationships are unknown or uncertain, in an animal population that is genotyped with a High-Density (HD)
SNP Array. This method has a wide range of applications. In livestock populations, first-degree relationships are nearly always present. Although the advent of genomic methods meant that pedigree information necessary for breeding value estimation can now be replaced by genomic relationships in genomic best linear unbiased prediction (GBLUP) (10), and the inbreeding coefficient of individuals necessary to control economic losses from inbreeding depression (11) can be estimated from molecular marker data (12), accurate pedigree information is still key to animal populations where molecular information is not routinely available (e.g., (13)). However, collecting accurate pedigree information may be demanding because of gaps in data recording, loss of records, inadvertent errors in animal labelling or registration, inability to cost-effectively identify animals individually, or the inability to assign parents to offspring. For example, individual identification of small fish is often demanding, such that fish are commonly kept in families until they are large enough to be individually tagged (14). Assigning parents to offspring is not straightforward in multi-sire breeding schemes, such as those employed in cattle ranching operations where breeding and calving is unassisted and, therefore, it is not possible to correctly assign paternity (and sometimes maternity) to a given calf (15). Paternity and maternity identification errors may substantially negatively impact estimated breeding values, genetic trends, inbreeding, and result in the inability to identify truly superior animals in a population (16). Furthermore, parentage identification is important to companion animals to evaluate inbreeding and genetic diversity, pedigree structure, and for registrations purposes (17), in free-living animal populations to evaluate population and kinship structure, and genetic diversity (18), and for forensic human identification (19).

While the first parentage verification methods used blood groups (20), this was soon replaced by an international standard of the International Society of Animal Genetics (ISAG) for parentage verification and identity testing following DNA typing based on microsatellite markers (21), and more recently also based on SNP markers (22). Microsatellites are polymorphic codominant genetic markers containing repeated nucleotide sequences, with 2-10 nucleotides per repeated unit, that are present across the genome. Although they have been used and are still used widely for parentage verification and identity testing, some problems persist: microsatellite markers are not highly polymorphic in all species, the scoring of markers is not straightforward or automated, and they require a rather large (initial) investment in terms of labor and financial resources (23). These problems were large overcome by development of SNP markers which have only just been successfully applied in parentage verification in livestock (24), fish (25), companion animals (17), wild animals (18), and humans (19).
Because microsatellites are more polymorphic than the bi-allelic SNPs, parentage verification is accomplished by a larger number of SNPs than microsatellites in a panel. Between approximately 40 and 100 SNPs are equivalent to between 14 and 20 microsatellites; ISAG recommends a minimum number of 100 SNPs for parentage testing (26). Microsatellite and SNP panels for parentage verification are successful and particularly useful when HD SNP panels are too expensive for routine use, e.g., in smallholder systems (27). However, the Expectation-Maximization (EM) method applied to all SNPs in an HD SNP Array described in the present study has several additional advantages in populations where HD SNP Arrays are routinely applied, e.g., for genome-wide association studies (GWAS) and/or genomic selection, or when there are no cost limitations. Firstly, whereas microsatellite and SNP panels for parentage identification are designed and verified in different species and made available internationally (e.g., the Bovine ISAG SNP Parentage Panel based on 200 bovine SNP markers selected by ISAG) or may be tailored to specific breeds, the EM method can be applied to HD genotyped animals without prior evaluation and verification. Secondly, parentage test panels do not take into account genotyping errors. The EM method is easily applied to evaluate (a lower bound of) genotyping errors in individual experimental datasets, by identifying parent-offspring that are homozygous for alternative alleles. This method can be applied to investigate genotyping errors in different datasets using the same array. In addition, the nature of genotyping errors can be further investigated. For example, we identified “problematic” SNPs that particularly often rejected true first-degree relationships. Those should be eliminated from the data set for GWAS or Genomic Selection, but they should also be further investigated in order to understand why they do not follow autosomal Mendelian inheritance rules.

The method described in this study can be easily applied to animal populations for which a SNP array is available for the species in question. Although the present study was performed with an HD SNP array, arrays at lower densities are expected to be capable to draw similar conclusions and will be cheaper. Routine application of genomic selection requires at least a low-density array. Verification or detection of first-degree relationships, together with a measure of the genotyping errors of each batch may facilitate detection of errors and assure the quality of genotyping.

A simple statistic proposed in this study, rate of rejection of first-degree relationships, is helpful to verify or to detect paternities and maternities when testing a large number of SNPs. It is also shown that rate of rejection allows estimation of different types of relationships and even genetic differences between groups of animals since sires and dams in our study belong to different breeds. This statistic, nevertheless, is based on the simple
exclusion rule that two individuals that are homozygous for alternative alleles cannot have a parent-offspring relationship. A more complete assessment including likelihoods of all possible first, second and third-degree relationships has been proposed by Huisman (10). That work is aimed at reconstructing multigenerational pedigrees with a reduced number of SNPs. However, the use of Huisman’s (10) approach with full arrays either at high or low density is computationally impractical with today’s computer capacities. In addition, our approach based on many thousands of SNPs allows accurate estimation of genotyping errors and identification of SNPs wrongly rejecting many true parent-offspring relationships.

Conclusions
SNP arrays can be used to test or to verify paternities using the rate of rejection of first-degree relationships. The same material can be used to estimate genotyping errors due to the large number of SNPs tested in parent-offspring relationships. This approach helps to identify SNPs inconsistent with Mendelian rules of inheritance in multiple parent-offspring relationships.

Ethics approval and consent to participate

Funding
Genotyping was financed by National Spanish project AGL2016-75942-R (IBERFIRE).

Availability of data and materials
The genotype files generated and/or analyzed for the current study are available at Zenodo with DOI 10.5281/zenodo.5255900.

Author’s Contributions
LGR wrote the EM algorithm and analyzed the genotypic data; LGR and WR wrote the first version of the manuscript; EGI and EP run the experimental farm, took samples and contributed to the writing of the manuscript. FGR did all laboratory work and sample preparation. All authors read and approved the final manuscript.

Legend of figures

Figure 1. Distribution of the rate of rejection for all relationship in a crossbred experiment.

Figure 2. Distribution of the rate of rejection of first-degree relationships within dam-offspring, sire-offspring, offspring-offspring, sire-sire, dam-dam, and sire-dam relationship groups in a crossbred experiment.

Figure 3. Convergence of the Expectation-Maximization algorithm to estimate first-degree relationships using A) Dam-Offspring and B) Sire-Offspring relationships, C) Offspring-Offspring.

Figure 4. Genome-wide number of rejections for SNPs rejecting true parent-offspring relationships.

Figure 5. Histogram of the number of times a given SNP is rejected true parent-offspring relationships.

Figure 6. Cluster for SNP Affx-115017537 that rejected 126 times true first-degree relationships.
Figure 1.
Figure 2.
Figure 3.
Figure 4.
Figure 5.

Number of times a given SNP is rejected in true parent-offspring relationships.
Figure 6.
