Evidence for the existence of van der Waals loops in pressure \( p \) versus volume \( v \) plots has for some time supported the belief that melting in two dimensions is a *first* order phase transition. We report rather accurate equilibrium \( p(v) \) curves for systems of hard disks obtained from long Monte Carlo simulations. These curves, obtained in the constant volume ensemble, using periodic boundary conditions, exhibit well defined van der Waals loops. We illustrate their existence for finite systems that are known to undergo a *continuous* transition in the thermodynamic limit. To this end, we obtain magnetization \( m \) versus applied field curves from Monte Carlo simulations of the 2D Ising model, in the constant \( m \) ensemble, at the critical point. Whether van der Waals loops for disk systems behave in the \( L \to \infty \) limit as they do for the 2D Ising model at the critical point cannot be ruled out. Thus, the often made claim that melting in 2D is a first order phase transition, based on the evidence that van der Waals loops exist, is not sound.

64.70.Dv, 05.70.Fh, 64.60.Cn

Unphysical looking “loops” in pressure versus volume curves have been coming out of approximate calculations for nearly a century \([1]\). These so called van der Waals loops have also been shown up in computer simulations of melting for over three decades \([2–7]\). As Mayer and Wood pointed out \([8]\), pressures that increase with volume, that would be ruled out by van Hove’s theorem for macroscopic systems \([1]\), are indeed to be expected when simulating melting of finite systems. van der Waals loops that decrease as system sizes increase have been observed in simulations \([6,7]\). Their existence has almost invariably been taken as evidence of a first order phase transition \([2,3]\) (though not always \([5]\)) and this has contributed much to the often held belief that the solid-fluid phase transition in two dimensions (2D) is first order \([10,11]\).

The purpose of this paper is threefold: (1) to give examples of van der Waals loops that do sometimes show up for finite systems that undergo continuous phase transitions in the thermodynamic limit; (2) to point out that since their size (defined below) is exactly equal to the free energy barrier for nucleation of the other phase, it follows that van der Waals loops are to be taken as signs of *first* order transitions only if their size vanishes in the thermodynamic limit as the inverse of the linear system size \( L \); (3) to report accurate data for van der Waals loops that we have obtained for two dimensional systems of 256 and 1024 classical hard disks, in the fixed volume ensemble, and to show that their size dependence is in very good agreement with more extensive data that follow from simulations in the constant pressure ensemble (also known as the \( NpT \) ensemble) \([2,3]\) that seem to point to a second order transition, rather than to a first order one.

The pressure \( p(v) \) exerted by a system with a given fixed volume per particle \( v \) is usually obtained from Monte Carlo (MC) or from Molecular Dynamics simulations carried out at constant volume. In order to obtain \( p(v) \) one makes use of expressions that are derived from the virial theorem \([4]\), which in turn follow from the relation

\[
p(v) = -\frac{\partial f(v,T)}{\partial v},
\]

where \( T \) is the temperature and \( f \) is the Helmholtz free energy per particle. We have performed long Monte Carlo simulations \((1.2 \times 10^8 \) MC sweeps in each run, of which the first \( 0.3 \times 10^8 \) sweeps are allowed for equilibration) in the canonical ensemble for systems of 256 and 1024 hard disks. The results obtained are shown in Fig 1 (as \( \circ \) and \( \square \) for \( N = 256 \) and 1024, respectively).

Throughout this paper, “volume” \( v \) actually stands for the area of a two dimensional system; it is given in terms of the closest packing area \( v_0 \), and has therefore no units. The pressure \( p \) is actually a force per unit length, which we give in terms of \( kT/v_0 \) and has therefore no units.

There is an alternative way to obtain the same function, \( p(v) \), that illustrates how van der Waals loops come about for finite systems. Consider the probability density, \( P_p(v) \), that a system at a given pressure \( p \) have specific volume \( v \). \( P_p(v) \) can be obtained through Monte Carlo simulations carried out at a given pressure \( p \), in the \( NpT \) ensemble. Data for \( P_p(v) \) that have been obtained \([3]\) for a system of 256 hard disks in the solid...
and fluid phases are shown in Fig. 2a. Data for $P_p(v)$ exhibiting coexistence of both phases are shown in Fig. 2b [13]. The $p(v)$ curve that ensues in the canonical ensemble (that is, $-\partial f/\partial v$), can be obtained from $P_p(v)$, since $P_p(v)$ and $f(v)$ are related by

$$P_p(v) \propto \exp\{-[f(v) + pv]/NkT\}, \quad (0.2)$$

where $k$ is Boltzmann’s constant. Each data point $(v, p)$ exhibited in Fig. 1 either as a ● or as a ■, and in Fig. 3 as a •, has been obtained from an independent MC run at the corresponding value of $p$. Note that any two volumes, such as $v_a$ and $v_b$ in Fig. 3, that fulfill $p(v_a) = p(v_b)$ are most probable volumes (see Fig. 2) when $p$, instead of $v$, is fixed. On the other hand, $v_c$, which is the portion of the loop where $\partial p/\partial v > 0$ and satisfies $p(v_c) = p(v_a) = p(v_b)$, is the least probable volume.

Alternatively, $f(v)$ may, of course, be extracted from (at least in principle) $P_p(v)$ obtained from a single simulation at an arbitrary constant $p$, using Eq. (2). Pressure versus volume curves follow from Eq. (1). Data points thus obtained, from $P_p(v)$ for $p = 7.64$ and $N = 256$ (exhibited in Fig. 2b), are shown in Fig. 3 (as □). The good agreement between independent sets of the data points in Figs. 1 and 3 gives an indication of the accuracy of our equilibrium results.

For comparison, we also plot in Fig. 3 $p$ versus the mean volume $v$ that is obtained in the $NpT$ ensemble for a system of 256 disks (shown as ◊). No van der Waals loops obtain. This is because, in the $NpT$ ensemble, $\partial v/\partial p = -N((v - \langle v \rangle)^2)/kT$, which is clearly negative.

We next give an example that underscores the fact that while van der Waals loops follow for finite systems from first order phase transitions, the converse is not true. Consider the Ising model in 2D. The applied field $h$ versus magnetization, $m$, is shown in Fig. 4 for Ising systems of 64, 256 and 1024 spins, for periodic boundary conditions, at the critical temperature $T = T_c$. These curves are unusual because we obtained them from MC simulations in an constant $m$ ensemble, rather than in the more often used ensemble in which $h$ is fixed. In our simulations, we keep $m$ constant using the Kawasaki algorithm [15]. In it, one spin is flipped up while another spin is flipped down at each MC step. The canonical and $NpT$ ensembles, discussed above, correspond to the constant $m$ and constant $h$ ensembles, respectively.

We arrive at the $h(m)$ values for the constant magnetization ensemble given in Fig. 4, as follows. Consider first a simulation performed at constant $h$, in which spins are flipped, and the total magnetization $M$ (given by $Nm$) is consequently not conserved. Let $w(m + 2/N \leftarrow m)$ be the conditional probability that a system known to have an $M$ value make the transition $M + 2 \leftarrow M$ when no external field is applied. Since $P_h(m) \propto \exp[-Nf(m)/kT]$ for $h = 0$, we can write the detailed balance condition,

$$w(m + 2/N \leftarrow m)/w(m \leftarrow m + 2/N) = e^{-Nf(m+2/N)/kT}/e^{-Nf(m)/kT}. \quad (0.3)$$

Let the Hamiltonian $H$ become $H - hM$ when field $h$ is applied. Now, $h$ plays no role in a calculation in the constant $M$ ensemble, but an $h(m)$ can be obtained for the given value $m$ from the relation $h = \partial f(m)/\partial m$. Taking logarithms of both sides of the above equation gives $f(m + 2/N) - f(m)$ in terms of the transition rates. The approximation $f(m + 2/N) - f(m) = (2/N)[\partial f(m + 1)/\partial m]$ gives $h(m + 1) = (N/2)[f(m + 2/N) - f(m)]$. We thus arrive at

$$h(m) = -\frac{kT}{2} \ln \left[ \frac{w(m + 1/N \leftarrow m - 1/N)}{w(m - 1/N \leftarrow m + 1/N)} \right], \quad (0.4)$$

after shifting $m \rightarrow m - 1$ for symmetry’s sake. In order to obtain the transition rates, we proceed as follows. First note that the probability for an up spin flip from a given spin configuration is proportional to either 1 or $\exp(-\Delta E/kT)$, depending on whether the corresponding energy change $\Delta E$ is either negative or positive, respectively. Accordingly, after each MC sweep, having applied Kawasaki’s rule throughout the entire system, we assign to each spin down either the number 1 or the number $\exp(-\Delta E/kT)$, if flipping it up would lower its energy or raise it by $\Delta E$, respectively. (No spin is actually flipped.) The sum of such numbers $\int \exp(-\Delta E/kT)$ over all down spins in the system averaged over an MC run is our unnormalized estimate of $w(m + 1/N \leftarrow m - 1/N)$.

Alternatively, the same curves for $h(m)$ may be obtained from simulations in which $h$ is fixed, by applying the relation $h = \partial f(m)/\partial m$ to probability curves $P_h(m)$ that follow from such simulations. Results obtained in this fashion, from both the constant $m$ and the constant $h$ ensembles, are exhibited in Fig. 4.

We have also obtained $h(m)$ curves (not shown) for $T < T_c$ for the 2D Ising model. However, loop sizes for $T < T_c$ and for $T = T_c$ vary rather differently with system size. By loop size, we mean the free energy $\Delta g = \int h(m)dm$ over the domain defined by $m < 0$ and $h > 0$. Data points for $\Delta g/kT$ are shown in Fig. 5 for $T/T_c = 0.9, 0.95$ and 1. Data points for the Gibbs free energy

$$\Delta g = \int_{v_a}^{v_c} [p(v_a) - p(v)]dv \quad (0.5)$$

(the shaded area in Fig. 5) are also shown in Fig. 5 for disk systems of various sizes. In order to make $\Delta g$ unique, we choose $v_a$ such that $p(v_a)$ is the Maxwell construction pressure, $p_m$ [17], that is, $\int_{v_a}^{v_c} [p(v) - p_m]dv = 0$. From data points shown in Figs. 1 and 3, we obtain, making use of Eq. (3), the two data points shown in Fig. 5 as ● for systems of $L \times L$ spins for $L = 16$ and $L = 32$. Data from previous simulations in the $NpT$ ensemble are also shown (as ◊) for $L = 16, 20, 24$ and 32 [13]. The error bars shown in Fig. 5 follow from the procedure described in the Appendix.

As Lee and Kosterlitz have explained in some detail [18], the macroscopic limit $L\Delta g$ (a measure of the surface
tension) does not vanish for first order phase transitions. This follows from the following simple argument. As may be seen from Eq. (0.5) and comparison of Figs. 2 and 3, $L^d \Delta g$ (the system's dimension $d$ is 2 in this case) is the free energy barrier that is surmounted by the system when a fluctuation takes it over the top, at $v_c$, starting from the (locally) most probable volume $v_a$. We may therefore think of $L^d \Delta g$ as the free energy of the wall that arises between two coexisting phases when one of them is nucleated from the other one in order to make a transition from one phase to the other one. Since the wall thickness is finite for first order transitions, it follows then that $L^d \Delta g \sim L^{d-1}$, which is the desired result.

Inspection of Fig. 5 shows that vanishing of $L \Delta g$ in the $L \to \infty$ limit, as for the 2D Ising model at the critical point, can clearly not be ruled out for disk systems. Thus, the often made claim that melting in 2D is a first order phase transition, (tension) does not vanish for first order phase transitions. Indeed, whereas $P_\ell(m)$ for the 2D Ising model at the critical point is bimodal for periodic boundary conditions, it exhibits one single maximum (no van der Waals loops then) for free boundary conditions [14]. Analogously, no van der Waals loops are obtained for systems of disks for hard crystalline walls [3] for $N \leq 4096$ or for systems of disks on spherical surfaces [15]. This provides support for the proposition that melting of systems of hard disks in 2D unfolds through a continuous transition.

APPENDIX A:

We specify here how we obtain the error bars shown in Figs. 1 and 5. The error bars shown in Fig. 1 for data that follows from MC runs in the canonical ensemble are obtained as follows. We divide each MC run into 5 “time” intervals, and calculate an average pressure value for each one of the five intervals. Twice the values of the standard deviations thus obtained from each such set are exhibited in Fig. 1 as error bars.

There are two kinds of error bars shown in Fig. 5. We first discuss the ones that follow from MC runs in the $NpT$ ensemble. We have obtained the probabilities $P_p(v)$ from independent MC runs for various values of $p$. As discussed in the text, the free energy $f(v)$ is given by,

$$e^{-Nf(v)/kT} = P_p(v)e^{Np_v/kT}. \quad (A1)$$

Using six curves for $f(p)/kT$ thus obtained, we exhibit $N[f(v) + p_m v]/kT$ in Fig. 6, for various values of $p$ and $p_m = 7.865$, for systems of 1024 disks. Slightly different values of $L \Delta g/kT$ are obtained from each one of those $f(v) + p_m v$ curves (see Fig. 6), from which the standard deviation is obtained. It is shown as the error for $L = 32$ in Fig. 5. Other error bars shown in Fig. 5 for the values of $L \Delta g/kT$ that follow from the $NpT$ ensemble are obtained similarly.

We next explain how we obtain the error bars for the data points for $L \Delta g/kT$ shown as • in Fig. 5. These errors follow from the errors shown in Fig. 1 for values of $p(v)$ that were obtained from simulations in the canonical ensemble. An explanation is called for because the error evaluation procedure is not trivial: variations in $p(v)$ lead to variations in the Maxwell construction pressure and in the integration limits of Eq. (0.5). However, a bit of reflection shows that such changes in the limits of integration give contributions to errors in $\Delta g$ that are of second order in $\delta p(v)$ [where $\delta p(v)$ is the difference between an erroneous pressure and the correct one]. Accordingly, we shall neglect variations in $v_a$, $v_c$, and $v_b$ (which are defined as in Fig. 1). Thus, the first order change, $\delta p_m$, that is induced in the Maxwell construction pressure $p_m$, by errors in $p(v)$, is given by,

$$(p_m + \delta p_m)(v_b - v_a) = \int_{v_a}^{v_b} [p(v) + \delta p(v)] dv, \quad (A2)$$

which, by virtue of the definition of $p_m$ itself, leads to,

$$\delta p_m = \frac{1}{(v_b - v_a)} \int_{v_a}^{v_b} \delta p(v) dv. \quad (A3)$$

Now, the first order variation $\delta \Delta g$, which follows from Eq. (0.5), is given by,

$$\delta(\Delta g) = \delta p_m(v_c - v_a) - \int_{v_a}^{v_c} \delta p(v) dv, \quad (A4)$$

which, upon substitution of $p_m$ from Eq. (A3), becomes

$$\delta(\Delta g) = \frac{1}{(v_b - v_a)}[(v_c - v_a) \int_{v_a}^{v_c} \delta p(v) dv - (v_b - v_c) \int_{v_a}^{v_c} \delta p(v) dv]. \quad (A5)$$

Finally, we replace integrals by sums. Furthermore, we note that all errors obtained for $p(v)$ for different values of $v$ follow from different MC runs and are therefore assumed to be statistically independent. We thus arrive at the average value of $[\delta(\Delta g)]^2$,

$$\langle [\delta(\Delta g)]^2 \rangle^{1/2} = \frac{\Delta v}{(v_b - v_a)} (q + s), \quad (A6)$$
where
\[ q = (v_c - v_a) \left[ \sum_{v_c < v_i < v_b} \delta p(v_i)^2 \right]^{1/2}, \quad (A7) \]
\[ s = (v_b - v_c) \left[ \sum_{v_a < v_i < v_c} \delta p(v_i)^2 \right]^{1/2}, \quad (A8) \]
and \( \Delta v = v_{i+1} - v_i \). This is the desired expression.

FIG. 1. Pressure $p$ versus volume $v$ data points from MC simulations systems of $N$ disks. The “volume” $v$ stands for an area, it is given in terms of the closest packing area $v_0$. The pressure $p$ is a force per unit length, given in terms of $kT/v_0$. Neither $v$ nor $p$ have therefore any units. ◊ and ◇ stand for results from simulations in the constant volume ensemble for $N = 256$ and $N = 1024$, respectively. • and ■ stand for results, extracted from simulations in the $NpT$ ensemble making use of Eqs. (1) and (2), for $N = 256$ and $N = 1024$, respectively. All data points follow from runs of approximately $10^8$ MC sweeps, after equilibrating the system for $3 \times 10^7$ MC sweeps. For details about the error bars shown, see the Appendix.
FIG. 2. (a) Frequency of occurrence $P_p(v)$ for specific volume $v$ for a system of $N = 256$ for $p = 7.83$ (solid line) and for $p = 7.40$ (dashed line). The units for $v$ and $p$ are given in the caption for Fig. 1. (b) Same as for (a) but for $p = 7.64$. These curves follow from runs of over $2 \times 10^8$ MC sweeps. Lines shown go through datapoints obtained, one for each $\Delta v = 10^{-3}$ bin. Volume values where $\partial[f(v) + pv]/\partial v = 0$ are marked with arrows.
FIG. 3. Data points for $p$ vs volume for systems of $N = 256$ disks. ◇ stand for data points $(\langle v \rangle, p)$ obtained from simulations using the $NpT$ ensemble. The units for $v$ and $p$ are given in the caption for Fig. 1. □ are for the numerically obtained derivative $-\partial f(v)/\partial v$ from the frequency of occurrence $P_p(v)$ for a single pressure, $p = 7.64$, value. ● are for points $(p_0, v)$ fulfilling the relation $\partial[f(v) + p_0 v]/\partial v = 0$ where $f(v) + p_0 v$ follows from $\ln[P_p(v)]$ for $p = p_0$. For example, for $p = 7.64$ (marked with a dashed line in the figure) we find three different solutions $(v_a, v_c, v_b)$ (marked with arrows as in fig. 2b).
FIG. 4. Magnetic field $h$ versus magnetization $m$ for the 2D Ising systems of $L \times L$ spins at the critical temperature, for $L = 8, 16$ and 32. Continuous lines stand for data that follows from probability $P_h(m)$ curves, obtained from simulations in the constant $h$ ensemble for $h = 0$. The umbrella method was used to obtain $P_h(m)$, covering the whole range of $-1 \leq m \leq 1$ values with 16 “umbrellas”. Each one of the three continuous lines shown follows from 16 MC runs of $10^8$ sweeps over the entire system for $N \geq 12$ and $5 \times 10^6$ sweeps for $L = 8$. ■, ◦, and ◇ stand for $L = 8, 16$ and 32 respectively, obtained in the conserved magnetization $m$ ensemble (with the Kawasaki algorithm). Every point shown follows from a MC run of $5 \times 10^6$ sweeps for $L = 8$, and $10^8$ sweeps for $N \geq 12$. 
FIG. 5. Data points for $L\Delta g/kT$ for a system of $L \times L$ disks. ● and ○ stand for data obtained from systems of $L \times L$ hard disks in the constant volume and $NpT$ ensembles, respectively. ◊, ■ and + stand for the 2D Ising model at temperatures $T/T_c = 0.9, 0.95, 1$, respectively. Lines are only guides to the eye. Error bars for data points shown as ○ are approximately given by the size of the circles, except that the error is $(\pm 0.0006)$ approximately 4 times smaller for $L = 32$. For a detailed account about how these errors, as well as the error bars shown for the ● data points, were obtained, see the Appendix.
FIG. 6. Quantity $N[f(v) + p_m v]/kT$ versus $v$, up to a constant, obtained from MC simulations of systems of 1024 disks for each of the values of $p$ shown; $p_m = 7.865$. Each one of the six curves shown follows from a MC run of at least $2 \times 10^8$ MC sweeps over the whole system. Ideally, all curves should be equal. We define the free energy barrier, $\Delta G$ as the local maxima of $N[f(v) + p_m v]$ minus the average value of its two minimum values. All values of $\Delta G/kT$ thus obtained are shown in the figure. We obtain the average value $\Delta G/kT = 0.62$. The corresponding standard deviation is 0.02.
