ABSTRACT

This is the second paper of a series reporting the results from the PopStar evolutionary synthesis models. Here we present synthetic emission line spectra of Hii regions photoionized by young star clusters, for seven values of cluster masses and for ages between 0.1 and 5.2 Myr. The ionizing Spectral Energy Distributions (SEDs) are those obtained by the PopStar code (Mollá, García-Vargas & Bressan, 2009) for six different metallicities, with a very low metallicity set, Z=0.0001, not included in previous similar works. We assume that the radius of the Hii region is the distance at which the ionized gas is deposited by the action of the mechanical energy of the winds and supernovae from the central ionizing young cluster. In this way the ionization parameter is eliminated as free argument, since now its value is obtained from the cluster physical properties (mass, age and metallicity) and from the gaseous medium characteristics (density and abundances). We discuss our results and compare them with those from previous models and also with a large and dataset of giant Hii regions for which abundances have been derived in a homogeneous manner. The values of the [OIII] lines (at λλ 4363, 4959, 5007Å) in the lowest metallicity nebulae are found to be very weak and similar to those coming from very high metallicity regions (solar or over-solar). Thus, the sole use of the oxygen lines is not enough to distinguish between very low and very high metallicity regions. In these cases we emphasize the need of the additional support of alternative metallicity tracers, like the [SIII] lines in the near-IR.

Key words: ISM: HII regions – ISM: abundances – ISM: evolution – ISM: lines and bands

1 INTRODUCTION

Hii regions have been widely studied for the last three decades (Pagel, Edmunds & Smith, 1980; Evans & Dopita, 1985; Dopita & Evans, 1986; Díaz et al., 1987; Vílchez et al., 1988). In those studies the functional parameters, such as ionization parameter, effective temperature of the ionizing stars and oxygen abundance, were translated into physical parameters associated to the star clusters (mass, age and metallicity). In order to do this, several grids using evolutionary models plus photoionization codes were computed by our group (García-Vargas & Díaz, 1994, García-Vargas, Bressan & Díaz, 1995, García-Vargas, Mollá & Bressan, 1998) and others (Stasińska, 1978, Stasińska et al., 1983, Stasińska et al., 1986, Stasińska et al., 1990).

In the last decade the evolutionary synthesis technique has been improved with the inclusion of updated stellar tracks or isochrones, the use of better stellar spectra as input for the codes, a better treatment of binary stars, a wider wavelength coverage and a higher spectral resolution. Codes like starburst99 (hereinafter stb99 Leitherer et al., 1999), use the Geneva group stellar tracks and are tuned for star forming regions. On the contrary codes like pegase (Fioc & Rocca-Volmerange, 1997) or galaxev (Bruzual & Charlot, 2003) are specially computed for intermediate and evolved populations and use the Padova group stellar tracks. These codes, among others, have been intensively applied to spectrophotometric catalogues to derive the physical properties of stellar populations.

The results of these codes, mainly the SEDs, have been used in turn by many authors to compute models for star forming regions, Hii and starburst galaxies, or have been applied to particular cases. Recently, a more realistic approach to the Hii region structure, and therefore the ionization bubble, has been considered to improve photoionization model results. Thus, Mov, Rocca-Volmerange & Fioc (2001) analyzed coherently the stellar and nebular energy distributions of starbursts and Hii galax-
ies, by using PEGASE in addition to the photoionization code CLOUDY (Feerland et al. 1998), constructing models in which the filling factor and the radius of the nebula are fixed to obtain a range of values of the ionization parameter similar to those derived from observations. Dopita et al. (2003) used both PEGASE and ST99 models to compute the SEDs of young star clusters. Main discrepancies between the SEDs of these two grids of models were driven by the different evolutionary tracks used, Padovà’s for PEGASE and Geneva’s for ST99. They studied the emission line sequence and computed the HII region spectra as a function of age, metallicity and ionization parameter using the photoionization code MAPPINGS v0.3 (Sutherland & Dopita, 1993; Dopita et al., 2003). Groves, Dopita & Sutherland (2004). More recently Dopita et al. (2006a) used ST99 plus MAPPINGS III to produce a self-consistent model. In this model they consider that the expansion and internal pressure of the HII regions depends on the mechanical energy from the central cluster, replacing the ionization parameter by a more realistic one dependent on cluster mass and pressure in the ISM. A similar approach has been used by Stasińska & Izotov (2003). In this work they calculate photoionization models of evolving starbursts by using as ionising continuum the SEDs from the code by Schaerer & Vacca (1998). These models were computed for different metallicities bins to compare with the corresponding metallicity observations, assuming the geometry of an adiabatic expanding bubble, instead of that of a region with a fixed radius (like in García-Vargas et al. 1995a,b; Stasińska & Leitherer, 1996).

The present work is the second paper of a series of three dedicated to the PopStar models description and initial test-cases application. PopStar is a new grid of evolutionary synthesis models described in Mollá, García-Vargas & Bressan (2008) hereinafter Paper I, where their suitability to model stellar populations in a wide range of ages and metallicities is shown. These models are an updated version of García-Vargas et al. (1995b), García-Vargas, Mollá & Bressan (1998) and Mollá & García-Vareas (2000). One of the main improvements of this new grid is a very careful treatment of the emerging spectrum of hot stars, which can be either massive stars or post-AGB objects. In previous works by our group (García-Vargas & Díaz, 1994; García-Vargas et al. 1995a,b) hot massive stars were modelled using the atmospheres of Cleee & Middelmass (1987). In the new PopStar SEDs, NLTE blanketed models for OB, WR stars by Smith, Norris & Crowther (2002) have been used. These models include a detailed treatment of stellar winds which modifies the final SEDs obtained for young stellar populations and consequently the emission line spectrum of the surrounding nebula.

Our aim in the present work is to compute a set of updated photoionization models, and therefore emission line spectra, for HII regions following the evolution of the ionizing young star cluster, whose SED is computed by the evolutionary synthesis models PopStar. We also compare these results with a sample of HII regions where the metallicity has been carefully derived through the use of appropriate calibrators.

This grid of models has been computed without taking into account the presence of dust and this imposes some limitations to its use. Our purpose is to compute a grid of models covering the range of physical parameters found in G6EHR where the dust effect is weak on the optical spectral lines, which are the ones computed in this work. However, in starburst galaxies, where star formation is taking place inside molecular clouds where the dust is present, its effect can be very important. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models. The dust will absorb a fraction of the emitted ionizing photons and therefore will affect the derived value the young cluster mass using dust-free models.

2 SUMMARY OF THEORETICAL MODELS

2.1 Evolutionary synthesis models.

The SEDs used in this work have been taken from the new PopStar evolutionary models (Paper I). The basic model grid is composed by Single Stellar Populations (hereinafter SSPs) for 6 different Initial Mass Functions (IMF) from which only those with a Salpeter power law (Salpeter, 1955) and different mass limits have been used here: 0.85M⊙, 1.2M⊙, 1.5M⊙, 10M⊙, 100M⊙ (hereinafter SAL1), 0.15M⊙, 1.05M⊙, 100M⊙ (hereinafter SAL2), and 1M⊙ and 100M⊙ (hereinafter STB). None of the models include either binaries or mass segregation.

Finally, we must mention that one of the main differences between the isochrones from Geneva and Padova groups is the inclusion of stellar rotation. Stellar rotation affects the evolutionary tracks, lifetimes, and chemical compositions of massive stars, as well as the formation of red super-giants and WR stars (Maeder & Meynet, 2008; Meynet & Maeder, 2003). In particular, the rotation of a star plays a determinant role at very low metallicities, producing high mass loss where almost none was expected, as explained by Ekström et al. (2008, and references therein). The revised grid of stellar evolutionary tracks accounting for rotation, recently released by the Geneva group, has been implemented into the ST99 evolutionary synthesis code in the preliminary models by Vázquez et al. (2007). Massive stars are predicted to be hotter and more luminous than previously thought, this effect being higher for decreasing metallicity. Individual stars now tend to be bluer and more luminous, increasing by a factor of 2 (or even more) the light-to-mass ratios at ultraviolet to near-infrared wavelengths, as well as the total number of ionizing photons. However, we have not taken this effect into account because we have used SEDs based in a set of revised isochrones from the Padova group. This revision affects mainly the computation of intermediate age stellar populations (RGB and ABB phases), and does not include rotation.

Section 2 gives a summary of our theoretical evolutionary synthesis and photoionization models, the inputs and the hypotheses assumed for the grid calculation. Section 3 shows our model results in terms of the time evolution of emission lines. In this section we also include the comparison with the previous models by García-Vargas et al. (1995a,b). In Section 4 we present a discussion of the models based on the comparison with observed emission line ratios which have been carefully compiled from the literature for objects whose abundances have been consistently re-calculated using the appropriate techniques. This section also includes the guidelines for deriving the physical properties of the ionizing star clusters through the analysis of the corresponding gas emission line spectra. Finally, our conclusions are given in Section 5.
Isochrones are an update of those from Bressan et al. (1998) for 6 different metallicities: 0.0001, 0.0004, 0.0008, 0.02, and 0.05 the lowest metallicity set being now added. The age coverage is from log \( t \approx 5.00 \) to 10.30 with a variable time resolution of \( \Delta (\log t) = 0.01 \) in the youngest stellar ages. The details of the isochrones are described in Paper I.

Atmosphere models are from Lejeune, Cuisinier & Buser (1997) with an excellent coverage in effective temperature, gravity, and metallicities, for stars with Teff \( \leq 25000 \)K. For O, B and WR the code uses the NLTE blanketed models by Smith, Norris & Crowther (2002) at Z = 0.001, 0.004, 0.008, 0.02 and 0.04. There are no models available for Z = 0.0001, 0.0004 and Z = 0.04. For these stars, we have selected the models with the closest metallicity, that is, Z = 0.04 for the isochrones with Z = 0.05 and Z = 0.001 for isochrones with Z = 0.0001 and 0.0004. The possible misselection for the lowest metallicities is not important for what refers to WR stars since, in principle, there are no WR at these lowest Z. This is in any case a limitation of the models: the grid for NLTE atmosphere models is not as fine as the LTE Lejeune. There are 110 models for O-B stars, calculated by Pauldrach, Hoffmann & Lennon (2001), with 25000K < Teff \( \leq 51500 \)K and 2.95 \( \leq \log g \leq 4.00 \), and 120 models for WR stars (60 WN and 60 WC), from Hillier & Miller (1998), with 30000K \( \leq T^\ast \leq 120000 \)K and 1.3R\(_{\odot}\) \( \leq R^\ast \leq 20.3R_{\odot}\) for WN, and with 40000K \( \leq T^\ast \leq 140000 \)K and 0.8R\(_{\odot}\) \( \leq R^\ast \leq 9.3R_{\odot}\) for WC. T\(^\ast\) and R\(^\ast\) are the temperature and the radius at a Roseland optical depth of 10. The assignment of the appropriate WR model is consistently made by using the relationships among opacity, mass loss and velocity wind described in Paper I.

For post-AGB and PN with Teff higher than 50000K and up to 220000K the NLTE models by Rauch (2003) are taken. For higher temperatures PopStar uses black bodies. The use of these last models affects the resulting intermediate age SEDs, which are not used in the present work.

2.2 Photoionization models for H\(_\alpha\) regions.

We have studied the evolution of a cluster along the first 5.2 Myr, in 21 steps of time. Clusters older than this age do not have the necessary ionization photons to produce a visible emission line spectrum, although they are still detectable on H\(_\alpha\) images.1 Ionizing clusters have been assumed to form in a single burst with different masses. We have run models assuming seven values for the total cluster mass, 0.12, 0.20, 0.40, 0.60, 1.00, 1.50 and 2.00 \( \times 10^4 \) M\(_{\odot}\), using SAL2 IMF (with \( m_{\text{min}} = 0.15M_{\odot} \) and \( m_{\text{max}} = 100M_{\odot} \)). Masses in this range are able to provide the observed number of ionizing photons of most medium to large extragalactic H\(_\alpha\) regions. Also, in order to compare with our old photoionization models we have used SAL1 IMF.

We have used the photoionization code CLOUDY (Ferland et al., 1998) to obtain the emission line spectra of the modelled H\(_\alpha\) regions for different metallicities. The gas is assumed to be ionized by the massive stars of the young cluster whose ionizing spectra have been taken from the PopStar SEDs computed in Paper I, as explained in the previous section. The SEDs are given for a normalized mass of 1 M\(_{\odot}\), hence the stellar mass of the cluster must be used to scale the number of ionizing photons and other absolute parameters given by PopStar for each IMF. The shape of the ionizing continuum, the number of ionizing photons, Q(H), and the H\(_\alpha\) region radius, R\(_{\text{ff}}\), set by the action of the cluster mechanical energy, are obtained directly from the ionizing cluster parameters: mass, age and metallicity.

The chemical composition of the gas and its spatial distribution, assuming a given geometry, together with the medium density, are used as inputs for the photoionization code. It is assumed that both the cluster and the surrounding gas have the same chemical composition. The solar abundances are taken from Grevesse & Sauval (1998). The use of these solar abundances implies that Z\(_{\odot}\) = 0.017 2 thus, Z = 0.02 of our models does not correspond to the solar value but to 1.17 Z\(_{\odot}\).

The solar abundances are summarized in Table 1. Column 2. Some refractory elements, Na, Al, Si, Ca, Fe and Ni, must be depleted due to the presence of dust grains mixed with the ionized gas which can affect the UV photon absorption and decrease the electronic temperature. Solar depleted abundances, obtained using Garnett et al. (1995) depletion factors, are in Column 3. For each metallicity, the element abundances heavier than helium have been scaled by a constant factor, with respect to the hydrogen content, according to the solar depleted abundances, as given in Columns 4 to 8 of the table.

The radius of the modelled region has been derived from the mechanical energy produced by the expanding atmospheres of massive stars with strong winds. Castor, McCray & Weaver (1975) demonstrated that an early-type star with a strong stellar wind can blow out a large cavity or bubble in the surrounding gas. The wind-driven shell begins to evolve with an initial phase of free expansion followed by an adiabatic expansion phase, and then the material shall collapse into a thin, cold shell as a result of radiative cooling. At this stage the gas shall trap the ionization front and thus the radiative phase begins. In this phase the ionizing photons are

---

1 See García-Vargas, Mollá & Martín-Manjón, in preparation, where we calculate the photometric properties of young star clusters taking into account the contamination by the emission lines and the underlying old populations where these clusters are embedded in the computed colors, for an analysis about the cluster physical properties determined from the photometric information only.

2 Asplund, Grevesse & Sauval (2005) obtained a solar abundance Z\(_{\odot}\) = 0.012. This value is still questioned (Bahcall, Serenelli & Basu, 2005; Drake & Testa, 2005; Antia & Basu, 2005) because it does not fit the helioseismological constraints.
absorbed and the region cools via emission in the Balmer lines. In this process, the radius of the outer shock, $R_s$, evolves as:

$$R_s = 1.6(\epsilon/n)^{1/5}t^{3/5}(pc)$$

$\log L_{H\alpha} = 2.16 \times 10^{10} \text{ergs}^{-1}$
where $\epsilon$ is the total injected mechanical energy (SN and stellar winds) per unit time in units of $10^{56}$ ergs s$^{-1}$, $n$ is the interstellar medium density in units of cm$^{-3}$, and $r$ is the age of the shell in units of $10^4$ yr. Since we use the value of the energy at each time-step, this radius represents the instantaneous size of the region obtained by adding the energy produced by stellar winds and SN from one time step to the next. Therefore $\epsilon$ is this energy divided by the time step. We have used the radius given for each time $r$ and $1$ M$_\odot$ in Table 4 from Paper I, scaled to the stellar cluster mass of each model extrapolating this bubble geometry to a shell structure formed by the combined effects of the mechanical energy deposition from the massive stars winds and SN explosions belonging to the ionizing cluster. The ionized gas is assumed to be located in a thin spherical shell at distance $R_s$ from the ionizing source. This approach has the advantage of eliminating the ionization parameter as a free parameter in the models, being now computed from the physical properties of the evolving young cluster. This radius is still large enough when compared to the shell thickness as to validate the approximation of a plane-parallel geometry.

The hydrogen density has been considered constant throughout the nebula and an ionization-bounded geometry has been assumed, with the hydrogen density equal to the electron density for complete ionization (Case B of H recombination). We have computed models with two different values of $n_H$: 10 cm$^{-3}$ and 100 cm$^{-3}$, in order to check the density effect on the emitted spectrum. A density of 10 cm$^{-3}$ is representative of small-medium isolated HII regions (Castellanos et al. 2002; Pérez-Montero & Díaz 2005), while 100 cm$^{-3}$ is more appropriate for modelling HII galaxies (Hägele et al. 2008) and large circumnuclear HII regions (García-Vargas et al. 1997; Díaz et al. 2007), frequently found around the nuclei of starbursts and AGNs. Although the constant density hypothesis is probably not realistic, it can be considered representative when the integrated spectrum of the nebula is analyzed.

Using the number of ionizing photons, Q(H), the nebula size, $R_s$, and the hydrogen density, $n_H$, we can obtain the ionization parameter, $u$, given by:

$$u = \frac{Q(H)}{4\pi n_H R_s^2 c}$$

where $c$ is the speed of light. Under these assumptions, the parameter $u$ recovers its physical meaning since it is directly derived from the physical cluster’s properties. Hence, for a given IMF and $n_H$, each model is computed as a function of the cluster mass, age and metallicity. The values of $u$ derived for our set of models are within the range of observed values for HII regions.

Since the current set of models have been computed for medium to large extragalactic HII regions, whose measured reddening is usually very low and often consistent with the galactic reddening, we have not included dust effects, as explained before, except for the abundance depletion. Only when these models are used for obscured compact HII regions or for large star forming regions like starbursts galaxies, dust effects should be taken into account.

3 RESULTS

3.1 Emission lines.

Once the photoionization code is applied, we obtain the emission line spectra of the associated HII region produced by the ionizing cluster for every set of models. We have followed the evolution of the emitted spectrum during 5.2 Myr after the cluster formation. After this time, no emission line spectrum is produced due to the lack of ionizing photons. In the present study we have considered only the most intense emission lines in the optical spectrum which dominate the cooling for moderate metallicities. In higher (over solar) metallicity regions the cooling is shifted to the infrared.

The models results, assuming a SAL2 IMF for all masses and metallicities, are summarized in Table 2a and b), for values of $n_H$ o 10 cm$^{-3}$ and 100 cm$^{-3}$ respectively. Listed in columns 1 to 3 are: Z (metallicity), logarithm of the age in years, cluster mass (in M$_\odot$); in columns 4 to 20 we give the intensities relative to H$_\beta$ of the following lines: [OIII]$\lambda$3727, [OIII]$\lambda$5007, [OII]$\lambda$4959, [OIII]$\lambda$4363, [OI]$\lambda$6300, [NII]$\lambda$6584, [NII]$\lambda$6548, [SII]$\lambda$6716, [SII]$\lambda$6731, [SIII]$\lambda$6312, [SIII]$\lambda$9069, [SII]$\lambda$9532, [NeIII]$\lambda$5007, He I$\lambda$4471, He II$\lambda$4686, He II$\lambda$6583, He II$\lambda$6678; finally, in columns 21 to 23 we list the logarithm of the intensity of H$_\beta$ in erg s$^{-1}$ (log$\lambda$), the logarithm of the ionization parameter (log $u$) and the ionized region radius in pc ($R_s$).

Part of Table 2 for $Z$=0.008 and a cluster mass of $4\times10^5$ M$_\odot$ is shown as an example. The complete tables are available in electronic format.

3.2 Comparison with previous models

In order to evaluate the effect of the changes incorporated into the new models we have compared our present results with the previous ones given by García-Vargas et al. (1995a) by computing a set of models using the same input abundances and the same assumptions for the ionization parameter as in García-Vargas et al. (1995c). In those models the ionization parameter was calculated with a fixed radius of log $R_s$(cm) = 20.84. The results are shown in Fig. 1 where the emission line ratios as a function of the ionization parameter log $u$, for $Z = 0.02$ at ages of 2 Myr, 3 Myr, 4 Myr and 5 Myr can be seen. We have plotted the results for the following emission lines: [OIII]$\lambda$3727, [OIII]$\lambda$5007, [OII]$\lambda$6300, [NII]$\lambda$6584, [SII]$\lambda$6716 and [SIII]$\lambda$9069. In these figures, the dotted lines correspond to the models from García-Vargas et al. (1995b) while the solid lines correspond to the models presented here.

We can see that, in general, the emission lines resulting from García-Vargas et al. (1995b) models are more intense than in the models computed in the present work for the same value of the ionization parameter. This is due to the use in the new set of models of NLTE blanketed atmosphere models for massive stars, which produce fewer hard ionizing photons. This new set of models explains in a natural way the emission line ratios found in low excitation high metallicity HII regions, as we will show in Section 4 and therefore do not require ad hoc explanations to keep the number of hard ionizing photons to the observed values.

3.3 Emission-line evolution

In this work we follow the evolution of a given cluster during 5.2 Myr from their formation. After this time, in most cases and depending on metallicity, the gaseous emission lines are too weak to be measured due to the paucity of ionizing photons.

Figs 2a to 2c show the time evolution of the H$_\alpha$ luminosity and several emission line ratios, as labelled, selected to represent the most relevant ionization stages of the most common elements: [OIII]$\lambda$5007,4959/H$_\alpha$, [OII]$\lambda$3727/H$_\beta$, [OIII]$\lambda$3727/[OII]$,\lambda$5007,4959, [OII]$\lambda$6300/H$_\alpha$ and [NII]$\lambda$6584/H$_\alpha$ for models of different metallicity, computed with SAL2 IMF.
PopStar Models II: Optical emission-line spectra from H\textsc{ii} regions

Figure 1. Evolution of emission lines at Z = 0.02 and SAL1 IMF for n\textsubscript{H} = 10\,cm\textsuperscript{-3} and log R(cm) = 20.84. Dotted lines correspond to old models by García-Vargas et al.\textsuperscript{(1995b)} while solid lines correspond to new models.

Figure 2. a). Evolution of the H\textalpha\ luminosity and five emission line ratios for Z = 0.0001 (SAL2). The ratios are [OIII]\textlambda\lambda\,5007,4959/H\beta, [OII]3727/H\beta, [OII]/[OIII], [OI]6300/H\alpha and [NII]6584/H\alpha. The more appropriate hydrogen recombination line has been chosen for normalization in order to minimize reddening effects. Solid lines correspond to models with n\textsubscript{H} = 10\,cm\textsuperscript{-3} while dotted lines correspond to models with n\textsubscript{H} = 100\,cm\textsuperscript{-3}. Black, red, green, blue, yellow, brown and grey lines correspond to different cluster masses: 0.12, 0.20, 0.40, 0.60, 1.00, 1.50 and 2.00 × 10\textsuperscript{5}\,M\odot, respectively.

In each figure, different colours correspond to a different cluster masses, from 0.12 × 10\textsuperscript{5} to 2 × 10\textsuperscript{5}\,M\odot. The two different density cases, n\textsubscript{H}=10\,cm\textsuperscript{-3} and n\textsubscript{H}=100\,cm\textsuperscript{-3}, are represented by solid and dashed lines, respectively.

For the lowest abundance models (Z< 0.0001) emission line ratios involving oxygen lines are very weak (note the different scale in each metallicity panel) and its evolution is smooth. For intermediate metallicity cases, the emission lines are intense, increasing with cluster mass.

In the first Myr of the evolution, the [OIII]\textlambda\lambda\,5007,4959 lines
are intense and then they decrease to rise again at 3-4 Myr, due to the presence of WR stars, that makes the equivalent effective temperature of the cluster become higher and causes an increase of the excitation during a short time. The appearance of the WR features and their duration depends on the mass and metallicity of the cluster as discussed in Paper I. The [OII]λ3727 line shows moderate variations with metallicity. The [OII]/Hβ ratio increases after 3 Myr of the star formation, being almost constant for low metallicity models, before this age. As a result, the [OII]/[OIII] ratio is very low for all metallicities at ages younger than 4 Myr. The oxygen emission lines are most intense for models with Z=0.004. We will come back to the oxygen line evolution in the next section, when studying the diagnostic diagrams.

The low ionization line [OI]λ6300 is an indicator of the presence of strong winds and supernovae (Stasińska & Leitherer, 1996), and therefore, a burst age indicator. On the sole basis on the photo-ionization models, the intensity of this line increases with cluster age and [O/H] abundance, therefore it shows higher val-

**Figure 2.** b). Evolution of emission lines for Z = 0.0004 (SAL2). Different colors and line code have the same meaning as in Fig. 2a.

**Figure 2.** c). Evolution of emission lines for Z = 0.004 (SAL2). Different colors and line code have the same meaning as in Fig. 2a.
ues in old, evolved and high metallicity H\textsc{ii} regions. The addition of shock contributions (not included in our models), would render this value even higher.

Finally, the [NII]λ6584/H\alpha line intensity ratio, which is in principle a good metallicity indicator, increases with increasing metallicity, even for regions with metallicities higher than $Z=0.004$.

We have also produced photoionization models for ages older than 5.2 Myr (until 10 Myr) for the lowest metallicity cases, $Z=0.0001, 0.0004$ (see Fig. 3). The lower the metallicity, the hotter the ZAMS and the longer the time spent by stars in the ZAMS. Hence, for the lowest metallicity clusters ($Z=0.0001, 0.0004$) we have explored the evolution further, to 10 Myr. However, the ionization parameters obtained are low, producing very weak (and sometimes undetectable) emission lines from high-ionization stages, like [OIII], specially for the lowest masses. Of course, these regions do exist and produce a low-ionization spectrum, with observable [OI]...
Figure 3. The ionization parameter as a function of age (beyond 5.2 Myr) for a 1 × 10^5 M⊙ cluster, low metallicities (Z = 0.0001 and Z = 0.0004), and n_H = 10 cm⁻³.

Figure 4. Extended evolution (up to 10 Myr) of the Hα luminosity and five emission line ratios: [OIII]λ5007,4959/Hα, [OII]λ3727/Hα, [OII]/[OIII], [OI]λ6300/Hα, and [NII]λ6584/Hα, for a 1 × 10^5 M⊙ cluster, with Z=0.0001 (SAL2) and n_H = 10 cm⁻³.

Figure 5. Extended evolution (up to 10 Myr) of the Hα luminosity and five emission line ratios: [OIII]λ5007,4959/Hα, [OII]λ3727/Hα, [OII]/[OIII], [OI]λ6300/Hα, and [NII]λ6584/Hα, for a 1 × 10^5 M⊙ cluster, with Z=0.0004 (SAL2) and n_H = 10 cm⁻³.

Figure 6. The [SII]λ6717,31/Hα line ratio vs age (in Myr) for low metallicities (Z=0.0001 and Z=0.0004) and all masses. Solid lines join models with Z=0.0001 while dotted lines join models with Z=0.0004. Different colors correspond to different values of the cluster mass. Models with values of n_H = 10 cm⁻³ have been plotted in the upper panel while models with n_H = 100 cm⁻³ have been plotted in the lower one.

and [OII] and [NII] lines but negligible [OIII] line intensities which place them out of the plotted area of the diagnostic diagrams used in this work. Figures 4 and 5 illustrate this fact showing the results of the photoionization models for the 10 Myr evolution of a ionizing cluster of 1 × 10^5 M⊙ and a density of n_H = 10 cm⁻³ for two metallicities: Z=0.0001 and Z=0.0004.

Figs. 6 and 7 show the resulting sulphur emission line ratios: [SII]λ6717,31/Hα and [SII]λ6717,31/[SIII]λ9069,9532, as a function of the burst age. Sulphur line ratios were proposed as ionization parameter indicator by Díaz et al. (1991) and calibrations based on photoionization models at different metallicities were presented in ???. We have carried out a recalibration of this parameter using the models presented here that is detailed in Appendix A. Since the ionization parameter is directly related to the stellar cluster age, as suggested by García-Vargas et al. (1995a), we propose to use these sulphur lines as age indicators for Hα regions. Fig. 6 shows the [SII]λ6717,31/Hα ratio for the lowest metallicities (Z=0.0001 and Z=0.0004) and all masses. Models with different values of n_H have been plotted in different panels. For a given metallicity, the plot shows that the line ratios involving the sulphur lines are low and rather constant during the first 3 Myr of evolution. From 3 to 5 Myr, they increase smoothly with age for all cluster masses. The line ratios also increase with cluster mass at a given age but cluster mass can be constrained via the derived number of ionizing photons from Balmer line luminosities.

3.4 Emission line intensities and the ionization parameter.

Figs. 8 a) to e) show the intensity, with respect to Hα of the following emission lines: [OIII]λ3727, [OIII]λ5007, [OII]λ6300, [NII]λ6584, [SIII]λ6713, [SIII]λ9069 vs log u, obtained from the computed models, for metallicities Z = 0.0001, 0.0004, 0.004, 0.008 and 0.02. In each figure four panels are shown for ages of 2 Myr (top left), 3 Myr (top right), 4 Myr (bottom left) and 5 Myr (bottom right). Solid lines correspond to n_H = 10 cm⁻³ models while dotted lines correspond to n_H = 100 cm⁻³. In total 7 points per line are shown corresponding to 7 values of the cluster mass: 0.12, 0.20, 0.40, 0.60, 1.00, 1.50 and 2.00 ×10^5 M⊙. We can see in the figures that models with n_H = 10 cm⁻³ and 100 cm⁻³ follow the same trend, and cover different ranges of the ionization param-
For a given metallicity, the changes in the emission line spectrum and in the ionization parameter are due to the changes in the cluster mass, which determines the number of ionizing photons, and in the cluster age, which influences not only the total number of ionizing photons but also the overall ionization spectrum hardness and the ionized region size. For example, the \([\text{OIII}]\lambda 5007\) line is intense during the first few Myr of the cluster evolution, for all metallicities, and then it decreases, to rise again at 4 Myr due to the presence of WR stars that produces a harder ionizing continuum.

From our models we predict an intrinsic sizing effect in the \(\text{HII}\) region evolutionary sequence, which implies a natural decreasing of the ionization parameter. For a very young region whose ionization is dominated by the O-B stars, the size is still small but the number of ionizing photons is high, resulting in a high ionization state value, with this being higher, as expected, for the lower density case.

Figure 8. a). Evolution of emission line intensities, as labelled, normalized to the \(\text{H}\beta\) intensity for \(Z = 0.0001\) (SAL2) models as a function of the logarithm of the ionization parameter. Solid lines correspond to models with \(n_H = 10\ \text{cm}^{-3}\) and dotted lines correspond to models with \(n_H = 100\ \text{cm}^{-3}\).

Figure 8. b). Same as Fig. 8 but for \(Z = 0.0004\).
parameter. As the cluster evolves, the region size increases due to the stellar winds, but the number of ionizing photons decreases only slightly producing a decreasing ionization parameter, and therefore lower intensity lines. For the highest metallicities, this effect is more remarkable. High metallicity regions have less ionizing photons and more intense winds therefore implying a lower ionization parameter. In addition, the effective cooling of the gas is transferred from the optical emission lines to the near and mid infrared ones as metallicity increases. These two facts explain the fact that in high metallicity regions, the optical emission lines are extremely weak, reaching in most cases only about one per cent of the \( \text{H}_\beta \) line intensity. These lines are difficult to detect and this fact has biased the observational samples during a long time towards regions of a restricted metallicity range which has important implications for the interpretation of photometric samples of \( \text{H}_\alpha \) regions.
PopStar Models II: Optical emission-line spectra from H\textsubscript{ii} regions

4 DISCUSSION

4.1 Observational Data

We have used first a compilation of data on H\textsubscript{ii} galaxies, high and low metallicity H\textsubscript{ii} regions, and circumnuclear star forming regions (CNSFR), with emission line intensities measured both for the auroral and nebular [SIII] lines at $\lambda 6312$ and $\lambda \lambda 9069,9532$ respectively. The data for CNSFR can be found in Diaz et al. (2007) where the appropriate references for the rest of the objects in the compilation can also be found. For all the regions, the electron density has been derived using the [SII] ratio (Osterbrock, 1989).

For this sample, metallicities have been derived following standard techniques in the cases in which electron temperatures could be derived. Otherwise, an empirical calibration based on the $S_{23}/O_{23}$ parameter (see Diaz et al. (2007)) has been used.

Data from Castellanos et al. (2002a) correspond to H\textsubscript{ii} regions in the spiral galaxies: NGC628, NGC925, NGC1232 and NGC1637. The H\textsubscript{ii} regions have been splitted by density, which was derived from the [SII] ratio. For seven regions, ion weighted temperatures from optical forbidden auroral to nebular line ratios were obtained, and for six of them oxygen abundances were derived using empirical calibration methods. For the rest of the regions, metallicities have been estimated from the $S_{23}$ calibration (Pérez-Montero et al., 2006) and tailored photoionization models.

García-Vargas et al. (1997) give data of 4 H\textsubscript{ii} giant circumnuclear regions of NGC 7714. As usual, densities were derived from the [SII] lines. Oxygen abundances were obtained by the electron temperature method thanks to the direct detection of the [OIII] $\lambda 4363$ line.

Zaritski, Kennicutt & Huchra (1994) made an analysis of 159 H\textsubscript{ii} regions in 14 spiral galaxies, from which we have chosen those that have well measured [SII] $\lambda \lambda 6717,31$ and [SIII] $\lambda \lambda 9069,9532$ emission lines to obtain the density and the oxygen abundance through the $S_{23}$ parameter (Pérez-Montero et al., 2006). This reduces the number of H\textsubscript{ii} regions to 36.

We have also taken data from van Zee & Haynes (2006), corresponding to 67 H\textsubscript{ii} regions in 21 dIrr. They provide the emission line intensities of the [OII] $\lambda 3727$, [OIII] $\lambda \lambda 5007,4959$ and [SII] $\lambda \lambda 6717,31$ lines. In addition they also provide the [SII] line ratio, which we have used to derive the electron density. The [OIII] lines have been used to obtain the electronic temperature and consequently the oxygen abundance.

Data from Izotov & Thuan (2004) consist of H\textsubscript{ii} regions in 76 blue compact dwarfs (BCD) galaxies whose abundances have been derived using electron temperatured from the ratio of the nebular to auroral lines [OIII] lines. All the regions of this sample have
oxygen abundances lower than 12 + log(O/H) = 8.5. Data have been separated by density by means of the [SII] line ratio.

Finally, Yin et al. (2007) provide data for 531 galaxies and HII regions from the SDSS-DR4 sample, from which the [OIII] λ4363 line has been measured and the oxygen abundances have been derived by standard methods. These data do not include the [SII] lines and hence no electron density could be derived. The different observational data sources and the method used to derive the oxygen abundances are summarized in Table 4.

| Label | Observed Metallicity Range | Z in plotted models |
|-------|---------------------------|---------------------|
| 1     | 12+log(O/H) < 7.7         | 0.0004              |
| 2     | 7.7 < 12+log(O/H) < 8.4   | 0.0040              |
| 3     | 8.4 < 12+log(O/H) < 8.7   | 0.0080              |
| 4     | 8.7 < 12+log(O/H)         | 0.0200              |

4.2 Diagnostic Diagrams: optical emission line ratios

We have plotted together the model results and the observational data in different diagnostic diagrams in figures 9 to 12. These diagrams can be used to study the relationship among different emission line ratio and to extract information about the physical parameters of the ionizing clusters.

Each figure is divided in 4 panels, one per metallicity: Z = 0.0001 and 0.0004 (top left panel), 0.004 (top right panel), 0.008 (bottom left panel) and 0.02 (bottom right panel). The highest metallicity value of the grid, Z = 0.05, has been excluded due to the absence of spectroscopic data with those high abundances. The lowest metallicity model tracks are plotted in the same panel as those corresponding to Z = 0.0004 to compare the position in the diagram of the emission lines of such low metallicities. Solid and dotted lines represent models with n_H = 10 cm⁻³ and n_H = 100 cm⁻³ respectively. In each panel the model metallicity is the central value of the different ranges, except for ranges 1 and 4 that include data with metallicities lower than Z = 0.0004 and higher than Z = 0.02 respectively. Different line tracks correspond to the evolution of the models with different cluster masses, from the lowest one on the right to the highest on the left. The observational data, taken from different sources as explained in the previous section, whose derived metallicities are in range of the models we want to compare with, are shown in each panel. They have been divided by density and subdivided by metallicity according to the ranges given in Table 4.

The HII regions plotted here describe a well defined sequence in diagnostic diagrams which involve oxygen line ratios, like log([OIII]/Hα) vs log([OII]/Hα) and log([OIII]/Hα) vs log([OII]/[OIII]) (Fig. 9 and Fig. 10). Most of the observed regions are located in the panels corresponding to Z = 0.004 and Z = 0.008 since few data exist for very low or oversolar metallicities. In fact, this is a bias effect since most popular HII regions have been detected and catalogued through their high intensities of the [OIII] λλ5007,4959 lines, which happen in medium-low metallicity. Furthermore, it is at these metallicities, Z = 0.004 and Z = 0.008, that a direct measurement of the [OIII] λ4363 line, used to derive the oxygen abundance, is possible.

Models of Z = 0.0001, 0.0004 and Z = 0.02 do not have the aim of reproducing exactly the observation sequence but should be understood as metallicity limits for the observed regions. Observational data in these panels correspond to regions with metallicities lower than 12+log(O/H) = 7.7, in the first panel (upper-left), or higher than 12+log(O/H) = 8.7 in the last panel (bottom-right), as summarized in Table 4.

There are no observational data with Z < 0.0004. These regions have very low values of the [OIII] λ4363 line, undetectable with moderate size telescopes and standard S/N values, and therefore their abundances have not been derived.

Our models predict that very low metallicity regions have small sizes in Hα images where most of these HII regions are catalogued and therefore observational samples can be seriously biased towards medium to large size HII regions with metallicities Z > 0.001 (see Section 4.4 and fig. 13 for a detailed discussion). For high metallicities, the [OIII] λ4363 line is not strong enough to be detected at a level of T_e determination and abundances have been derived through alternative methods as already described.

Our models cover the observational data range corresponding to different cluster masses. Different masses imply different numbers of ionizing photons and hence different values of the ionization parameter. These values decrease with time as the clusters evolve. The models involving the most massive stellar clusters have the highest ionization parameters, due to their higher number of ionizing photons at a given age. Less massive clusters follow a similar time evolution to the most massive ones, but starting at a lower initial value.

As explained before, regions with intense [OIII] λλ5007,4959/Hα line ratios correspond to the highest ionization stages. For a given cluster mass, as the cluster evolves, the high excitation emission lines tend to decrease while [OII]/Hα increases. This is due to the change of the ionization parameter with cluster evolution. For a very young region, whose ionization is dominated by O-B stars which produce a great amount of ionizing photons, the size is still small, and the resulting ionization parameter is high. As the cluster evolves, the region size increases due to the stellar winds while the number of ionizing photons remains almost constant (or even decreases) with respect to early phases. This effect makes the ionization parameter, hence the emission line intensities and in particular the oxygen lines, to decrease.

This evolution influences also the data sample since early ages result in more compact regions (therefore high surface brightness) with high ionization parameters. Thus, the emission line intensities of the [OIII] λλ5007,4959 lines are higher, increasing their detectability in a given sample obtained with the same instrumental configuration. In fact, most of the derived ages for those regions would be younger than 5 Myr, when they emit enough ionizing photons to produce a detectable Hα luminosity and from those, most of them would be biased towards younger ages (less than 3.5 Myr).

In all Figs. 9 to 13 there are not observations found in the tail of our models with high [OIII] λλ5007,4959 line intensities. These values imply very low ionization parameters, that indicates more diffuse regions with low excitation. Since in most samples only the brightest HII regions have been selected, due to their conspicuous Hα emission or their high values of the [OIII] λλ5007,4959 line intensities the lowest excitation regions tend to be excluded. Some of these regions could also be older low metallicity regions (in the age range from 5 to 10 Myr, see Figs. 9 and 10).

The influence of the electron density, although of second order, should also be considered. The models with n_H = 100 cm⁻³ show lower values of the ionization parameter. However, the radiation has more particles per cm⁻³ to ionize, and the excitation
Figure 9. Diagnostic diagram showing $\log([\text{O}III]_{\lambda\lambda 5007,4959}/[\text{H}\beta])$ vs $\log([\text{OII}]_{\lambda 3727}/[\text{H}\beta])$ for models computed with SAL2 IMF. Each panel shows models for a different metallicity and the corresponding observational data in that metallicity range. Observational data come from: Zaritski, Kennicutt & Huchra (1994) (circles), Izotov & Thuan (2004) (squares), Castellanos et al. (2002) (diamonds), van Zee & Haynes (2006) (triangles up), García-Vargas et al. (1997) (red triangles down), and Díaz et al. (2007) (asterisks of different colours: black: CNSFR; green: high metallicity HII regions; brown: low metallicity HII regions; magenta: HII galaxies). Filled symbols represent objects with $n_{\text{H}} = 100 \text{cm}^{-3}$, while open symbols have $n_{\text{H}} = 10 \text{cm}^{-3}$, for data whose density has been obtained from the [SII] ratio.

degree is higher, producing model sequences shifted upwards from the lower density ones. More significant differences between models of different densities are found in the highest metallicity diagrams (Z=0.02).

4.3 Sulphur and nitrogen emission line ratios.

Diagnostic diagrams involving \(\log([\text{NII}]\lambda 6584/H\alpha)\) and \(\log([\text{SII}]\lambda 6717,31/H\alpha)\) ratios have the advantage of using lines very close in wavelength, and therefore virtually reddening-free.

In large star forming regions, like starburts galaxies, the relationship between the excitation parameter \([\text{OIII}]\lambda 5007,4959/H\beta\) and the metallicity indicator \([\text{NII}]\lambda 6584/H\alpha\) gives us information about the youngest populations plus the star formation rate (Kennicutt, Tamblyn, & Congdon 1994). At the beginning of the evolution H\(\alpha\) emission is intense and comes from the ionizing photons produced by the most massive stars, most of them still in the main sequence. This number of ionizing photons increases with the cluster mass and decreases with metallicity. As the galaxy evolves, the H\(\alpha\) emission line decreases, while the [NII]\lambda 6584 line increases because of the gas ejection by stars.

The [NII]\lambda 6584/[OII]\lambda 3727 ratio was introduced as a good metallicity indicator by Dopita et al. (2000). Nitrogen is a secondary element, or, at least, it has a strong secondary component, which makes the ratio [NII]/[OII] to increase with metallicity. Besides, the value of the mean temperature of H\(\text{II}\) regions decreases as metallicity increases. When metallicity rises, the electron temperature becomes too low to excite the O\(^+\) transitions, hence [OII] decreases while [NII] does not, thus increasing the [NII]/[OII] ratio. A good correlation has been found between [NII]/[OII] and the N\(^+\)/O\(^+\) ionic abundance ratio, which is assumed to trace the N/O ratio (Pérez-Montero & Díaz 2005). Also, Díaz et al. (2007) have shown that a very tight correlation between [NII]/[OII] and N/O exists for high metallicity H\(\text{II}\) regions and circumnuclear star forming regions, which follow a sequence of increasing N/O ratio with increasing emission line ratio.

In our diagnostic diagrams of Fig. 12 we can see how this ratio changes with metallicity. For low metallicity models, both the [OIII]/H\(\beta\) ratio and [NII]/[OII] ratio are low. As metallicity increases both line ratios also increase. When metallicity reaches the limit of Z=0.01, [OIII] starts to decrease while [NII]/[OII] ratio is still growing. At Z=0.02 the models show low values of [OIII] and high values of [NII]. The only available observational data in this part of the plot are high metallicity H\(\alpha\) regions and CNSFR, show-
ing high values of [NII]/[OIII], which indicate high N/O abundance ratios, as can be seen in the sequence of Diaz et al. (2007).

Regarding the nitrogen abundance, it is well known that N is mainly primary for low metallicities and it is always possible to scale the N abundance that we include as input in clowd by using a given function, such as the one obtained by Mollá et al. (2006) for the relationship of N/O vs O/H. However, we remark that in the models presented in this paper, we use SSP models where chemical evolution has not been taken into account, either for N or for the other elements as Fe or Ca. The nitrogen abundance has been scaled to the solar value as it has been done for the rest of the elements. Each element has its own evolution and in order to take this into account it is necessary to make precise calculations following a consistent method. This method can be seen in our previous works (Martín-Manjón et al. 2008; Martín-Manjón 2009) where we present photoionization models that use as input abundances the results obtained from chemical evolution models.

Finally, Fig. 13 shows the [SII]λ6717;31/Hα ratio vs [OIII]λ5007;4959/Hβ also almost reddening-independent. We can see that high values of the [SII]λ6717;31 line imply a low ionization parameter, and therefore a low [OIII] emission line intensity. However, the [OIII]λ5007;4959 lines are very metallicity dependent, and a low intensity of this emission line could be due to a high metallicity rather than to a low ionization parameter produced by an evolved population. Although both ratios are indicators of the ionization parameter, the values of Hα derived from oxygen emission line ratios can be lower than the values derived from sulphur emission line ratios, which are not so metallicity dependent.

4.4 Abundance determinations in Hα regions and model consistency

Emission lines allow the determination of abundances by a direct method based on the electronic temperature, T_e, derived from suitable emission lines from which those of [OIII] are the most popular. We have obtained oxygen abundances from the modelled emission lines in order to check which is the most effective method to recover the oxygen abundance used as input for the models. An accurate analysis requires the detection of the auroral line [OIII]λ4363 with an intensity larger than 5 per cent of H_e.

Fig. 14 shows the evolution of the [OIII]λ4363/H_e ratio for each metallicity, n_H=10, and for cluster masses of 0.12, 0.20, 0.4, 0.6 and 1×10^5 M_⊙. This ratio is high for Z=0.0004 and Z=0.004, close to 5 per cent of H_e in the first Myr of the evolution. However, for both, Z=0.0001 and Z=0.008, [OIII]λ4363/H_e has comparable values and below standard detection limits. Thus, the non detection of this line can indicate either a high metallicity or a low oxygen content. For Z=0.02 there is no [OIII]λ4363 line produced for this density case.

Fig. 15 shows the comparison between model oxygen abundances and the ones obtained by empirical methods. It can be seen that, from our photoionization models, we obtain the auroral line [OIII]λ4363 along the whole cluster evolution for metallicities in the range 0.0001< Z < 0.008. The [OIII] line electron temperature method gives good results for all of them, with differences lower than 0.05 dex between input and derived abundances.

At Z = 0.008, corresponding to an oxygen abundance of 12+log(O/H) =8.5, the [OIII]λ4363 line intensity range goes from 1.62 per cent of the H_e intensity 1 Myr after the star formation, to 0.82 per cent 4 Myr after the burst. However, despite this line being detectable at this metallicity, the electronic temperature method is not able to reproduce the input metallicity of the model. Simple photoionization models are not able to reproduce the derived T_e in some situations. Stasińska (1972, 2002, 2005) showed that for high metallicity Hα region models, the oxygen abundance derived from predicted emission line ratios and the T_e-method is lower than the one used as input in the models. These differences may be significant when large temperature gradients or fluctuations are present. In these cases, the temperature obtained from the emission line, T_e(OIII), is different from that derived from the [OIII] line ratio, T_e, and from the average ionic temperature T(O^+) (with T_e(OIII) and T_e obtained from the models not being the representative temperature of the high ionization O^+ zone. Fig. 16 shows a plot similar to Fig.1 of Stasińska (2005) comparing a sequence of model derived oxygen abundances as a function of the input values. In this diagram, we can see that both sets of values coincide for low metallicities; for metallicities around 8.6 however, deviations become notorious and for higher metallicities the deviations are much more significant.

The abundances analysis in high metallicity Hα regions is hampered by the fact that oxygen optical lines act as main coolant for the nebula, hence a higher oxygen abundance leads to a more effective cooling. As the gas cools down, the electron temperature gets lower and the optical [OIII] forbidden lines get weaker. In general, this low excitation makes any temperature-sensitive lines in the optical range too weak to be measured. For this reason empiri-
versus the age of the ionizing star cluster. Lines in orange, black, and this process is controlled by the metallicity. In the worst case, the ionized nebula. The time step in our models corresponds to the electron temperature (given by the metallicity). This is clearly seen in Fig. 17 where dotted and solid lines overlap and the ionized region age is almost constant along the cluster evolution. According to the computed models, the average equilibrium age is reached around \( t_{eq} = 13.6, 3.1, 0.2, 0.1 \) and 0.05 Myr for metallicities \( Z = 0.0001, 0.0004, 0.004 \) and 0.02 respectively. Solid lines refer to models for a cluster mass of \( 1 \times 10^5 \, M_\odot \) while dotted lines to models for a cluster mass of \( 0.12 \times 10^5 \, M_\odot \).

A first conclusion to be extracted from this graph is that the age of the ionized region does neither depend on the cluster mass nor on the cluster age but it is controlled by the metallicity. This implies that neither the total number of ionizing photons nor the ionizing spectrum shape have a significant role in setting the equilibrium time of the ionized regions, which is controlled by the electron temperature (given by the metallicity). This is clearly seen in Fig. 17 where dotted and solid lines overlap and the ionized region age is almost constant along the cluster evolution. According to the computed models, the average equilibrium age is reached around \( t_{eq} = 13.6, 3.1, 0.2, 0.1 \) and 0.05 Myr for metallicities \( Z = 0.0001, 0.0004, 0.004 \) and 0.02 respectively.

The second conclusion is that there are two metallicity regimes in which the ionizing cluster age has to be interpreted in a different way from the nebular emission line spectrum. In moderate to high metallicity H\( \alpha \) regions (\( Z \geq 0.004 \)) the ionized nebula equilibrium time is shorter than the ionizing cluster age by a factor between 4 and 10. This means that for regions with metallicities above 0.004 we will derive the same age for the ionizing cluster whether we look directly to the embedded cluster (whenever possible) or we observe the cluster effects on the surrounding nebula, that is the nebular emission line spectrum. In these cases, the resolution time, and therefore the error with which we can determine this age, is around 0.05 Myr at \( Z = 0.02, 0.1 \) Myr at \( Z = 0.008 \) and 0.2 Myr at \( Z = 0.004 \). In this metallicity regime, if we detect WR bumps in the optical spectrum or O, B and WR stars from UV images, we can assure, according to our results, that these stars are the ones responsible for the detected nebula ionization. On the contrary, in low metallicity H\( \alpha \) regions, there is a delay between the time at which we observe the ionized region and the age of the stellar cluster responsible for this ionization. At \( Z = 0.0004 \) this delay is of the order of 3 Myr, what is consistent with the value of 1 Myr derived by [Wofford (2009)] for \( Z = 0.001 \). The delay can be as long as 13 Myr.
4.6 Unveiling the physical properties of the ionizing clusters

The purpose of this piece of work is to show that it is possible to unveil the properties of the young cluster responsible for the ionization on the basis of the emission line spectrum of the ionized gas. In what follows we suggest some recommendations to find the physical properties of the dominant young ionizing population (see Flow Diagram in Fig. 18).

- The first parameter than can be determined is the electron density, which is derived from the [SII]$_{\lambda\lambda 6716,6731}$ lines. This value influences the ionization parameter and therefore it is an important input for our models.
- The metallicity can be derived or constrained once the electron density has been determined. If the value of [OII]$_{\lambda 3727}/H_\beta$ is higher than 0.023, then abundances can be derived by standard methods using the electron temperature calculated from the [OIII]$_{\lambda\lambda 4959,5007}$ line ratio. We remark that the absence (or a very low value) of optical [OIII] lines is an indicator of very low or very high metallicity. PopStar includes models with metallicity as low as $Z \approx 0.0001$ and as high as 0.0080 or other $Z$ but $t \geq 4.5$ Myr. Values higher than those are usually not found in optical or infrared selected samples since these regions are efficiently cooled by infrared lines and have a very faint optical emission line spectrum.

- The age should be constrained once the metallicity evaluation has been carried out. We propose to use the diagnostics with [SII]$_{\lambda\lambda 6716,6731}/H_\beta$ (Fig. 6), for low metallicity regions, and [SII]$_{\lambda\lambda 6716,6731}/[SIII]_{\lambda\lambda 6066,6932}$ and [SII]$_{\lambda\lambda 6716,6731}/H_\beta$ (Fig. 7), for high metallicity regions. In both cases, we need to use the electron density to select among different sets of models. We have computed models for two density values: 10 cm$^{-3}$ and 100 cm$^{-3}$, which we recommend to use when electron density is less than 50 cm$^{-3}$ or higher than 50 cm$^{-3}$, respectively, and up to a maximum value of 400 cm$^{-3}$. On the basis of these diagrams and the observed values of the line ratios, we can distinguish if the ionizing cluster is younger or older than 3 Myr. The resolution at which we can estimate the age depends on the equilibrium time as discussed in section 4.5. In the case of low metallicity regions (below $Z = 0.004$) the equilibrium time is of order, or even longer than the ionizing cluster age. This has to be taken into account when observations of the embedded stars are available, since in this low metallicity scenario those stars are the result of the evolution of the ionizing cluster and not the ionizing cluster itself.

- The luminosity of H$_\beta$ emission line is directly related to the number of ionizing photons, and therefore to the mass of the cluster. However, H$_\beta$ luminosity depends not only on the cluster mass...
but also on the age and metallicity, even during the first 5 Myr of evolution (see Fig. 2) when the emission line spectrum in the optical is detectable, according to our models. Moreover H$_\beta$ is detected up to an age of 20 Myr, when the emission line spectrum is not yet detectable (we remind the reader that this paper is focused on the first few Myr when emission lines are prominent since these are the regions available in most H$_\alpha$ region catalogues). Due to the former reasons, it is difficult to derive the mass without previous estimates of metallicity and age. Therefore we propose to derive the mass of the cluster from the H$_\alpha$ luminosity (Fig. 2) using the previously found restrictions on metallicity and age.

Finally, we can use the values of the complete set of emission lines to check the consistency of our determination.

Since this process is slow to be applied to a large sample of objects, we are developing a fast software tool, based on the previous guidelines and using minimization algorithms, to find the best model that fits the emission line values and determine the physical properties of the young cluster responsible for the ionization of a given H$_\alpha$ region, when spectroscopic data are available.

5 SUMMARY AND CONCLUSIONS

We present a new grid of evolutionary models as a tool to estimate the mass, age and metallicity of the dominant ionizing stellar population of a given H$_\alpha$ region from its optical emission line spectrum.

We provide a complete set of photoionization models for H$_\alpha$ regions along the first 5.2 Myr of their evolution, using as ionizing source a very young star cluster obtained from the theoretical evolutionary synthesis models PopStar (Mollá et al. 2009). The basic grid is composed by SSPs computed with different IMFs and a wide range of metallicities (Z=0.0001, 0.0004, 0.004, 0.008, 0.02 and 0.05). A Salpeter IMF with $m_{\text{min}}=0.15M_\odot$ and $m_{\text{p}}=100M_\odot$ has been used in this work. The ionizing cluster is assumed to form in a single burst. Our grid considers five values of the total cluster mass (0.12, 0.20, 0.40, 0.60, 1.00, 1.50 and 2x10$^3M_\odot$), covering the range of observed H$_\alpha$ regions. As the cluster evolves, the stellar winds and supernovae blow the material, determining the H$_\alpha$ region size. This material is ionized by the emergent continua. We use the photoionization code cloudy to obtain the corresponding H$_\alpha$ region emission line spectrum once the equilibrium is reached.

We present diagnostic diagrams where we compare our model results with a large sample of observed H$_\alpha$ regions, whose metallicities have been consistently computed in a homogeneous manner according to the most appropriate method for each metallicity range. It is found that, in general, our models can satisfactorily reproduce the observations.

Finally, we show that the emission line spectrum from an ionized region provides a powerful tool to unveil the physical properties of the embedded young cluster responsible for the gas ionization and propose some guidelines to constrain its physical properties.

APPENDIX A: IONIZATION PARAMETER RECALIBRATION.

This appendix includes a re-calibration of the ionization parameter for low and high metallicity HII regions with sulphur lines. As we have explained in the paper, we do not use the ionization parameter as an input for our models since we derive it from the physical properties of the ionizing clusters and the assumed geometry of the ionized nebula. However, since many other models use this magnitude to parametrize their grids or use different geometries for the ionized regions, we have considered interesting to obtain a recalibration of the relationship between the ionization parameter and the sulphur lines. We have used for that the results from our models, as a self-consistent set of values typical for HII regions.

The [SII]$_{\lambda\lambda 9069,9532}$ line ratio has been shown to be a good ionization parameter indicator for moderate to high metallicities ([Diaz et al. 1995]), with little dependence on metallicity. Garcia-Vargas et al. (1995a) proposed to use the ratio [SII]/[SIII] to derive the ionization parameter of high metallicity regions (Z > 0.004). We have re-calibrated this relationship for each model. This calibration has been made for values of the ionization parameter log u in order to obtain accurate calibrations.

For low metallicity models (Z < 0.004) we have re-calibrated this relationship for each model. This calibration has been made for values of the ionization parameter log u in order to obtain accurate calibrations.

For high metallicity models we find a cubic polynomial relation between log u and log [SII]/[SIII]. We have re-calibrated this relationship for each model. This calibration has been made for values of the ionization parameter log u in order to obtain accurate calibrations.

For low metallicity models (Z < 0.004) the calibration has been made using log[SII]/H$_\alpha$, finding a cubic polynomial relationship with log u for values of log u < -2.

For n$_{H_\alpha}$=10 the fittings are:

\[ \log u = -2.865 - 1.175x + 0.139x^2 - 0.135x^3 \] (Z=0.008, Z=0.004)
\[ \log u = -2.705 - 1.736x + 0.698x^2 - 0.973x^3 \] (Z=0.002)

where x = log([SII]/[SIII])$_{\lambda\lambda 9069,9532}$.

For n$_{H_\alpha}$=100, we obtain:
\[ \log u = -3.136 - 0.810x + 0.685x^2 - 0.784x^3 \] (Z=0.008, Z=0.004)
\[ \log u = -2.938 - 1.051x + 0.043x^2 - 0.482x^3 \] (Z=0.02)

where x = log([SII]/[SIII])$_{\lambda\lambda 9069,9532}$.

For low metallicity models (Z < 0.004) the calibration has been made using log[SII]/H$_\alpha$, finding a cubic polynomial relationship with log u for values of log u < -2.

For n$_{H_\alpha}$=10 the fittings are:

\[ \log u = -2.865 - 1.175x + 0.139x^2 - 0.135x^3 \] (Z=0.008, Z=0.004)
\[ \log u = -2.705 - 1.736x + 0.698x^2 - 0.973x^3 \] (Z=0.002)
Figure A1. Calibration of the ionization parameter $u$ from the $[\text{SII}]\lambda\lambda6717,31/[\text{SIII}]\lambda9069,9532$ line ratio for high metallicity models: $Z=0.004$ (black dots), $Z=0.008$ (red dots), $Z=0.02$ (green dots), and two particle densities, $n_H=10$ cm$^{-3}$ (upper panel) and $n_H=100$ cm$^{-3}$ (lower panel). The calibration has been made for values of $\log u < -2$ and it is represented by orange dots.

Figure A2. Calibration of the ionization parameter $u$ from the $[\text{SII}]/\text{H}_{\alpha}$ line ratio for the models with metallicities $Z=0.0001$ (black dots) and $Z=0.0004$ (red dots), and both densities: $n_H=10$ cm$^{-3}$ (upper panel) and $n_H=100$ cm$^{-3}$ (lower panel). The calibration is represented by orange dots.

$$\log u = 18.89 + 33.00 x + 15.69 x^2 + 2.33 x^3 \ (Z=0.0001)$$
$$\log u = -2.51 + 3.96 x + 3.54 x^2 + 0.69 x^3 \ (Z=0.0004)$$

where $x = [\text{SII}]\lambda\lambda6717,31/\text{H}_{\alpha}$

For $n_H=100$ the fittings give the following result:

$$\log u = -19.95 - 19.29 x - 7.56 x^2 - 1.07 x^3 \ (Z=0.0001)$$
$$\log u = -11.75 - 12.98 x - 6.60 x^2 - 1.26 x^3 \ (Z=0.0004)$$

where $x = [\text{SII}]\lambda\lambda6717,31/\text{H}_{\alpha}$
