Abstract

We construct and study loop quantum cosmology (LQC) when the Barbero–Immirzi parameter takes the complex value \( \gamma = \pm i \). We refer to this new approach to quantum cosmology as complex LQC. This formulation is obtained via an analytic continuation of the Hamiltonian constraint (with no inverse volume corrections) from real \( \gamma \) to \( \gamma = \pm i \), in the simple case of a flat FLRW Universe coupled to a massless scalar field with no cosmological constant. For this, we first compute the non-local curvature operator (defined by the trace of the holonomy of the connection around a fundamental plaquette) evaluated in an arbitrary spin \( j \) representation, and find a new close formula for its expression. This allows us to define explicitly a one parameter family of regularizations of the Hamiltonian constraint in LQC, parametrized by the spin \( j \). It is immediate to see that any spin \( j \) regularization leads to a bouncing scenario. Then, motivated in particular by previous results on black hole thermodynamics, we perform the analytic continuation of the Hamiltonian constraint to values of the Barbero–Immirzi parameter given by \( \gamma = \pm i \) and to spins \( j = \frac{s}{2}(-1 + is) \) where \( s \) is real. Even if the area spectrum then becomes continuous, we show that the complex LQC defined in this way does also replace the initial big-bang singularity by a big-bounce. In addition to this, the maximal density and the minimal volume of the Universe are obviously independent of \( \gamma \). Furthermore, the dynamics before and after the bounce is not symmetrical anymore, which makes a clear distinction between these two phases of the evolution of the Universe.
1. Motivations

The discreteness of space at the Planck scale is certainly one of the most important and fascinating predictions of loop quantum gravity (LQG) [1–3]. In fact, it has been expected for a long time that the smooth differentiable structure of space-time (inherited from general relativity) should be modified at this fundamental scale and replaced by a new type of quantum geometry. LQG has been one of the first approaches (not to say the first one) in quantum gravity to propose a framework in which the appearance of a quantum geometry is manifest. Even if the discreteness of space has been proved only at the kinematical level so far (where the quantum dynamics is not taken into account), it has been rigorously established based on the hypothesis that quantum states of geometry are one-dimensional excitations which live in the so-called Ashtekar–Lewandowski Hilbert space. The question of the quantum dynamics is still largely open, and it is not obvious that the discreteness will remain at the physical level [4, 5]. Nonetheless, the spin-foam formulation of the dynamics of LQG (see the review [6] and references therein) seems to predict that the discreteness remains at the physical level.

The Barbero–Immirzi parameter $\gamma$ [7, 8] plays a central role in the scenario which leads to the discreteness of space at the Planck scale. The physical relevance of $\gamma$ shows up directly in the expression for the area spectrum because $\gamma$ enters the formula for the area gap $\Delta \ell_p^2$, where $\ell_p$ is the Planck length and $\Delta = 4\pi\sqrt{3} \gamma$. To have a deeper understanding of the significance of $\gamma$, it is essential to have a look at the origins of LQG. In [9], Ashtekar showed that complex gravity can be formulated as a gauge theory where the connection takes values in a chiral component of the complex Lie algebra $\mathfrak{sl}(2, \mathbb{C})$. The complex theory has to be supplemented with reality conditions in order to ensure the equivalence with classical real (first order) gravity. Not only does gravity feature a lot of similarities with a gauge theory when written in the Ashtekar formalism, but also the constraints emerging in the Hamiltonian formulation are simple polynomials of the fundamental variables. This last property contrasts strongly with what happens in the usual ADM formulation where the constraints are highly non-polynomial functionals of the phase space variables. This new formulation raised the hope of performing for the first time the canonical quantization of gravity and then opening a promising road toward quantum gravity. However, the fact that the gauge group is complex makes the problem of quantizing the theory too complicated, and even totally unsolved up to now. Technically, the main difficulty relies on the highly nonlinearity of the reality conditions, which no one knows how to handle at the quantum level. The Barbero–Immirzi parameter was introduced to circumvent this problem because it allows one to reformulate gravity as a real gauge theory whose gauge group is $SU(2)$. The price to pay is that the Ashtekar–Barbero connection is not a space-time connection [10, 11] and the Hamiltonian constraint is not a polynomial functional of the fundamental variables anymore. Therefore, by going to the $SU(2)$ connection variables, one loses some of the very interesting features of the original (complex) Ashtekar formulation of gravity. Nonetheless, one can start the quantization of the theory and construct at least the kinematical Hilbert space from the harmonic analysis on $SU(2)$. This is a major improvement compared to the complex theory, where no Hilbert space structure has been found so far, even at the kinematical level. Therefore, introducing $\gamma$ allows one to turn, at the kinematical level, the complex gauge group $SL(2, \mathbb{C})$ into the real compact gauge group $SU(2)$. In that respect, the Barbero–Immirzi parameter
(when it is real) is intimately linked to the fact that the gauge group is $SU(2)$, and in turn directly related to the discreteness of the spectra of the geometric operators. The physical consequences of the presence of $\gamma$ in LQG are manifold. The parameter $\gamma$ plays a central role in both the bouncing scenario of the Universe in loop quantum cosmology (LQC) (see the reviews [12–14]) and in the derivation of the Bekeinstein–Hawking black holes entropy (with the rightly famous $1/4$ factor) at the semi-classical limit [15–21].

Nonetheless, the importance of $\gamma$ at the quantum level strongly contrasts with its irrelevance at the classical level, where it disappears totally from the classical equations of motion. Some arguments have been proposed to explain these discrepancies (see [22] and references therein) but none were totally convincing. In a recent series of papers [23–29], we have studied this puzzle in great detail, in particular in the context of three-dimensional gravity and black hole thermodynamics. In both cases, we arrived at the conclusion that the Barbero–Immirzi parameter should not play any role in LQG, and everything points toward the idea that $\gamma$ should be fixed to its original value $\gamma = \pm i$. In other words, we argued that working with the imaginary value $\gamma = \pm i$ is the only choice which will lead to a consistent quantum theory, accompanied by a proper (canonical or covariant) dynamics and possessing a correct semiclassical and continuum limit. This expectation is furthermore motivated by the geometrical significance carried by the complex (chiral or self-dual) Ashtekar connection defined for $\gamma = \pm i$, and is supported by remarkable additional facts [32–40]. While quantizing the self-dual theory remains an immensely hard problem because of the reality conditions, one reasonable point of view is to see $\gamma$ as a regulator which should be sent back to the original complex value $\gamma = \pm i$ at some point. This idea was shown to work exactly in the context of three dimensional geometry [26, 27], and was applied in the context of black hole thermodynamics to recover the Bekenstein–Hawking entropy [28] with its logarithmic corrections [30]. We showed, in both cases, that fixing the Barbero–Immirzi parameter to $\gamma = \pm i$ and performing at the same time the analytic continuation of the spin $j$ representations (coloring the spin-network edges) to $j = \frac{1}{2}(-1 + is)$ where $s$ is a real number reproduces exactly the expected results, i.e. the right geometric spectra in three dimensional gravity and the Bekenstein–Hawking formula for the black hole entropy. The group theoretical interpretation of this analytic continuation is clear and consists in replacing the unitary irreducible representations of $SU(2)$ by the principal (continuous) series of unitary representations of the non-compact gauge group $SU(1, 1)$ to color the spin-network edges. Thus, these representations play apparently a very important role in three dimensional LQG and in black hole thermodynamics, but the question of whether they are still relevant in the full theory in four dimensions is still open, and very complicated to answer. As a first step toward answering this question, it is interesting to apply the same analytic continuation in the context of LQC, where the dynamics is a priori non-trivial (contrary to three dimensional geometry where the theory is topological, and contrary to black hole thermodynamics where we look at a system at equilibrium). We hope that such a model will help us understand the quantization of the full complex theory of gravity and also find our way toward the resolution of the reality conditions.

The aim of this article is precisely to perform the analytic continuation to $\gamma = \pm i$ in the context of LQC. We consider the simplest cosmological model, namely the flat ($k = 0$) FLRW cosmology coupled to a massless scalar field which plays, as usual in LQC, the role of a clock. We want to understand if the bounce scenario survives the analytic continuation and is still a feature of the complex theory. To do so, we proceed in two steps. First of all, we compute the non-local curvature operator evaluated in any spin $j$ representations of $SU(2)$. This operator is the building block of the Hamiltonian constraint in LQC and has been
computed so far mainly in the fundamental spin $1/2$ representation. To our knowledge, there is only one very interesting paper [31] where the question of considering spins different from $1/2$ in LQC was studied. As a first result, we find a new and simple closed formula for the non-local curvature operator in any finite dimensional representation. Then, we perform the analytic continuation of the curvature operator, which is obtained by fixing $\gamma = \pm i$ and replacing the half-integer $j$ by the complex number $j = \frac{i}{2}(-1 + is)$, where $s \in \mathbb{R}$. We proceed exactly as we did in three dimensional LQG and black hole thermodynamics. We show that, even if the representations become continuous, the area spectrum is real and the curvature operator remains bounded after the analytic continuation. This means that the curvature is never singular during the history of the Universe. Therefore, the original singularity is resolved and generically replaced by a bounce. Contrary to what happens in real LQC, the maximal density of the Universe (at the bounce) does not depend on any free parameter (since $\gamma$ has been fixed to $\pm i$).

The paper is organized as follows. We start in section 2 by a brief summary of the main aspects of LQC. We recall that the non-local curvature operator is the building block in the construction of the quantum dynamics. Usually, it is evaluated in the spin $1/2$ representation to achieve the best possible coarse grained homogeneity. However, for our purposes (in order to perform the analytic continuation), we need the expression of the non-local curvature operator evaluated in any spin $j$ representation. Fortunately, we obtain a new simple and closed formula for it. In section 3, we study the analytic continuation to $\gamma = \pm i$ and $j = \frac{i}{2}(-1 + is)$, where $s \in \mathbb{R}$. We write the regularized Hamiltonian constraint (with no inverse volume corrections) in the complex theory. Afterwards we show, in the effective theory framework first and then also using the so-called exactly solvable LQC methods, that it leads generically to a resolution of the initial singularity and to the emergence of a quantum bounce. We finish with a discussion and some perspectives.

2. LQC and non-local curvature operator in any representation

The goal of this section is twofold. First, following [41], we briefly summarize the basis (foundations, results and notations) of LQC in the simplest cosmological space-time, i.e. the flat ($k = 0$) FLRW model with no cosmological constant ($\Lambda = 0$) minimally coupled to a massless scalar field. We will recall in particular that the non-local curvature operator is the key ingredient inherited from quantum geometry in the construction of LQC. This operator is the loop regularization of the classical curvature and is responsible for the replacement of the original singularity by a bounce. In standard LQC, the non-local curvature operator is defined in the spin $1/2$ representation, namely it is given as the trace of the holonomy of the connection around a fundamental plaquette evaluated in the spin $1/2$ representation. The choice of the spin $1/2$ is clearly motivated by technical reasons (it makes its computation much simpler and it makes the energy density of the massless scalar field positive) but not solely. It is commonly argued that the evaluation in the spin $1/2$ representation enables one to achieve the best possible coarse grained homogeneity. Furthermore, the choice of the spin $1/2$ can be further motivated by the assumption that the quanta of space are minimally excited and that the Universe expands (or contracts) by adding quanta (or removing quanta) rather than changing the representations on the spins\(^5\). However, we will need the evaluation of the non-local curvature operator in any spin $j$ representation for defining the analytic continuation.

\(^5\) We would like to thank E Wilson-Ewing for having raised this point.
This is what we are going to do in a second part, and we will obtain a new simple and close formula for this evaluation.

2.1. LQC for FLRW model with a massless scalar field: short review and notations

LQC is a proposal for quantizing cosmological space-times based on the philosophy of LQG. As in the full theory, LQC is based on the (Ashtekar–Barbero) connection formulation of gravity, and the elementary variables are given by holonomies along edges and fluxes across surfaces associated to arbitrary graphs immersed in the space, viewed as a topological space. In the flat FLRW cosmology, the topology of space is either $\mathbb{R}^3$ or $\mathbb{T}^3$, the three-torus, and to construct properly the canonical quantization of such cosmologies, it is necessary to introduce a non-dynamical fiducial metric on the space $q$, together with a fiducial cell $C$. Typically, we choose the cell to be a cube whose length is $\ell_0$ with respect to the fiducial metric. Concerning the fiducial metric, we fix it for simplicity to the flat metric $q^i_a = \delta^i_a$ even if this is not necessary a priori. A complete discussion on the fiducial dependence of the LQC phase space structure can be found in [41].

2.1.1. Connection dynamics: the classical phase space. The homogeneity and isotropy of space-time imply that we can choose the Ashtekar–Barbero connection $A^i_a$ and its conjugate electric field $E^a_i$ of the form

$$A^i_a = \ell_0^{-1} c \delta^i_a \quad \text{and} \quad E^a_i = \ell_0^{-2} p \delta^a_i,$$

where $c$ and $p$ are functions of time only. To these geometrical variables, one adds the pair of conjugate variables $(\Phi, \Pi)$ to parametrize completely the phase space of an FLRW cosmology minimally coupled to a massless scalar field $\Phi$. The Hamiltonian analysis of the action of gravity coupled to the scalar field $\Phi$ leads immediately to the following definition of the Poisson brackets

$$\{c, p\} = \frac{8 \pi G \ell_0^3}{3} \quad \text{and} \quad \{\Phi, \Pi\} = 1.$$

Note that the choice of the normalization factors (depending on $\ell_0$) in (2.1) makes the Poisson bracket between the dynamical variables $c$ and $p$ independent of the fiducial structure. With this choice, the quantities $c$ and $p$ are not sensitive to the fiducial structure (neither of the fiducial metric nor of the fiducial cell). Therefore we can fix $\ell_0 = 1$ without loss of generality, which is what we do from now on. Note however that the fiducial structure does not disappear in the quantum theory when one considers inverse volume corrections in the Hamiltonian constraints, and the fiducial metric may also enter in the quantum uncertainties relations [42, 43]. To complete the description of the physical phase space, we add that the lapse $N$ is a non-dynamical variable in the theory, it plays the role of a Lagrange multiplier which enforces the Hamiltonian constraint $C_H$ given by (note that in all this paper we will not consider the inverse volume corrections)

$$C_H = C_{\text{grav}} + C_m \quad \text{with} \quad C_m = \frac{\Pi^2}{2 |p|^{3/2}} \quad \text{and}$$

$$C_{\text{grav}} = -\frac{1}{16 \pi G \ell_0^2} \varepsilon^{ij}_k \delta^a_i \delta^b_j p^{1/2} F^{k}_{ab},$$

(2.3)
where the curvature of the connection $F_{ab}^i$ reduces in the FLRW model to the simple form
\[ F_{ab}^i = \epsilon_{ab}^i c^2. \] (2.4)

This leads immediately to the following final expression for the total Hamiltonian $H$:
\[ H = N C_H, \quad \text{where} \quad C_H = \frac{1}{2} \left( \Pi^2 - \frac{3}{4\pi G} p^2 c^2 \right) \] (2.5)

As in pure gravity, $C_H$ is a first class constraint which is responsible for the invariance under time reparametrization of the theory. Furthermore, the Hamiltonian $H$ vanishes on shell and allows one to define, as a Hamiltonian vector field, time derivatives of any function $\phi$ of the phase space according to
\[ \dot{\phi} = \{ \phi, H \} \approx N \{ \phi, C_H \}, \] (2.6)

where the symbol $\approx$ refers to a weak identity (i.e. the identity holds only on the constraints surface). The freedom in the choice of the lapse function $N$ corresponds to the gauge freedom to choose the time variable for the dynamics.

2.1.2. Quantization of the holonomy-flux algebra in LQC. The quantization of such a theory (where the matter is a massless scalar field) leads generically to a singularity at the origin of the Universe in standard Wheeler–DeWitt quantum cosmology. The singular behavior of usual quantum cosmologies originates from the fact that the curvature (2.4) is unbounded from above, and then it can be infinite. This happens precisely at the origin of the Universe. Some scenarios to resolve the singularity were proposed but none are totally convincing (see [41] and references therein). Most of them consisted in considering particular types of matter fields coupled to gravity. LQC proposes a much deeper scenario to avoid the singularity based on the fundamental structure of space inherited from LQG. Physically, the resolution of the singularity can be viewed as a consequence of the discreteness of the geometric operators and more precisely of the existence of a minimal spacial surface, hence a minimal spacial volume for the Universe. In that sense, the minimal volume (or equivalently the area gap) plays the role of a UV cut-off in quantum cosmology. More rigorously, it is the particular structure of the kinematical Hilbert space of LQG which is deeply responsible for the resolution of the original singularity. In full LQG, the algebra of kinematical operators form the so-called holonomy-flux algebra which admits a unique unitary irreducible representation which behaves correctly under the action of space diffeomorphisms (the action is unitary) [44]. The corresponding Hilbert space is generated by one-dimensional excitations associated to a graph $\Gamma$ immersed in the space which are constructed from the holonomy of the connection along the edges of the graph $\Gamma$. The spin-network states form a dense basis of this Hilbert space. They are totally characterized by a colored graph, i.e. a graph whose edges are colored with spin $j$ representations of $SU(2)$ and whose nodes are colored with intertwiners between $SU(2)$ representations. As we will illustrate later on in the case of cosmology, the fact that fundamental excitations of quantum gravity are holonomies along the edges of the connection and not the connection itself is intimately linked to the resolution of the singularity.

The hypothesis of homogeneity and isotropy simplify drastically the holonomy-flux algebra. Indeed, spin-network states corresponding to cosmological quantum states are associated to graphs whose edges are parallel to the edges of the cell $C$ defined above in the introduction of this section. Furthermore, it is commonly assumed that the edges are colored by a spin $1/2$ representation in order to achieve the best possible coarse grained homogeneity.

6 As there is only one constraint in the theory, the constraint is necessarily first class.
As a consequence, holonomies $h_\ell$ of the (homogeneous and isotropic) Ashtekar–Barbero connection (2.1) along a line $\ell'$ parallel to one of the edges of the cell $C$ and evaluated in the spin $1/2$ representation are the building blocks of kinematical states in LQC. If we denote by $\mu$ the length of $\ell'$ with respect to the fiducial metric $q$, it is immediate to show that

$$h_\ell = \exp \left( \int_{\ell'} \text{d}x^a A^i_a \tau_i \right) = \exp(\mu c \tau_\ell) = \cos \left( \frac{\mu c}{2} \right) + 2 \sin \left( \frac{\mu c}{2} \right) \tau_\ell, \quad (2.7)$$

where $\ell'$ has been identified with its direction and then takes value in the set $\{1, 2, 3\}$. Here $\tau_\ell$ are the generators of $\text{su}(2)$ evaluated in the fundamental representation, they satisfy the Lie algebra relation $[\tau_i, \tau_j] = e_i^a \tau_a$ and the normalization property $\tau_\ell^2 = -1/4$ for any $\ell'$. We can choose a basis such that they are explicitly given by the following $2 \times 2$ matrices:

$$\tau_1 = \frac{1}{2} \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \quad \tau_2 = \frac{1}{2} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \tau_3 = \frac{1}{2} \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}. \quad (2.8)$$

As we have just said in the general discussion above, fundamental variables in LQC kinematics are the elements $h_\ell$, or equivalently they are (complex) exponentials of the connection $c$ and not the connection itself. It is important to note that one cannot recover, for instance, the connection by a derivation of $h_\ell$ with respect to $\mu$ because the holonomy-flux algebra representation is not weakly continuous, hence deriving the holonomy operator $h_\ell$ is not a well-defined action. For that reason, the Hamiltonian constraint $C_H$, as it is written in (2.5), is not a well-defined operator acting on the LQC kinematical states and needs to be regularized. The regularization is constructed as in gauge theory where the curvature (2.4) is expressed in terms of holonomy variables $h_\ell$ only.

2.1.3. Regularization of the curvature operator. The key point to find a suitable regularization of the curvature (2.4) is the formulae

$$F_{ab}^{\ell} = \frac{1}{\text{tr}_j(\tau_\ell^2)} \lim_{\text{Ar}_\square \to 0} \frac{\text{tr}_j(h_{\square,ab}^{\ell}\tau^2)}{\text{Ar}_\square} \quad \text{with} \quad \text{tr}_j(\tau^2) = -j(j + 1)(2j + 1)/3,$$

$$= -\frac{d(d^2 - 1)}{12}, \quad (2.9)$$

where $h_{\square,ab}$ is the holonomy around a square plaquette whose edges are parallel to the directions $a$ and $b$ of the fiducial $C$, $\text{Ar}_\square$ its area with respect to the flat fiducial metric $q$ and $\text{tr}_j(X)$ denotes the trace of the element $X$ (which belongs to the enveloping algebra of $\text{su}(2)$) in the spin $j$ representation of dimension $d = 2j + 1$. The holonomy around the plaquette can be obviously expressed in terms of the holonomies $h_a(\bar{\mu})$ and $h_b(\bar{\mu})$ along the edges of length $\bar{\mu}$ (with respect to the fiducial metric fixed such that $\ell_0 = 1$ from the beginning) and directions $a$ and $b$ respectively as follows:

$$h_{\square,ab} = h_a(\bar{\mu})h_b(\bar{\mu})h_a(\bar{\mu})^{-1}h_b(\bar{\mu})^{-1}. \quad (2.10)$$

From the quantum point of view, the limit where $\text{Ar}_\square$ vanishes is not defined, again because of the lack of weak continuity property of the kinematical Hilbert space representation (known as the Ashtekar–Lewandowski representation). Physically, we can say that the limit does not exist because the existence of a minimal area in the theory or equivalently an area gap forbids us to send the area of any surface to zero. At most, we can send the area to its minimal value (the discreteness of the area spectrum is closely related to the continuity properties of the Ashtekar–Lewandowski representation). Determining the minimal value of
the area $\Delta$ is equivalent to determining the expression of the minimal length $\mu$ of its edges. As we see from the notations, we work in the so-called improved $\bar{\mu}$-scheme where it was shown that

$$\mu = \ell_p \frac{\Delta^{1/2}}{|p|^{1/2}},$$

(2.11)

$\Delta$ being the quantum of area (in Planck unit with $\ell_p^2 = G$) carried by each edge of the spin-network state representing a homogeneous and isotropic quantum state of geometry. The consequence is that the classical curvature is replaced in LQC by a non-local curvature operator which clearly needs ordering prescriptions to be well-defined.

To be more explicit, let us fix the spin in (2.9) to the value $j = 1/2$ as it is usually done in LQC. This choice is motivated by the fact the quantum states in quantum cosmology are colored with spin $1/2$ representations (to achieve the best possible coarse grained geometry), and then it is natural (and technically simpler) to define the curvature operator in term of holonomies evaluated in the two-dimensional representation as well. Nonetheless, we will shortly discuss this choice in the following subsection. When $j = 1/2$, $\Delta$ reduces to the area gap $\Delta = 4\pi\sqrt{3}\gamma$ and the expression of the holonomy (2.10) simplifies as follows:

$$h_{\square ab} = \cos (\mu c) + \frac{1}{2} \sin^2 (\mu c) + \sin^2 (\mu c) e_{ab} \tau_c + (1 - \cos (\mu c)) \sin (\mu c) (\tau_a - \tau_b).$$

(2.12)

The calculation of the non-local curvature operator $\hat{F}_{ab}^\ell$ (the hat notation allows one to distinguish the local curvature from the quantum non-local one) follows immediately:

$$\hat{F}_{ab}^\ell = \frac{\sin^2 (\mu c)}{\bar{\mu}^2} e_{ab}^\ell + \frac{1 - \cos (\mu c)}{\bar{\mu}^2} \sin (\mu c) (\delta_a^\ell - \delta_b^\ell).$$

(2.13)

The second term in the rhs of the previous equation is often omitted. The reason is that the curvature appears in the Hamiltonian constraint (2.3) in the form $e^{ab} F_{ab}^\ell$ and then this second term disappears from the Hamiltonian because of symmetry properties. In fact, it is implicitly assumed in the literature that $\ell$ is different from $a$ and $b$ when one writes the components $F_{ab}^\ell$ of the curvature.

To simplify the study of the quantum dynamics, it is convenient to change variables and to consider $b = c/p^{1/2}$ instead of the original connection $c$. The reason is that, at the classical level, $b$ is conjugated to the volume $V = |p|^{3/2}$ in the sense that $\{b, V\} = 4\pi G$, and this simplifies highly the resolution of the Hamiltonian constraint as we are going to see shortly. When expressed in terms of $b$ and $V$, the total Hamiltonian (2.5) becomes

$$\dot{H} = \Pi_m - \frac{3}{8\pi G} \frac{\sin^2 (\mu b)}{V^2}$$

(2.14)

with $H_m = \frac{\Pi^2}{2V}$ and $\lambda = \ell_p \sqrt{\Delta}$. This expression is the starting point of the study of the dynamics in LQC. There remain ordering ambiguities to understand when we promote the Hamiltonian constraint as an operator acting on a suitable Hilbert space. The reason is that the quantum operators $\hat{b}$ and $\hat{V}$ corresponding respectively to the quantizations of $b$ and $V$ are not commuting. These aspects have been deeply studied and were nicely reported in [48] and [41] for instance.

2.1.4. Effective dynamics. There exists a simple way to see how the Hamiltonian constraint (2.14) leads generically to a bouncing Universe in LQC without entering into the details of the quantization [49]. The method we are talking about is known as the effective analysis of the
dynamics. However, even if this method is qualitatively very interesting, it misses some important aspects that can be analyzed only from a rigorous analysis of the quantum theory.

In the effective analysis, one interprets the Hamiltonian $\hat{H}$ as a classical function and not as a quantum operator. Then we immediately get the energy density of the scalar field from $\hat{H} = 0$:

$$\rho = \frac{H_m}{V} = \frac{3}{8\pi G\gamma^2} \frac{\sin^2(\lambda b)}{\lambda^2}. \quad (2.15)$$

Therefore, we obtain directly a first indication of the existence of a bounce because $\rho$, viewed as a function of $b$, is now bounded (compared to the standard Wheeler–DeWitt quantum cosmology) with a maximum $\rho_{\text{max}} = 3/(8\pi G\gamma^2\lambda^2)$. This is fundamentally due to the finiteness of $\lambda$ and then to the existence of an area gap in LQG. If the energy density is bounded, then there is no more singularity and there may exist a minimal volume of the Universe. In fact, we can show that this is generically the case from a careful analysis of the quantum dynamics (under some conditions on the quantum states) as reviewed in [12].

There is a second (certainly more spectacular) indication for the resolution of the initial singularity and the emergence of a bounce scenario. It is based on the the analysis of the modified Friedmann equation induced by the dynamics of LQC. The modified Friedmann equation is very easy to obtain and relies on the calculation of the time derivative of the volume $V = \{V, C_H\}$ where the time parameter is the cosmic time (i.e. $N = 1$). From this straightforward computation, we obtain (the details can be found in [46] for instance)

$$\left(\frac{\dot{a}}{a}\right)^2 = \left(\frac{\dot{V}}{3V}\right)^2 = \frac{8\pi G}{3} \rho \left(1 - \frac{\rho}{\rho_{\text{max}}^2}\right). \quad (2.16)$$

The scale factor $a$ is related to the volume by $V = a^3$ and $(\dot{a}/a)$ represents the usual Hubble parameter which can be expressed in terms of the Ashtekar connection $c$ or equivalently $b$. The modified Friedmann equation has been studied intensively [47] and it can be shown precisely that it describes a bouncing Universe. Without going into the details, it is easy to see that the Universe admits a minimal volume which is reached when $\rho = \rho_{\text{max}}$ (whence $V = 0$).

Furthermore, everything happens as if the quantum gravity effects manifest themselves near the origin as a pressure which forbids the Universe from collapsing and then removes the original singularity.

2.2. The non-local curvature operator evaluated in any spin $j$ representation

The regularization of the curvature operator is the cornerstone of LQC. It is mathematically based on the techniques used in full LQG and it is physically responsible for the resolution of the initial singularity. However, the regularization procedure is not unique and suffers from ambiguities. The main ambiguity relies on the choice of the spin $j$ representation in (2.9). By construction, the classical curvature does not depend on that choice but the value of the spin $j$ becomes relevant at the quantum level, when the limit $\mu \to 0$ is replaced by $\mu \to \bar{\mu}$ in (2.9). Some aspects of this ambiguity were studied in [31] and similar ones in the full theory were discussed in [50]. The article [31] has been, to our knowledge, the only one to discuss the choice of the spin in the regularization of the curvature operator for LQC.

To have a deeper understanding of the role of $j$ in the regularization of the curvature, it would be much better to have an explicit and simple expression of the trace $\text{tr}(\hat{h}_\lambda^\ell \tau^j)$ involved in the definition of the non-local curvature operator, which is missing up to our knowledge (in [31] the trace was expressed as a finite sum only). But we are going to provide
in this section a new and simple expression for the trace in any spin \( j \) representation. This new formula is clearly a good starting point for the study of the ambiguity we mentioned above and its effects on the dynamics of LQC. However, we are not interested in studying this aspect here that we postpone for later [51]. We are more interested in the analytic continuation of LQC to complex Barbero–Immirzi parameters, more precisely to \( \gamma = \pm i \). However, we argued in the introduction that solely fixing \( \gamma = i \) is meaningless in LQG. Instead, one should send both \( \gamma \) to \( i \) and the discrete spin \( j \) representations (coloring the spin-network edges) to the complex values \( j = \frac{1}{2}(-1 + is) \). To adapt this construction in the context of LQC, we need to write the non-local curvature, hence \( \text{tr}(\hat{h}_{\square} \tau^j) \), as an analytic function of \( j \) (and also \( \gamma \)). This is exactly what we are going to do in this section.

We proceed as follows. To lighten the notations, we choose to compute \( \text{tr}(\hat{h}_{\square} \tau^j) \), the other components will be directly obtained from permutations between the indices. First we remark that

\[
\text{tr}(\hat{h}_{\square} \tau^j) = \frac{\partial}{\partial \epsilon} \text{tr}(h_{123}(\epsilon)) \bigg|_{\epsilon=0}, \quad \text{where} \quad h_{123}(\epsilon) = h_{\square} g_3(\epsilon)
\]

and \( g_3(\epsilon) = \exp(\epsilon \tau_3) \). (2.17)

Then the calculation reduces in computing the trace of the group element \( h_{123}(\epsilon) \in SU(2) \) in the spin \( j \) representation. We know from representation theory that such a trace is given by the character

\[
\text{tr}(h_{123}(\epsilon)) = \chi_j(\theta(\epsilon)) = \frac{\sin(d \theta(\epsilon))}{\sin(\theta(\epsilon))}
\]

where \( \theta(\epsilon) \in [0, \pi] \) is the conjugacy class of \( h_{123}(\epsilon) \). Now, the point is that we can obtain the angle \( \theta(\epsilon) \) using the \( su(2) \) fundamental representation where \( h_{123}(\epsilon) \) is a two-dimensional matrix which can be easily computed from (2.12). Then a direct calculation leads to:

\[
\chi_{1/2}(\theta(\epsilon)) = 2 \cos(\theta(\epsilon)) = \text{tr}_{1/2}(h_{123}(\epsilon)) = (2 \cos(\lambda b) + \sin^2(\lambda b)) \cos(\frac{\epsilon}{2}) - \sin(\frac{\epsilon}{2}) \sin^2(\lambda b).
\]

(2.19)

The expression of (2.17) in terms of the variable \( b \) follows immediately:

\[
\text{tr}(\hat{h}_{\square} \tau_3) = \frac{\partial}{\partial \theta} \left( \frac{\sin(\lambda b)}{\sin \theta} \right) \times \left( \frac{\partial}{\partial \epsilon} \text{tr}(\hat{h}_{\square} \tau^j) \bigg|_{\epsilon=0} \right) = \frac{\sin^2(\lambda b)}{4 \sin \theta} \times \frac{\partial}{\partial \theta} \left( \frac{\sin(\lambda b)}{\sin \theta} \right)
\]

(2.20)

Note that the angle \( \theta \) with no \( \epsilon \) dependence is defined by \( \theta = \theta(0) \). Its expression in terms of \( b \) is obtained from the relation (2.19) between \( b \) and \( \theta(\epsilon) \) with \( \epsilon = 0 \), and a short calculation leads to:

\[
\sin^2\left(\frac{\theta}{2}\right) = \sin^4\left(\frac{\lambda b}{2}\right)
\]

(2.21)

which defines totally \( \theta \in [0, \pi] \) in terms of \( b \). As an immediate consequence, the relevant components of the non-local curvature operator regularized using the spin \( j \) representation (of dimension \( d \)) are given by \( \hat{F}_{ab} = \epsilon_{abc} \hat{F}^c_{12} \) (when \( \epsilon_{abc} \neq 0 \)) with:

\[
\hat{F}^3_{12} = -\frac{3}{d(d^2-1)} \left| p \right| \frac{\sin^2(\lambda b)}{\lambda^2} \frac{1}{\sin \theta} \times \frac{\partial}{\partial \theta} \left( \sin(\lambda b) \right)
\]

(2.22)
Note that $\lambda / \Delta = \ell_p$ should take different values depending on the choice of the spin $j$. Indeed, in the $\mu$-scheme, it has been argued that $\Delta$ represents the quantum of area (in Planck units) carried by spin-network describing LQC quantum states. If this is indeed the case, then $\Delta = -d_{41}^2 / 2$. One could also argue that $\Delta$ is simply the area gap (the minimal area) in Planck units of LQG in which case it is independent of $j$.

We finish this section with some examples.

1. When $j = 1/2$ ($d = 2$) we recover immediately the expression (2.13).
2. When $j = 1$ ($d = 3$) we find after a straightforward calculation:

$$\hat{F}_{12}^3 = |p| \frac{\sin^2(\lambda b)}{\lambda^2} \cos \theta = |p| \frac{\sin^2(\lambda b)}{\lambda^2} \left( 1 - 2 \sin^4 \left( \frac{\lambda b}{2} \right) \right).$$

(2.23)

For any finite values of $j$, the dynamics of LQC leads to a resolution of the singularity since the non-local curvature is bounded from above, and so is the energy density. However, the precise dynamics is modified and depends strongly on the choice of the representation. These aspects have been explored in [31] and are revisited in [51]. Here we briefly underline some difficulties which may arise for $j > 1/2$. From $C_H = 0$ and defining the energy density of the matter content by $\rho = H_m / V$ one easily gets the modified Friedmann equation relating $\rho$ to the non-local curvature for any $j$:

$$\rho = \frac{-9}{8\pi G r^2 d (d^2 - 1)} \frac{\sin^2(\lambda b)}{\lambda^2} \frac{1}{\sin \theta} \times \frac{\partial}{\partial \theta} \left( \frac{\sin (d\theta)}{\sin \theta} \right).$$

(2.24)

The shape of the rhs of the above is displayed in figure 1 for four values of the spin representation, $j = 1/2$, 1, 3/2 and 10. This is shown in Planck units defining $\rho_m = 1 / G^2$.

Figure 1. Energy density as a function of $b$ as derived from the vanishing of the Hamiltonian constraint, $C_H = 0$, in Planck units $\rho_m = 1 / G^2$. In the left panel, $\Delta$ is assumed to be given by the area gap, $\Delta = 4\pi \sqrt{3}$, and therefore does not depend on the chosen representation $j$. In the right panel, $\Delta$ is given by the quantum of area associated to the chosen representation $j$, i.e. $\Delta = 4\pi \sqrt{d^2 - 1}$. This second option makes the maximal energy density lower. This also makes the range of values of $b$ to depend on $j$ since $0 \leq b \leq \pi / 2$ with $\lambda(j) = \ell_p (4\pi \sqrt{d^2 - 1})^{1/2}$. For both cases, the dotted, dashed, and dashed–dotted vertical lines flag the value of $b$ for which the energy density first becomes negative for $j = 1$, 3/2 and 10, respectively.
negative values for \( j > 1/2 \). This would mean that the energy density itself could become negative-valued. However, from its definition, one easily figures out that \( \rho = H_n/\sqrt{V} = \Pi^2/(2V^2) \) which is positive-valued. Then, the variable \( b \) should be restricted to belong to some range for which the energy density is positive. This still raises some issues since the Hubble parameter is non-vanishing at the smallest value of \( b \) for which the energy density would become negative, called \( b_s \) hereafter. (Those values for \( j > 1/2 \) are depicted by vertical lines in figure 1.) The Hubble parameter is indeed given by \( (\dot{a}/a) \propto \frac{\partial}{\partial b} \) which is non-zero when the sign of \( \rho \) firstly changes at \( b_s \). This is clearly shown for e.g. \( j = 1 \) in figure 1 where the change of sign occurs at \( b_s \sim 0.88 \). This means that there is a priori no dynamical reason for this change of sign not to be crossed. (We stress that the point \( b_s \) would be only asymptotically reached, and therefore never crossed, if the Hubble parameter were vanishing at \( b_s \).)

### 3. Complex LQC

Now we have all the necessary tools to perform the analytic continuation and to study the dynamics of LQC when \( \gamma = \pm i \). In the first subsection, we will construct the analytic continuation of the non-local curvature operator. In the second subsection, we will study the induced effective theory. We see immediately from the previous section that if we set \( \gamma = \pm i \) without changing the representations \( j \), the curvature is no more bounded and the original singularity is not removed. If we add the condition \( j = \frac{1}{2}(-1 + is) \) with \( s \) real, not only does the area spectrum remain positive but also we recover the bouncing scenario though the precise history of the Universe is very different from real LQC. For instance, the energy density is no more periodic which implies that the history of the Universe is not periodic either as it is in real LQC.

The case \( s = 0 \) (equivalently \( j = -1/2 \)) is the analogous of \( j = 1/2 \) in the sense that it allows one to achieve the best possible coarse grained geometry in the complex theory. Therefore, we study more precisely this situation and show that, exactly as in usual LQC, the energy density is always positive. The dynamics before and after the bounce are totally different which makes a clear distinction between the contracting and the expanding phases of the evolution of the Universe. This contrasts with what happens in usual LQC where the dynamics after and before the bounce are totally symmetric.

#### 3.1. Analytic continuation: \( \gamma = \pm i \) and \( j = \frac{1}{2}(-1 + is) \)

We proceed now to the analytic continuation. To do so, we need to make explicit the \( \gamma \)-dependence in the Hamiltonian constraint. Indeed, \( \gamma \) is hidden in the connection variable \( c \) and appears clearly when we recall its relation to the usual scale factor \( a \) which is \( c = \gamma \dot{a} \). As a consequence, the variable \( b \) is also proportional to \( \gamma \) and then it will be useful in this section to make this proportionality relation explicit. For that reason, from now on, we change slightly the notations as follows:

\[
\tilde{c} \longrightarrow c = \gamma \tilde{c} \quad \iff \quad b \longrightarrow b = \gamma \dot{b}. \tag{3.1}
\]

In fact, \( \tilde{c} \) represents the extrinsic curvature in homogeneous and isotropic geometries. When we fix the Barbero–Immirzi parameter to \( \gamma = \pm i \), the variable \( b \) becomes purely imaginary. If we naively believe this is the only changing in the theory (to recover self-dual variables), then we could directly implement it in the expression (2.14) of the regularized (with spin 1/2) Hamiltonian constraint and we would see immediately that the energy density (2.15) is no
more bounded from above. The consequence is that we would lose the bouncing scenario and the original singularity would not be resolved in complex LQC.

In fact, we miss an important ingredient. When $\gamma = \pm i$ in LQG, we must change at the same time the representations $j$ coloring the spin-networks according to $j = \frac{1}{2}(-1 + is)$ with $s$ real, for the area eigenvalues to remain real (or equivalently for the area operator to be a well-defined self-adjoint operator). Indeed, the quantum of area $a(j)$ carried by a link colored with the spin $j$ remains real under this change, as seen in the following

$$a(j) = 8\pi\ell_p^2 \sqrt{j(j + 1)} \rightarrow a(s) = \pm 4\pi\ell_p^2 i\sqrt{s^2 + 1} = 4\pi\ell_p^2 s\sqrt{s^2 + 1},$$  \hspace{1cm} (3.2)

where we choose the square root such that the area is positive. Note that the cases $\gamma = +i$ and $\gamma = -i$ are totally equivalent and, without loss of generality, we will consider only the case $\gamma = +i$ in the rest of the article. An important consequence is that, even if their expressions change, $\Delta$, hence $\lambda (2.14)$, are non-negative real constants. They may depend on $s$ exactly as they may depend on the representation $j$ in usual real LQC. But for the reasons we have already mentioned above, we take $\Delta$ to be simply the area gap which becomes in the complex theory

$$\Delta = 4\pi\ell_p^2.$$  \hspace{1cm} (3.3)

It is obviously independent of $\gamma$, in that sense it is universal.

At this point, to obtain the complex Hamiltonian constraint, it remains to understand how $\theta$ changes when $\gamma = i$ in analyzing the relation (2.21). To that aim, we first notice that (2.21) is totally equivalent to the relation (on the rhs)

$$\sin^2 \left( \frac{\theta}{2} \right) = \sin^4 \left( \frac{ib}{2} \right) \iff \sin^4 \left( \frac{\theta}{2} \right) = \sin^4 \left( \frac{ib}{2} \right)$$  \hspace{1cm} (3.4)

when $\theta$ and $b$ are real. However, when $b$ is imaginary, these two relations are not equivalent and lead to inequivalent definitions of the angle $\theta$. Fortunately, only the second relation gives a consistent and simple definition of $\theta$ which is

$$\theta \rightarrow i\tilde{\theta} \in i\mathbb{R} \quad \text{with} \quad \sin \left( \frac{\tilde{\theta}}{2} \right) = \sinh^2 \left( \frac{ib}{2} \right).$$  \hspace{1cm} (3.5)

where we assumed that $\tilde{\theta} > 0$ for simplicity but without loss of generality. If we have started with the first identity in (3.4), we would have obtained a complex angle $\tilde{\theta}$ (with non-zero real and imaginary parts) which would have produced a complex energy density which is of course physically irrelevant.

The expression of the local curvature operator in the complex theory follows immediately

$$\tilde{F}_{12}^3 \rightarrow \tilde{F}_{12}^3 = \frac{3}{s^2 + 1} \left[ \frac{\sinh^2 (ib)}{s^2} \right] \frac{1}{\sinh \tilde{\theta}} \times \frac{d}{d\tilde{\theta}} \left( \frac{\sin (s\tilde{\theta})}{\sinh \tilde{\theta}} \right),$$  \hspace{1cm} (3.6)

where $\tilde{\theta} > 0$ has been defined above (3.5). As a consequence, the regularized Hamiltonian constraint (depending on the choice of $s$) is given by

$$H \rightarrow \tilde{H} = N \left( H_m + \frac{3}{8\pi G} |v|^{1/2} \tilde{F}_{12}^3 \right),$$  \hspace{1cm} (3.7)

where the matter field energy $H_m = \Pi^2 / 2 V$ is unchanged. We supplement the expression of the Hamiltonian constraint with the Poisson brackets between the new (complex) geometric variables (in fact only the connection variable is new, the electric field is unchanged)
and we obtain the complete definition of the dynamics of LQC in complex Ashtekar variables.

3.2. Effective dynamics in the complex theory

This section aims at studying the effective dynamics induced by the Hamiltonian we have just described in the previous part. We follow exactly the classical analysis recalled in subsection (2.1.4). First, we compute the energy density \( \tilde{\rho} \) of the scalar field in the complex theory:

\[
\tilde{\rho} = \frac{H_m}{V} = -\frac{9}{8\pi G s\left(s^2 + 1\right)} \frac{\sinh^2\left(\frac{\tilde{b}}{\lambda}\right)}{\lambda^2} \frac{1}{\sinh\tilde{\theta}} \times \frac{\partial}{\partial\tilde{\theta}} \left( \frac{\sin \left(s\tilde{\theta}\right)}{\sinh \tilde{\theta}} \right).
\]

\[
= -\frac{9}{8\pi G s\left(s^2 + 1\right)} \frac{\sinh^2\left(\frac{\tilde{b}}{\lambda}\right)}{\lambda^2} \frac{\coth\sin \left(s\tilde{\theta}\right) - s \cos \left(s\tilde{\theta}\right)}{\sinh^2\tilde{\theta}}.
\] (3.9)

Here we have not specified yet the value of the representation \( s \). We will discuss this particular point later on. Before going further, we remark that the energy density \( \tilde{\rho} \) is much simpler when it is expressed in terms of \( \tilde{\theta} \) than in terms of the complex (modified) connection \( \tilde{b} \). Physically, \( \tilde{\theta} \) represents somehow the curvature because it is the conjugacy class of the holonomy \( h_{ab} \) around plaquettes. In that sense, the curvature might be a more natural variable than the connection itself to study the dynamics. Note that this remark holds also in the usual real case when the non-local curvature operator is regularized with an arbitrary spin \( j \).

The bounce occurs because the energy density remains bounded after the complexification procedure. To see this is indeed the case, we show that \( \tilde{\rho} \) is not singular at \( \tilde{b} = 0 \) or equivalently at \( \tilde{\theta} = 0 \) (even if there is a \( \sinh^2 \tilde{\theta} \) in the denominator) and we also show that it vanishes when \( \tilde{b} \) becomes big. For that purpose, we compute the following small \( \tilde{b} \) and large \( \tilde{b} \) expansion:

\[
\tilde{\rho} \sim \frac{3}{8\pi G} \tilde{b}^2 \quad \text{when} \quad \tilde{b} \ll 1
\] (3.10)
\[
\hat{\rho} \sim \frac{9}{8\pi G s(s^2 + 1)^2} \exp\left(-\tilde{\theta}\left(\sin(s\tilde{\theta}) - s\cos(s\tilde{\theta})\right)\right) \quad \text{when} \quad \tilde{b} \gg 1. \quad (3.11)
\]

As \(\lim_{\theta} \hat{\rho} = 0 = \lim_{\theta} \tilde{\rho}\), and as \(\tilde{\rho}\) admits no pole, then \(\hat{\rho}\) is necessarily bounded, hence the bouncing scenario. The shape of the energy density as a function of \(\tilde{b}\) is depicted in figure 2 for \(s = 0\) (left panel) and for selected values of \(s > 0\) (right panel), explicitly showing that \(\hat{\rho}\) admits a maximal value. As it is already the case in real LQC, the energy density as a function of \(\tilde{b}\) may become negative-valued for \(s > 0\). However, contrary to the real case with \(j = 1/2\), one cannot write explicitly a modified Friedmann equation which would involve the Hubble constant and the energy density only. It is only when \(\tilde{b} \ll 1\) (equivalently when \(\tilde{\theta} \ll 1\)) that one recovers trivially the standard classical Friedmann equation (in cosmic time, i.e. \(N = 1\))

\[
V = \{ V, C_H \} = V\{\hat{\rho}, V\} = 3 V\tilde{b} \quad \Rightarrow \quad \left(\frac{\dot{a}}{a}\right)^2 = \left(\frac{\dot{V}}{3V}\right)^2 = \frac{8\pi G}{3} \tilde{\rho} \quad (3.12)
\]

as expected. In the quantum regime, there is no such an exact equation. We can obviously say that the bounce occurs when the energy density is maximal, but even a close formula for the maximal energy density does not exist. For these reasons, it is very complicated to study analytically the evolution of the Universe for generic values of \(s\). Note that there is no simple closed formula of the modified Friedmann equation even in usual real LQC when one considers a regularization of the curvature operator with a spin \(j\) greater than \(1/2\). It is therefore not surprising that a similar phenomenon exists in the complex theory.

We also note that the Hamiltonian for the matter content is unchanged compared to real LQC since it does not depend on the connection variable. One therefore recovers the standard expressions for the energy density as a function of the free scalar field as well as the Klein–Gordon equation for the dynamics of the free scalar field respectively given by

\[
\rho = \frac{1}{2} \dot{\phi}^2, \quad \phi + \frac{\dot{V}}{V} \phi = 0.
\]

To have a better understanding of the dynamics in complex LQC, we proceed as in the standard real approach and we choose the smallest representation \(s\) to regularize the Hamiltonian constraint. We can refer to the same argument as in the real theory to explain this choice. Indeed, this choice corresponds to quantum cosmology states with the best possible coarse grained homogeneity. In the complex theory, we have to choose \(s = 0\) in which case the edges of the corresponding spin-network states carry an area equal to the area gap \(\Delta = 4\pi^2 p^2\) (3.3). Therefore, an edge colored with \(s = 0\) is not equivalent to an edge not colored at all in the complex theory. With this choice the Hamiltonian constraint and the energy density simplify according to the formulae:

\[
\hat{H} = N(H_m - \rho V) \quad \text{with} \quad \rho = \frac{9}{8\pi G} \frac{\sin^2(2\tilde{b})}{\lambda^2} f(\tilde{\theta}). \quad f(\tilde{\theta}) = \frac{\tilde{\theta} \coth \tilde{\theta} - 1}{\sinh^2 \tilde{\theta}}. \quad (3.13)
\]

Contrary to the cases where \(s \neq 0\), the energy density does not oscillate. Its dynamics is much simpler: it first increases until it reaches its maximal value \(\rho_{\text{max}}\) and then it decreases exponentially when \(\tilde{b}\) (or \(\tilde{\theta}\)) becomes larger and larger. The shape of \(\hat{\rho}\) as a function of \(\tilde{b}\) as derived from the rhs of equation (3.13) is depicted in the left panel of figure 2 for \(s = 0\), clearly showing that it is bounded from above. To analyze further it is interesting to compute (and eventually to solve in some regimes) the dynamical equations satisfied by the physically relevant phase space parameters. It is easy to show that the connection variable \(\tilde{b}\) satisfies:
As $\rho > 0$ when $s = 0$, $\tilde{b}$ decreases when the cosmic time increases. In other words, $\tilde{b}$ and $t$ go in opposite directions which means that the large $b$ and small $\tilde{b}$ asymptotic regimes correspond respectively to the state of the Universe before and after the bounce.

It is also very interesting to compute the Hubble parameter (or equivalently the time evolution of the volume variable $V$ which is conjugate to $\tilde{b}$). Its expression as a function of $\tilde{b}$ is given by:

$$\frac{\dot{a}}{a} = \left\{ \tilde{b}, H_m - \dot{\rho}V \right\} = -4\pi G \left( \frac{H^2}{2V^2} + \dot{\rho} \right) \approx -8\pi G \tilde{\rho}.$$  \hspace{1cm} (3.14)

This is displayed in figure 3 as the solid-black curve. The energy density is also shown as a dashed curve, where it has been rescaled to be clearly displayed. This shows that the maximum of the energy density is indeed reached for a vanishing Hubble parameter.

Using the equality (which follows immediately from (3.5))

$$\frac{\partial}{\partial \tilde{b}} = \lambda \frac{\sinh \left( \lambda \tilde{b} \right)}{\cosh \left( \tilde{b}/2 \right)} \frac{\partial}{\partial \tilde{b}},$$  \hspace{1cm} (3.16)

one arrives immediately at:

$$\frac{\dot{a}}{a} = \frac{3}{2\lambda} \left[ \sinh \left( 2\lambda \tilde{b} \right) \times f \left( \tilde{b} \right) + \frac{\sinh^3 \left( \lambda \tilde{b} \right)}{\cosh \left( \tilde{b}/2 \right)} \times \frac{\partial f}{\partial \tilde{b}} \right].$$  \hspace{1cm} (3.17)

This is displayed in figure 3 as the solid-black curve. The energy density is also shown as a dashed curve, where it has been rescaled to be clearly displayed. This shows that the maximum of the energy density is indeed reach for a vanishing Hubble parameter, thus changing its sign at the bounce. Even if the singularity is removed and the Universe is bouncing when its volume achieves a minimal value, the precise dynamics is rather different than the real LQC dynamics. First of all, the energy density is no more periodic as we have already said. Then the behaviors of the Universe before and after the bounce are very different and not symmetric as is the case in usual LQC. This allows one to make a clear distinction between what happens before and after the bounce. For all these reasons, the dynamics of complex LQC seems to feature more interesting physical properties than the usual LQC. However, it is technically more involved to handle.
To illustrate this different phenomenology, let us study the dynamics in the two asymptotic regimes $\bar{b} \ll 1$ and $\bar{b} \gg 1$. The corresponding asymptotic for the energy densities has been computed previously (3.10). For small values of $\bar{b}$, the energy density is proportional to $\bar{b}^2$, hence one recovers the standard Friedmann equation as expected.

For large values of $\bar{b}$, the phenomenology is more interesting. The energy density decreases exponentially with $\bar{b}$ and this leads to a different version of the Friedmann equation. In that limit (keeping in mind that $\bar{b}$ and $\bar{\theta}$ are positive), the curvature variable $\bar{\theta}$ and the ‘connection’ variable $\bar{b}$ are related by

$$2 \exp\left(\frac{\bar{\theta}}{2}\right) \sim \exp\left(\bar{b}\right).$$

This relation enables us to write the energy density as a function of $\bar{b}$ only from which we can extract the Hubble parameter as follows:

$$\bar{\rho} \sim \frac{36}{\pi G \lambda} \bar{b} e^{-2\bar{b}} \implies \frac{\dot{a}}{a} \sim -96 \bar{b} e^{-2\bar{b}}.$$ (3.18)

These two equations give the following modified Friedmann equation relating the ‘expansion’ rate $(\dot{a}/a)$ of the Universe to the energy density $\bar{\rho}$ of its content (here a massless scalar field) in the regime where $\bar{b} \gg 1$:

$$\frac{\dot{a}}{a} \sim -\frac{8\pi G \lambda}{3} \times \bar{\rho}.$$ (3.19)

In this regime, the Hubble parameter is therefore linearly related to the energy density. By squaring the above, one obtains

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3} \frac{\bar{\rho}}{\rho_\lambda} \text{ where } \rho_\lambda = \frac{3}{8\pi G \lambda^2}$$

is a constant with the dimension of an energy density ($\lambda^2$ has the same dimension as $G$), and which is of the order of a hundredth of the Planck energy density, $\rho_\lambda \approx 0.0095 \times \rho_{\text{Pl}}$. This has to be compared to the standard Friedmann equation $(\dot{a}/a)^2 = (8\pi G/3) \times \bar{\rho}$. This shows that this branch $\bar{b} \gg 1$ corresponds to a low energetic Universe ($\bar{\rho} \rightarrow 0$) but with a non-classical effective dynamics for its expansion rate. This differs from real LQC in which two asymptotically classical branches ($\lambda b \rightarrow 0$ and $\lambda b \rightarrow \pi$) are connected via the bounce. Here, one connects a non-classical branch ($\bar{b} \rightarrow +\infty$) for which the energy density is linearly related to the expansion rate, to an asymptotically classical branch ($\bar{b} \rightarrow 0$) for which one recovers the classical quadratic relation between the energy density and the expansion rate. We will discuss and propose physical interpretations for this results in the last section 4.

For the moment, let us go further in the analysis of this regime by integrating the time evolution of the scalar field $\Phi(t)$ and the scale factor $a(t)$. This can be solved exactly. From the Klein–Gordon equation for the free massless field, one easily obtains

$$\bar{\rho}(t) = \bar{\rho}_0 \left(\frac{a_0}{a(t)}\right)^6,$$

where $\bar{\rho}_0$ and $a_0$ are the values of $\bar{\rho}$ and $a$ at a given time $t_0$. Plugging this into the equation (3.19), the modified Friedmann equation can be solved as a function of the scale factor and we get:
where the time parameter is the cosmic time (from the beginning). Clearly, as time increases, the scale factor decreases and the energy density increases. We stress that the square root involved in the scale factor is always definite for $\tilde{b} \gg 1$. The above-derived explicit solution for $a(t)$ is valid as long as the modified Friedmann equation (3.19) is valid (i.e. $\tilde{b} \to \infty$), that is as long as $\tilde{\rho} \ll \rho_\lambda$. (We note that $\tilde{\rho}_0$ is assumed to be much smaller than $\rho_\lambda$, and that the relation $\rho \propto a^{-6}$ is valid on the entire range of values of $\tilde{b}$ since it only derives from the Klein–Gordon equation without any further assumption.) From the requirement that our approximation holds only for $\tilde{\rho}(t) \ll \rho_\lambda$, this fixes the time scale on which the above expression is valid to be:

$$t - t_0 \ll \frac{\lambda \rho_\lambda}{6 \tilde{\rho}_0} \left[ 1 - \frac{\tilde{\rho}_0}{\rho_\lambda} \right].$$

Since $\tilde{\rho}_0/\rho_\lambda \ll 1$, it is easily checked that the square root involved in $a(t)$ is positive-definite.

Note that such an expression is valid only if $\tilde{b} \gg 1$, which means that the energy density must be very low and the scale factor large. When the scale factor in the previous expression becomes at the order of 1 (or smaller), the previous expression is no more a good approximation.

For completeness, we derive the expression of the free scalar field as a function of time. This is easily done using the expression of $\tilde{\rho}$ as a function of the scale factor:

$$\Phi(t) = \Phi_0 + \frac{\lambda \Phi_0 \rho_\lambda}{3 \tilde{\rho}_0} \left[ 1 - \left[ 1 - 6 \frac{\tilde{\rho}_0 t - t_0}{\rho_\lambda} \right]^{1/2} \right],$$

where $\Phi_0$ and $\Phi_0$ are the values of the field and its derivative at $t_0$. For increasing time, the scalar field is as expected monotonically increasing which justifies its use as a clock in this regime. As for the expression of the scale factor, such an expression is valid only when $\tilde{b} \gg 1$.

3.3. Exactly solvable complex LQC

To finish with the dynamics, we study the so-called exactly solvable complex LQC. It is indeed well known that LQC can be solved exactly if one uses the scalar field as an internal clock and also if one works in a suitable representation of the quantum algebra of operators. In this representation, the quantum states are functions of $\tilde{b}$ and the volume (or a related quantity) $V$ is an operator which acts as a derivation. In other words, one chooses a polarization such that $\tilde{b}$ is the coordinate and $V$ the conjugate momentum. To make the exact resolution of the dynamics more concrete we recall that the phase space is locally parametrized by the pairs of canonically conjugate variables

$$\{ \Pi, \Phi \} = 1 \quad \text{and} \quad \{ \tilde{b}, v \} = 1 \quad \text{with} \quad v = \frac{V}{4\pi G}.$$

Furthermore, in harmonic time (where $N = V = a^3$), when one expresses the Hamiltonian constraint with previous variables, one obtains immediately
\[ \rho = - \frac{1}{\sqrt{12\pi G}} \int_{b_0}^b \frac{dt}{u} = \frac{1}{\sqrt{12\pi G}} \log b \]
when \( b \gg 1 \) then \( x(b) \sim \frac{1}{24} \sqrt{\frac{\lambda}{2\pi G}} \int_{b_0}^{b} du \frac{\exp(\lambda u)}{\sqrt{u}} \sim \frac{1}{24} \sqrt{\frac{1}{2\pi G\lambda}} \frac{\exp(\lambda b)}{\sqrt{b}}. \) (3.27)

Therefore \( x(b) \) is an increasing function which runs from \(-\infty\) to \(+\infty\) as it should. The shape of the function \( x(b) \) on the whole set \( b \in ] -\infty, +\infty[ \) is given in the left panel of figure 4. From the asymptotic expressions of \( x(b) \) and \( \tilde{\rho} \) for \( b \ll 1 \) and \( b \gg 1 \), one easily derives the dependance of \( X \) as a function of \( x \) in these regimes to be (remembering that \( X \propto \sqrt{\rho} \)):

\[
X \sim \exp(x) \quad \text{for} \quad x \to -\infty \quad (i.e. \quad b \ll 1), \quad \text{and} \quad X \sim \frac{1}{x} \quad \text{for} \quad x \to +\infty \quad (i.e. \quad b \gg 1).
\]

Once we obtain the equation (3.25) for the wave function, we can proceed exactly as in usual real LQC [41]. The invariance of the theory under inversion of the triad leads to the symmetry condition \( \chi(x, \Phi) = -\chi(-x, \Phi) \) and then we can write the general solution of the Klein–Gordon equation as \( \chi(x, \Phi) = (F(x_+) - F(x_-))/\sqrt{2} \). The function \( F \) is an arbitrary complex-valued function on the real line (constrained to satisfy some integration properties) and \( x_\pm = \Phi \pm x \) correspond to the left/right moving coordinates. The physical inner product between two such states \( \chi_1 \) and \( \chi_2 \), associated to the functions \( F_1 \) and \( F_2 \), is the standard one:

\[
\langle \chi_1, \chi_2 \rangle = i \int_{-\infty}^{+\infty} dx \left( \partial_x F_1(x_+) F_2(x_+) - \partial_x F_1(x_-) F_2(x_-) \right), \tag{3.28}
\]

where \( \bar{F} \) stands for the complex conjugate of \( F \).

We can now evaluate the expectation value of the volume operator \( \hat{V} = 4\pi \hat{g} \) on a state \( \chi \) characterized by a function \( F \). Following what is done in usual LQC, in the \( b \) representation, \( \hat{v} \) is defined as the self-adjoint part of \( -\partial_b \) and therefore acts as a derivative operator. Due to the previous change of variables, it is defined in \( x \) variables as the self-adjoint part of \( -\partial_x \) and therefore it is explicitly given by:

\[
\hat{v} = -\frac{i}{2} \left( \frac{1}{X(x)} \partial_x + \partial_x \frac{1}{X(x)} \right) \tag{3.29}
\]

as an operator acting on functions of \( x \). The fact that we choose the self-adjoint part is equivalent to choosing a symmetric order in the quantization of the classical volume operator. As a consequence, we obtain immediately:

\[
\langle \chi, \hat{V} \chi \rangle = 4\pi G \int_{-\infty}^{+\infty} dx \left| \frac{\partial F^2}{\partial x} \left( \frac{1}{X(x - \phi)} + \frac{1}{X(\phi - x)} \right) \right| \tag{3.30}
\]

which converges when \( \chi \) is a normalizable state. Finally, we obtain immediately that, whatever the normalizable state \( \chi \) is, the expectation value of the volume operator is bounded from below according to

\[
\langle \chi, \hat{V} \chi \rangle \geq \frac{8\pi G}{X_{\text{max}}} \int_{-\infty}^{+\infty} dx \left| \frac{\partial F^2}{\partial x} \right|, \tag{3.31}
\]

where \( X_{\text{max}} \) is the maximum of \( X \). This implies necessarily the existence of a bounce. Furthermore, as in usual LQC, the expectation value of the volume tends to infinity when \( \phi \to \pm \infty \).

4. Discussion

Motivated by new ideas coming from black hole thermodynamics, we have constructed a new theory of LQC where the Barbero–Immirzi parameter takes the complex value \( \gamma = \pm i \). This
construction relies on the analytic continuation of the regularized Hamiltonian constraint from real values of \( \gamma \) to the complex value \( \gamma = \pm i \). For the area operator to remain positive and self-adjoint (i.e. with real and positive eigenvalues), it is furthermore necessary to change the representation \( j \), which enters in the construction of the non-local curvature operator, into the complex number \( j = \frac{1}{2}(-1 + is) \), where \( s \in \mathbb{R} \). This allowed us to define the Hamiltonian constraint for the new ‘complex LQC’ that we studied mainly for \( s = 0 \). Using first effective theory methods and then exactly solvable LQC techniques, we analyzed the dynamics in detail. We showed that the bouncing scenario remains and the bounce relates two different branches of the Universe: a standard GR branch at the semi-classical limit (after the bounce) and a new non ‘classical’ branch (before the bounce). The latter phase corresponds to a Universe with low energy density but with high curvatures (because \( b \) is large). Such Universes were also discovered in the totally different context of brane cosmology [52] and it would be certainly very interesting to try to make a link between these two approaches if there exists any. On the other hand, it is obviously possible to transform the unconventional Friedmann equation (3.19) into the usual one with a simple redefinition of the time variable \( \tau \) (which satisfies \( d\tau = (\rho)^{3/2}dt \)). Even if the time \( \tau \) is no more the usual cosmic time in the standard GR branch, it could be possible that it plays such a role in the non-standard branch.

We hope to study all these aspects in the future.

To go further and understand more deeply this complex LQC, we need a detailed study of the quantization and a precise construction of the kinematical and physical quantum states. In standard LQC, the expression of the non-local curvature operator (among other things) allows us to define the quantum states as trigonometric functions of the variable \( b \). In the complex theory, the suitable variable to work with seems to be the curvature \( \tilde{\theta} \) rather than the connection variable \( \tilde{b} \). Furthermore, the non-local curvature operator involves trigonometric and hyperbolic functions of \( \tilde{\theta} \) and then it is expected that the quantum states would be defined as sums of functions of the type \( \exp(-m\tilde{\theta} + in\tilde{\theta}) \). We hope to study all these aspects in detail: construction of the scalar product, action of the Hamiltonian constraint, robustness of the bouncing scenario, etc. Such a model could help us in understanding the quantization of the full complex theory of gravity and also finding our way toward the resolution of the reality conditions. It would be also very instructive to study the model in the framework of spin-foam models and to make a link with spin-foam cosmology [53]. This could open a new door toward the understanding of the dynamics in LQG.

Acknowledgments

It is a pleasure to thank M Geiller and E Wilson-Ewing for their comments and their help to improve the manuscript.
