Abstract—The effects of hardware-induced crosstalk in MIMO transmitters, subject to nonlinear power amplifier distortion, are considered in this paper. A methodology that provides tractable results and a clear understanding of the effects of crosstalk on transmitter performance is introduced and applied to different transmitter models. In particular, a physically motivated $2 \times 2$ MIMO transmitter model, which is subjected to input and output crosstalk, is studied in detail, as well as a behavior motivated transmitter model, which is subjected to linear crosstalk. For the latter structure, asymptotic results, when the number of transmitters tends to infinity, are derived. These results provide insight into different 1D and 2D transmitter structures in the massive MIMO scenario. The methodology provides tractable analytical results of the performance of the transmitter. It is shown that the transmitter crosstalk degrades the performance in terms of normalized mean squared error with 3 dB going from a $2 \times 2$ set-up to a 1D array of a massive amount of transmitters, and an additional 3 dB loss going from a 1D to 2D transmitter structure. Transmitter input power back-off optimization is further studied, with back-off determination that takes the effects of MIMO crosstalk into account in order to increase the energy efficiency of the transmitter.

Index Terms—Orthogonal frequency division multiplexing (OFDM), input back-off, massive MIMO, power amplifier, transmitter hardware imperfections.

I. INTRODUCTION

An ideal radio frequency transmitter modulates and amplifies its input baseband signal without introducing any nonlinear distortion or memory effects. This holds true both for single-input-single-output (SISO) as well as $M \times M$ multiple-input-multiple-output (MIMO) transmitters. However, there is no such thing as ideal radio frequency transmitters because they suffer from hardware imperfections that influence their performance. Practical MIMO transmitters have recently entered the scene. Compared to traditional SISO transmitters, they allow both for a reduction of the size of the transmitter and improved price-performance metrics. Besides the in-channel dynamic effects and nonlinearities present in a practical SISO transmitter, the MIMO transmitter adds additional artifacts, for instance, leakage between the transmitter branches or antennas, or so called crosstalk, that negatively influence its performance [1]. The crosstalk may originate from a plurality of sources, including circuit board couplings [1]. Currently, the MIMO transmitters are typically $2 \times 2$ structures, e.g., for IEEE 802.11 [2], [3], LTE [4], and 79 GHz radar [5], with tailored $2 \times 2$ MIMO approaches for digital error correction [6]. In particular, the crosstalk was identified as a key issue for the 5-GHz 108-Mb/s $2 \times 2$ MIMO WLAN transceiver in [2]. Work on $M \times M$ MIMO transmitters for $M > 2$ include the effects of housing the transmitters on a fixed physical space [7] and system identification and measurements on $3 \times 3$ MIMO set-ups [8], [9].

With the massive MIMO trend [10], [11], large-$M$ transmitter structures can be expected, and they will have imperfections included. Understanding these new transmitter structures as illustrated in Fig. 1 is one of the main motivations for this paper. This paper studies the behavior and performance of $M \times M$ MIMO transmitters based on a methodology that dates back to the classical work of Bussgang [12]. Early results on the performance of SISO systems under different kinds of nonlinearities include the work of [13], [14]. The methodology has recently gained renewed popularity and has been used to analyze the performance of orthogonal frequency domain multiplexing (OFDM) excited transmitters, spanning from the SISO case in [15]–[18], $2 \times 2$ MIMO transmitters in [19], to multi user massive MIMO scenarios including quantized precoding [20], 1-bit ADCs in uplink [21], [22], and precoding and quantization in the downlink [23].
In this paper, this traditional methodology is employed to the analysis of MIMO transmitters with crosstalk and nonlinear distortion. It provides tractable analytical results that provide a clear understanding of the transmitter behavior, without relying on laboratory experiments or numerical simulations, such as the behavior modeling work [6], [24]. Behavior models can be used in digital predistortion design [6], [25] and in numerical system simulations [26], whereas analytical expressions for the nonlinear distortion noise can be used in decoding algorithms [27]. The focus of the present work is on details of the transmitter’s hardware impairments, namely crosstalk before and after the amplifiers and amplifier nonlinear distortion; previous work on hardware impairments in MIMO [28] and massive MIMO transmitters and systems [29]–[31] focus on system performance but are less detailed on the specific impairments - crosstalk and nonlinear distortion combined - in this paper. In [32] the effect of crosstalk before the amplifier in 2 × 2 transmitters on bit error rate was investigated.

A methodology to analyze the performance of nonlinear MIMO systems is presented, where the contributions are focused on a flexible, yet compact model-based description of the imperfections of the transmitter, using common quality measures for hardware impairments like nonlinear distortion and crosstalk. Although the presented methodology is generic, here it is applied to M × M MIMO baseband behavior models of radio frequency transmitters. Results are included for both 2 × 2 MIMO transmitters, to transmitters with an arbitrary amount of M branches. As a special case, asymptotic transmitter performance when M → ∞ is included which provides insight for the effects of nonlinear distortion for the massive MIMO set-up. The approach provides the researcher and practitioner with a methodology to understand the nonlinear behavior of a MIMO transmitter, including the nonlinear distortion, the effects of crosstalk, and how the performance depends on the correlation of the input streams that can be a result of digital beamforming or precoding. It is, thus, useful for transmitters in applications such as point-to-point and massive MIMO. The performance of entire communication systems is, however, not analyzed. Such analyses would include also channel and receiver models.

The paper it motivated by its contributions to the understanding of dirty radio MIMO transmitters [33]:

- **Generic methodology for nonlinear systems:** The paper provides a generic approach using a matrix-based methodology to analyze static nonlinear MIMO systems which are subject to Gaussian input excitation. The methodology is well suited to analyze the behavior of radio frequency transmitters which are subject to OFDM input streams. The strength of the methodology is first illustrated by considering a model of a 2 × 2 MIMO radio frequency transmitter which is subject to input- and output crosstalk [19]. This transmitter model relies on the physical properties of co-located transmitters. This is illustrated in Fig. 2. It is shown that the methodology is able to derive results that conform with the recent theoretical and experimental work on the provided structure [19], [34], which both used a direct and accordingly cumbersome analytical approach to analyze the performance of the transmitter. First, this physically motivated transmitter model is analyzed, followed by the introduction of an alternative model that grasps the main behavior of the original model even though it is not physically motivated. The alternative model simplifies the analysis of M × M transmitters for M ≥ 2, which is the main focus of the present work.

- **Crosstalk in dirty MIMO transmitters:** It is shown that the dominant behavior of a contemporary 2 × 2 MIMO radio frequency transmitter which is subject to input and output crosstalk can be accurately described by an alternative model containing, so called, linear crosstalk. The linear crosstalk models the leakage from a transmitter branch to its neighbor branches linearly, and thus is a mathematical simplification of the physical crosstalk that appear both before and after the nonlinearity. To analyze M × M transmitters for an arbitrary number of branches, it is an important finding, due to the reduced mathematical complexity that provides expositive performance expressions in closed form. With this finding in mind, a M × M transmitter is analyzed in detail with the proposed methodology, concluding with a closed form expression for the normalized mean squared error (NMSE) for finite values of M, as well as limiting values when M → ∞. The NMSE is the employed quality measure of the transmitter [19].

- **1D and 2D physical spaces for dirty massive MIMO transmitters:** Increasing the number of M branches asks for understanding of the dirty radio effects, when different 1D and 2D physical spaces are proposed by the designers. A linear array of transmitters and a 2D rectangular design are both illustrated in Fig. 1. In particular, 2D grid placements have been identified as a key technology for 5G New Radio [35]. The performance of dirty MIMO transmitters subject to their 1D or 2D physical space is investigated, with respect to the inherent transmitter crosstalk. The derived results on transmitter NMSE are used to study the transmitter performance under different constraints on the transmitter layout.

The paper is organized as follows. In Sec. II, the applied methodology is presented, and closed form results are derived...
for the Bussgang gain matrix, the properties of the nonlinear distortion error, and the total error of the considered transmitter system. In Sec. III, the derived methodology is applied to an established $2 \times 2$ MIMO transmitter model, verifying the work in [19]. Based on the obtained results, an alternative behavior model structure is suggested that grasps the dominant behavior of the original model. The alternative model is suitable for the analysis of $M \times M$ MIMO transmitter models for $M > 2$ in different 1D and 2D structures. Sec. IV provides an analysis of the $M \times M$ MIMO transmitter set-up, including the asymptotic massive MIMO case when $M \to \infty$. Sec. V provides the conclusions of the work.

II. ANALYZING NONLINEAR MIMO SYSTEMS

We present the theory in some detail. Parts of Sections II.A and II.B have been presented earlier [20]. We develop a formalism for treating nonlinearities with a linear and a nonlinear part, suitable for RF transmitters.

A. Signal Model

Consider a static and linear $M \times M$ MIMO system excited by the vector input $u$, that is

$$r_o = H_o u,$$

where the $M \times M$ matrix $H_o \in \mathbb{C}$ contains the weights for the desired linear relations. Equation (1) describes an ideal $M \times M$ MIMO power amplifier with gain $h_o$ when the matrix $H_o = h_o I$, where $h_o$ is the common gain in the different branches, and $I$ is the unity matrix of proper dimension. It should be noted that the model (1) is static, and thus the time index is not explicitly shown.

Considering OFDM, the input $M$-vector $u$ is modeled as zero-mean complex-Gaussian with covariance matrix [36]

$$U \triangleq E[uu^H],$$

where superscript $H$ denotes Hermitian transpose, and $E[\cdot]$ denotes statistical expectation. The covariance matrix $U$ describes both the input crosstalk and the possible correlation of the input streams due to linear precoding or beamforming. In this work, only crosstalk is considered because it is known that on average linear precoding or beamforming do not influence the NMSE of the transmitter [19]. With reference to Fig. 2, the signal $u$ (exciting the nonlinearities) is, in general, an internal transmitter signal; however, in this work, it is typically used to refer to the input signal (exciting the nonlinearity). The practical MIMO system is subject to nonlinear distortion and inter-channel crosstalk. To capture these effects, the practical $M$-vector output $r$ is modeled by

$$r = Hu + Gf(u),$$

where the $M \times M$ matrix $H \in \mathbb{C}$ contains the weights for the linear relations, that is, the desired small signal gain and the input linear crosstalk. Furthermore, $G \in \mathbb{C}$ is a weighting $M \times N$ matrix and $f(u) \in \mathbb{C}$ denotes the $N$-column vector with, for the application, relevant nonlinear terms up to a given polynomial order.

Let $y$ denote the baseband model of the observable transmitter output, that is

$$y = Pr + n,$$

where the $M \times M$ matrix $P \in \mathbb{C}$ in (4) handles possible output crosstalk, and $n$ is the zero-mean complex-valued Gaussian thermal noise, independent of the input $u$. The covariance of the thermal noise is denoted by $N$, that is

$$N \triangleq E[nn^H].$$

B. Bussgang Gain of Nonlinear System

To perform the analysis, the MIMO system signal $r$ after the nonlinearity (3) is expressed as an attenuated version of the input $u$, and a distortion noise $v$. Here, the distortion noise $v$ is uncorrelated to both the input $u$ and the thermal noise $n$. Accordingly, by construction, the output $r$ in (3) should fulfill

$$r = s + v,$$

where $s$ in (6) is a linearly transformed version of the input $u$, that is

$$s = A H u.$$  \hspace{1cm} (7)

In (7), the $M \times M$ matrix $A \in \mathbb{C}$ is called the Bussgang gain to honor the initial work [12]. An expression for $A$ is derived next.

It is clear from (7) that the covariance of $s$ reads

$$S \triangleq E[ss^H] = A H U H^H A^H.$$  \hspace{1cm} (8)

For the distortion noise $v$ in (6) to be uncorrelated with the input $u$ it is required that

$$E[vuu^H] \triangleq 0,$$  \hspace{1cm} (9)

where $0$ is the zero matrix of appropriate size. With the requirement (9), define

$$W \triangleq E[rr^H],$$  \hspace{1cm} (10)

as the output-input cross correlation matrix. It follows directly from the original signal model (3) that $W$ defined in (10) can be expressed as

$$W = H U + G \bar{U}.\hspace{1cm} (11)$$

In (11), the $N \times M$ matrix $\bar{U}$ contains the higher order moments of $u$, and is defined by

$$\bar{U} \triangleq E[f(u)u^H].$$  \hspace{1cm} (12)

Now, starting with the model (6) that introduces the distortion noise, the correlation matrix $W$ in (10) can alternatively be expressed as

$$W = E[ss^H] + E[vv^H] = AHU,$$  \hspace{1cm} (13)

where (7) and (9) were used in the second equality. Assuming that the involved matrix inverses exist, the Bussgang gain $A$ follows from (13) as

$$A = W U^{-1} H^{-1} = I + \underbrace{G \bar{U} U^{-1} H^{-1}}_{A_{\Delta}},$$  \hspace{1cm} (14)
where the second equality follows from (11). In (14), the Bussgang matrix $A_\Delta$ is defined as a part of the Bussgang gain $A$, that is $A = I + A_\Delta$. Note that the Bussgang gain $A$ is a function of the system matrices $H$ and $G$, and the moment properties of the input signal $u$ via $U$ and $\overline{U}$. For a linear system, $G = 0$ in (3) and accordingly $A = I$, as expected.

C. Distortion Noise Properties

The model (6)-(7) describes the output from the nonlinear function in terms of a linearly attenuated replica of the input $u$, and a distortion noise $v$. The properties of the latter term is as follows. From (6), the distortion noise reads

$$v = r - s.$$  

The distortion noise covariance $V$ is defined by

$$V \triangleq E[vv^H] = R - S,$$  

where $R \triangleq E[rr^H]$ and $S$ is defined in (8). The second equality in (16) follows since $s$ and $v$ are uncorrelated.

In order to calculate $R$ in (16), note from the original signal model in (3) that

$$R = E[(Hu + Gf(u))(Hu + Gf(u))^H]$$

$$= HUH^H + 2R[H \overline{U} H^H] + GUG^H,$$  

where $R[z]$ denotes the real part of $z \in \mathbb{C}$, and the higher order moment matrix $\overline{U}$ of size $N \times N$ is introduced as

$$\overline{U} \triangleq E[f(u)f(u)^H].$$  

In a similar vein, first note that $S$ in (16) is given in (8). Now, inserting the Bussgang gain derived in (14) into (18) yields

$$S = (I + G \overline{U}^{-1}H^{-1})HUH^H(I + G \overline{U}^{-1}H^{-1})^H$$

$$= HUH^H + 2R[G \overline{U} H^H] + GUG^H.$$  

Now, inserting the results (17) for $R$ and (19) for $S$ into the expression (16) for the error covariance $V$, a straightforward calculation yields

$$V = G(\overline{U} - \overline{U} \overline{U}^{-1} \overline{U}) G^H.$$  

The covariance $V$ of the distortion error $v$ is a function of the system matrix $G$, and the moment properties of the input signal $u$ via $U^{-1}$, $\overline{U}$ and $\overline{U}$.

D. Properties of the Transmitter Output Error

Using (6)-(7), the observable transmitter output $y$ in (4) reads

$$y = PAH u + P v + n.$$  

With the observable baseband output $y$ in (21), and the ideal output $r_o$ according to (1), the error signal $e$ is given by

$$e \triangleq y - r_o = (PAH - H_o)u + Pu + n.$$  

The introduced signal $\tilde{u}$ captures the (linear part of the) error due to crosstalk and Bussgang attenuation, $\tilde{v}$ is the nonlinear distortion noise, and $n$ the thermal noise. From (3), (7) and (15) we get

$$\tilde{v} = (P(AI - A)u + PGf(u), \tilde{v}_L, \tilde{v}_NL),$$  

where $\tilde{v}_L$ is linear and $\tilde{v}_NL$ nonlinear in $u$. The three terms in (22) are jointly uncorrelated. Accordingly, the error covariance $E \triangleq E[ee^H]$ reads

$$E = \tilde{U} + PVP^H + N,$$  

where $\tilde{U} \triangleq E[\tilde{u}\tilde{u}^H]$ is to be decided, $V$ is given by (20), and $N$ is the thermal noise covariance (5). From (22), it follows that the covariance matrix $\tilde{U}$ that is eminent in (24) is given by

$$\tilde{U} = (PAH - H_o)U(PAH - H_o)^H.$$  

E. Transmitter Figures of Merit

Since the focus of the paper is on the behavior and performance of the transmitter only, figures of merit reflecting the quality and performance of the communication link are not considered. Such figures require channel and receiver models. We refer to e.g. [37], [38] for such studies. Accordingly, the NMSE is adopted as the main figure of merit, where it is defined for the $\ell$:th branch by (that is, $\ell = 1, \ldots, M$)

$$\text{NMSE}_\ell \triangleq \frac{[E]_{\ell,\ell}}{\gamma_\ell^2},$$  

where $[\cdot]_{\ell,\ell}$ denotes the $(\ell, \ell)$:th element of the matrix within the brackets, and where the normalization $\gamma_\ell^2$ is with respect to the average input power and the ideal gain. With an ideal gain $h_o$ and input variance $\sigma^2$ in all the $M$ branches, the normalization reads

$$\gamma_\ell^2 = h_o^2 \sigma^2, \quad \ell = 1, \ldots, M.$$  

If it is assumed that the channel and receiver impairments are perfectly known and compensated for, the terms linear in $u$ in (22) and (23) can be neglected and the NSME becomes identical to the error vector magnitude (EVM) [29]. To analyze the cross-branch properties of the transmitter, additional figures of merit, such as the normalized error covariance (NEC) can be defined in a similar vein as the NMSE [19], but is beyond the scope of this paper.
As a complement to the NMSE we use a measure of the out-of-band error, which only is affected by the transmitter’s nonlinear properties. The out-of-band error of channel $\ell$ is conventionally measured by the adjacent channel power ratio (ACPR) (also called adjacent channel error power ratio) [6]

$$ACPR_{\ell} \triangleq \frac{\int_{\text{adj.ch.}} E_{\ell}(\omega) \, d\omega}{\int_{\text{ch.}} E_{\ell}(\omega) \, d\omega},$$  

(28)

where $E_{\ell}(\omega)$ is the power spectral density (PSD) of the error signal and $Y_{\ell}(\omega)$ is the signal’s PSD. Notice that in (28) the numerator is integrated over the adjacent channel and the denominator of the channel itself. The channel limits are given by the spectrum masks of the telecommunication standard in question. The terms in (22) and (23) that will contribute to the error signal in the adjacent channel are $\nu_{NL}$ and $n$, and, hence, in (28)

$$E_{\ell}(\omega) = V_{NL,\ell}(\omega) + N_{\ell}(\omega),$$  

(29)

where $V_{NL,\ell}(\omega)$ and $N_{\ell}(\omega)$ are the PSD of the $\ell$th branch of $\nu_{NL}$ and $n$, respectively. With the approximation that the linear gain is the same as the ideal gain and that the power of the nonlinear distortion is small compared to the power of the signal $y_{\ell}$, we get for the denominator in (28)

$$\int_{\text{ch.}} Y_{\ell}(\omega) \, d\omega \approx h_0 \sigma^2 + \int_{\text{ch.}} N_{\ell}(\omega) \, d\omega.$$  

(30)

### III. 2 × 2 MIMO With Input and Output Crosstalk

The presented methodology is applied to the frequently used 2×2 transmitter model in Fig. 2 and verifies some of the results from the literature. The main result is an analytical expression for the NMSE as a function of parameters for the crosstalk, nonlinearity, and thermal noise. For experimental validations of the model, we refer to [34]. Based on the obtained results, an alternative behavior model is proposed. The alternative model accurately grasps the dominating behavior of the transmitter and neglects the less dominant terms.

#### A. Signal Model

With reference to Fig. 2, let the power amplifier output be described by

$$r_1 = u_1 + \rho u_1 |u_1|^2,$$  

(31)

$$r_2 = u_2 + \rho u_2 |u_2|^2.$$  

(32)

In (31)-(32), the compression parameter $\rho$ is assumed real-valued, and $\rho \leq 0$. A quasi-static performance analysis is possible by letting $\rho$ and other parameter values (as defined below) be complex-valued [19]. However, such analysis will not, except for the specific case, provide additional information worth the extra effort required. For the considered 2 × 2 behavior model, the reader is referred to [19] for such an analysis. We restrict the analysis to third order nonlinearities. Polynomial models with higher order terms, $\rho_n u |u|^{n-1}$, where $n = 3, 5, \ldots$, could, however, be used. The third order terms are typically dominating and can be estimated from quality measures for amplifiers such as the 1 dB compression point or third order intercept point [39]. Nonlinear functions other than polynomials could be analyzed, in which case the calculation of $\overline{U}$ and $\overline{U}$ would be different. For example, experimentally determined amplitude (AM/AM) and phase (AM/PM) distortion data could be used and $\overline{U}$ and $\overline{U}$ calculated numerically.

Using the matrix formulation, (31)-(32) is rephrased as

$$r = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} u + \rho \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} |u_1|^2 \\ |u_2|^2 \end{pmatrix}.$$  

(33)

$$H = I, \quad G = \rho I, \quad f(u)$$

The input $u$ is subject to crosstalk, that is the covariance matrix $\mathbf{U}$ reads

$$U = \sigma^2 \mathbf{Q} \mathbf{Q}^H,$$  

(34)

where

$$\mathbf{Q} = \begin{pmatrix} 1 & \delta \\ \delta & 1 \end{pmatrix},$$  

(35)

where $\delta \in \mathbb{R}$ models the input crosstalk, and $\sigma^2$ is the joint power of the uncorrelated inputs before the crosstalk, aka $x_1$ and $x_2$ in Fig. 2. The crosstalk is typically caused by circuit board couplings and is therefore modeled as a static linear reciprocal network [39]. Explicitly, combining (34) and (35), the covariance matrix $\mathbf{U}$ reads

$$\mathbf{U} = \sigma^2 \mathbf{Q}^{-1} \left( \begin{array}{cc} 1 + \delta^2 & 2\delta \\ 2\delta & 1 + \delta^2 \end{array} \right).$$  

(36)

To calculate the NMSE, the crosstalk induced correlation has to be compensated for. Accordingly, the ideal system $H_{\nu}$-matrix in (1) is given by

$$H_{\nu} = \mathbf{Q}^{-1} \left( \begin{array}{cc} 1 & -\delta \\ -\delta & 1 \end{array} \right),$$  

(37)

where the second equality directly follows from (35).

The components of the transmitter output $y$ read

$$y_1 = r_1 + \tilde{n}_1 + \mu (r_2 + \tilde{n}_2),$$  

(38)

$$y_2 = r_2 + \tilde{n}_2 + \mu (r_1 + \tilde{n}_1),$$  

(39)

where $\tilde{n}_1$ and $\tilde{n}_2$ are jointly uncorrelated thermal noises with common variance $\sigma_n^2$, and where $\mu \in \mathbb{R}$ denotes the output crosstalk. Using the matrix formulation, (38)-(39) is expressed as

$$y = \begin{pmatrix} 1 & \mu \\ \mu & 1 \end{pmatrix} r + \mathbf{n},$$  

(40)

where the covariance $\mathbf{N}$ of the equivalent thermal noise $\mathbf{n}$ is $(n_1, n_2)^T$ due to the crosstalk reads

$$\mathbf{N} = \sigma_n^2 \left( \begin{array}{cc} 1 + \mu^2 & 2\mu \\ 2\mu & 1 + \mu^2 \end{array} \right).$$  

(41)
B. Bussgang Matrix and NMSE

For the considered 2 × 2 transmitter model, it is shown in Appendix V-A that the Bussgang gain in (14) reads

\[ \mathbf{A} = \mathbf{I} + 2\rho \sigma^2 (1 + \delta^2) \mathbf{I}, \]  

(42)

that is, \( \mathbf{A}_\Delta = \alpha_\Delta \mathbf{I} \) with reference to (14). As further shown in Appendix V-A, the covariance \( \mathbf{V} \) of the distortion noise \( \mathbf{v} \) in (15) reads

\[ \mathbf{V} = 2\rho^2 \sigma^6 \begin{pmatrix} (1 + \delta^2)^3 & 8\delta^3 / (1 + \delta^2)^3 \\ 8\delta^3 / (1 + \delta^2)^3 & 1 \end{pmatrix}. \]

(43)

Due to symmetry, the NMSE is equal in both branches, that is \( \text{NMSE}_\ell = \text{NMSE} \) for \( \ell = 1, 2 \). The terms in the NMSE are derived in Appendix V-A, and the result is given in (44), shown at the bottom of this page.

In (44), \( a = 1 + a_\Delta \) is the scalar Bussgang gain given by the diagonal elements of \( \mathbf{A} \), with \( a_\Delta = 2\rho (1 + \delta^2) \sigma^2 \) according to (42). The NMSE shown in (44) is known from [19], where it was based on a cumbersome direct calculation of the NMSE. Accordingly, the proposed methodology provides a flexible tool for analytical and numerical evaluations of this class of models, which was not provided in [19].

In a first order approximation, the NMSE in (44) is given by

\[ \text{NMSE} \approx 6\rho^2 \sigma^4 + (\delta + \mu)^2 + \frac{\sigma_n^2}{\sigma^2}, \]

(45)

where \( \approx \) denotes an approximate expression where only the dominant terms are retained. The derivation is outlined in Appendix V-A. In (45), the linear crosstalk parameter \( \xi = \delta + \mu \) was introduced, which is a parameter that will be frequently used in the sequel.

To get an approximate expression for the ACPR we use that for the output crosstalk \( \mu \ll 1 \) in (23), (31), and (31), and get that \( v_{\mathbf{NL,}\ell} = \rho u_{\ell} |u_{\ell}|^2 \). The PSD of the nonlinear distortion, \( V_{\mathbf{NL,}\ell}(\omega) \) is obtained from frequency domain convolutions of the Fourier Transform of \( v_{\mathbf{NL,}\ell} \). The bandwidth of \( v_{\mathbf{NL,}\ell} \) is three times that of the \( u_{\ell} \) (the channel bandwidth). We use that the adjacent channels bandwidth is the same as the channel's bandwidth and use no guardbands. From (28), (29) and (30) we then get

\[ \text{ACPR}_\ell \approx \frac{0.5\rho^2 \sigma^6 + 0.3\sigma_n^2}{h_0 \sigma^2 + 0.3\sigma_n^2}, \]

(46)

C. An Alternative MIMO Transmitter Model

As is evident from the full expression of the NMSE in (44) and its approximation in (45), the performance is determined by the dominant terms. Consider the alternative behavior model in Fig. 3, which is a 2 × 2 MIMO system with uncorrelated inputs, that is \( \mathbf{U} = \sigma^2 \mathbf{I} \) and the system description given by

\[ \mathbf{r} = \begin{pmatrix} 1 & \xi \\ \xi & 1 \end{pmatrix} \mathbf{u} + \rho \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} u_1 |u_1|^2 \\ u_2 |u_2|^2 \end{pmatrix}, \]

(47)

where \( \xi = \delta + \mu \). Furthermore, there is no direct output crosstalk, that is \( \mathbf{P} = \mathbf{I} \) and \( \mathbf{N} = \sigma_n^2 \mathbf{I} \), or

\[ \mathbf{y} = \mathbf{r} + \mathbf{n}. \]

(48)

With \( \mathbf{U} = \sigma^2 \mathbf{I} \), it directly follows that \( \mathbf{U} \) in (12) reads \( \mathbf{U} = 2\sigma^2 \mathbf{I} \), and \( \mathbf{U} \) in (18) reads \( \mathbf{U} = 6\sigma^2 \mathbf{I} \), respectively. Using (14), a direct calculation provides us with the Bussgang matrix, that is \( \mathbf{A}_\Delta = 2\rho \sigma^2 \mathbf{H}^{-1} \). To calculate the error covariance \( \mathbf{E} \) in (24), both \( \mathbf{V} \) in (20) and \( \mathbf{U} \) in (25) are required. An expression for the covariance \( \mathbf{V} \) directly follows as

\[ \mathbf{V} = 2\rho^2 \sigma^6 \mathbf{I}. \]

(49)

The covariance matrix of the linear distortion \( \tilde{\mathbf{U}} \) in (25) is derived in Appendix V-B, that is

\[ \tilde{\mathbf{U}} = \sigma^2 \begin{pmatrix} 4\rho^2 \sigma^4 + \xi^2 & 4\rho \xi \sigma^2 \\ 4\rho \xi \sigma^2 & 4\rho^2 \sigma^4 + \xi^2 \end{pmatrix}. \]

(50)

The error covariance \( \mathbf{E} \) in (24) now follows by summing up (49), (50) with the thermal noise covariance \( \mathbf{N} = \sigma_n^2 \mathbf{I} \), or restricting the summation to the diagonal terms

\[ \mathbf{E}|_{\ell, \ell} = 4\rho^2 \sigma^6 + \xi^2 \sigma^2 + 2\rho^2 \sigma^6 + \sigma_n^2. \]

(51)

Accordingly, the NMSE for a 0 dB gain transmitter, which is equal in the two branches due to the symmetry of the problem, reads

\[ \text{NMSE} = 6\rho^2 \sigma^4 + \xi^2 + \frac{\sigma_n^2}{\sigma^2}. \]

(52)

In Fig. 4, the NMSE (44) and (52) (and, accordingly, also the approximative expression (45) that coincides with (52))
The behavior of the physical NMSE of the model with linear crosstalk closely resembles $\propto$ powers. In Fig. 4 a line $20 \log_{10} \sigma$ are displayed for a crosstalk of $\delta = -25$ [dB] and with $\delta = \mu$. The power amplifier compression parameter is given by $\rho = -0.05$. Thermal noise variance is given by $\sigma_n^2 = 10^{-4}$, or $-10$ [dBm]. From the figure, it is clear that the NMSE of the model with linear crosstalk closely resembles the behavior of the physical $2 \times 2$ MIMO transmitter model.

Using polynomials of higher order than three gives terms $\propto \rho_3 n \sigma_6$ (and higher orders in $\sigma^2$) in the expressions for NMSE vs. $\sigma^2$. Such terms affect the NMSE at high input powers. In Fig. 4 a line $\propto \sigma^6$ is shown to illustrate the behavior and for comparison with the term due to third order nonlinearities ($\propto \sigma^3$).

The derivation and expression for the ACPR is the same for the alternative model, Fig. 3, as for the model in Fig. 2, i.e. as in (46). In Fig. 5 the ACPR is shown as obtained from (46) with the same parameters as for the NMSE shown in Fig. 4. Notice that the scale of the x-axis in Fig. 5 is different from that in Fig. 4. In Fig. 5 three regions I, II, and III are indicated. In region I, the ACPR describes the nonlinear distortion. In region II, the out-of-band error is dominated by the thermal noise; in the channel the thermal noise is small. In region III, which is of little practical interest, the thermal noise dominates in the out-band.

Using other numerical values for the noise variance, $\sigma_n^2$, compression parameter, $\rho$, and crosstalk, $\xi = \delta + \mu$, gives qualitatively the same behavior of the NMSE and ACPR as in Figs. 4 and 5 with the main behavior given by the straight lines.

In summary, the input crosstalk determined by $\delta$ and the output crosstalk determined by $\mu$ can approximately be replaced with a linear crosstalk from the adjacent branch to the output of the branch, with gain $\xi = \delta + \mu$. This observation is used to study general $M \times M$ MIMO transmitters below.

**IV. $M \times M$ MIMO With Linear Crosstalk**

In this section, a $M \times M$ transmitter with linear crosstalk is considered, where $M$ can be large (that is, as $M \to \infty$).
Finally, \( \hat{U} \) is required, which is derived in Appendix V-C. All the required information is now available to calculate the error covariance \( \mathbf{E} \) in (24). In (58), \( \mathbf{V} \) is diagonal, i.e., the distortion noise of the different branches is uncorrelated, which is in agreement with [29], [37]. Notice that for the model in Fig. 2, \( \mathbf{V} \) in (43) has off-diagonal elements, indicating partly correlated distortion noise. However, the off diagonal elements are \( \propto \delta^3 \) and the diagonal elements are \( \approx 1 \) and typically \( \delta \ll 1 \). For the model in Fig. 3, \( \mathbf{V} \) in (49) becomes identical to (39) if \( \delta \) is neglected. Below the NMSE corresponding to (58) in (24) is studied.

### B. NMSE and Input Back-off for NMSE Minimization

The NMSE for the \( \ell \)th branch reads

\[
\text{NMSE}_\ell = 6 \rho_\ell^2 \sigma^4 + \sum_{m=1}^{M-\ell} |h_m|^2 + \sum_{m=1}^{\ell-1} |h_m|^2 + \frac{\sigma_n^2}{\sigma^2}. \tag{59}
\]

In (59) the elements of \( \mathbf{H} \), \( h_m \), that contain the crosstalk, are arbitrary, and hence, different physical models for the cross talk and transmitters of arbitrary geometry can be studied if the corresponding \( h_m \) are known. Before analyzing the NMSE in (59) in detail for specific \( \mathbf{H} \), corresponding to the 1D and 2D cases in Fig. 11, note that although the NMSE depends on \( \mathbf{H} \), its minimization with respect to the average input power \( \sigma^2 \) does not. The minimum NMSE is obtained in the \( \ell \)th branch with the average input power \( \sigma_\ell^2 \) given by

\[
\sigma_\ell^2 = \arg \min_{\sigma^2} [\text{NMSE}_\ell] = \sqrt{\frac{\sigma_n^2}{12 \rho_\ell^2}}, \tag{60}
\]

where \( \min[\cdot] \) denotes the minima of the function within the brackets. It should be noted that the optimal input power back-off (60) only depends on the properties of the considered branch via the compression parameter \( \rho_\ell \) and the power of the thermal noise \( \sigma_n^2 \). In particular, the average input power minimizing the NMSE is independent of the actual crosstalk, the nonlinear properties of the other branches, and the actual number of \( M \) branches. Inserting the numerical values that were used to generate the plots in Fig. 4 into (60) result in an optimal (that is, minimizing NMSE) average input power \( \sigma_\ell^2 \) of 21.7 [dBm], which also is displayed in Fig. 4. The small shift to the right in the minimum of the NMSE from (44) to (45) seen in Fig. 4, is negligible in practical cases. The larger the crosstalk, the larger the shift will be. The minimum of the NMSE of (45) will always be shifted to the right in the figure, for physically realistic values of the crosstalk.

The assumptions made when deriving the approximate expression for the ACPR in (46) are valid also in the \( M \times M \) case. Thus, (46) can be used and the behavior will be the same as in Fig. 5, also for \( M \times M \) transmitters.

### C. NMSE for 1D Transmitter Layouts

A natural extension of the \( 2 \times 2 \) MIMO case to its \( M \times M \) counterpart considers a linear placement of the individual transmitters according to Fig. 1, that is the system matrix \( \mathbf{H} \) is Toeplitz and given by

\[
\mathbf{H} = \text{Toeplitz}(1, \xi, \xi^2, \ldots, \xi^{M-1}). \tag{61}
\]

In (61), \( \xi \in \mathbb{R} \) is the parameter of the linear crosstalk, that is \( \xi = \delta + \mu \), and given in dB as \( 20 \log_{10} \xi/2 \) [dB] to be consistent with the set-up in Sec. III. The direct coupling of non-adjacent channels soon becomes small and we therefore neglect it. However, direct coupling of non-adjacent channels could be modelled by \( \xi^n \), where \( n \) is smaller than two. More complicated models or experimental values for the crosstalk could be modelled by \( h_m \) in (59).

Now, the asymptotic NMSE for a given branch \( \ell \), when the number \( M \) of transmitters tends to infinity can be calculated, that is

\[
\text{NMSE}_\ell = \lim_{M \to \infty} \text{NMSE}_\ell. \tag{62}
\]

From (59), it follows that for the 1D structure in Fig 1, the asymptotic NMSE reads

\[
\text{NMSE}_\ell = 6 \rho_\ell^2 \sigma^4 + C_\ell \xi^2 + \frac{\sigma_n^2}{\sigma^2}, \tag{63}
\]

where

\[
C_\ell = \begin{cases} 
1 & \ell = 1 \\
1 - \xi^2 & \ell = 2 \\
1 - 2\xi^2 & \ell = M/2.
\end{cases} \tag{64}
\]

In (64), \( M/2 \) should be read as the centrally located transmitter in the 1D array, and \( C_\ell \) values for \( \ell > M/2 \) follow by symmetry, that is \( C_{M-\ell} = C_\ell \), etc. The \( C_\ell \) values are explicitly given in Appendix V-C, but are observed to monotonically increase from \( \ell = 1 \) to \( \ell = M/2 \). Since \( |\xi| \ll 1 \), in practice \( C_\ell \) in (64) equals the number of nearest neighbours, that is

\[
C_\ell \approx \begin{cases} 
1 & \ell = 1, M \\
2 & \ell = 2, \ldots, M-1.
\end{cases} \tag{65}
\]

Accordingly, there is approximately a 3 [dB] drop in NMSE performance in the non-boarder branches compared with the two boarder branches when the transmitter is operating under optimal input power back-off. The result (63) indicates that the reduction in performance over the \( 2 \times 2 \) set-up due to a massive amount of 1D-distributed transmitters is 3 [dB], excluding the two branches at the boarders. In fact, the minimum NMSE for a system with non-negligible crosstalk is well approximated at optimal input back-off (60) by

\[
\min[\text{NMSE}_\ell] \approx \begin{cases} 
\xi^2 & \text{boarder branches} \\
2\xi^2 & \text{non-boarder branches}.
\end{cases} \tag{66}
\]

The underlying exact result leading to (66) is rather unaffected by the actual number of \( M \) branches, e.g. for the numerical values used to generate Fig. 4, the loss in performance in a non-boarder branch going from \( M = 3 \) to \( M \to \infty \) is in the order of a tenth of a dB.

As crosstalk has already been identified as a key issue for \( 2 \times 2 \) transmitters, additional efforts are required to handle it for \( M > 2 \). For all non-boarder branches, there will be an

\[ \text{NMSE}_\ell = 6\rho^2_\ell \sigma^4 + C_\ell \xi^2 + \frac{\sigma^2_\ell}{\sigma^2}, \tag{67} \]

where \( C_\ell \approx 4 \) for non-boarder branches, \( C_\ell \approx 3 \) for edge branches, and \( C_\ell \approx 2 \) for the four corner branches, given the assumed properties of the crosstalk. For transmitter grids with non-negligible crosstalk, the minimum NMSE for a 2D structure is described by

\[
\min[\text{NMSE}_\ell] \approx \begin{cases} 
2 \xi^2 & \text{corner branches} \\
3 \xi^2 & \text{edge branches} \\
4 \xi^2 & \text{non-boarder branches},
\end{cases} \tag{68}
\]

which provides a typical (for the non-boarder branches) deterioration of the NMSE of around 3 [dB] compared with the 1D structure, and 6 [dB] compared with the NMSE of a 2 × 2 transmitter. The results are illustrated in Fig. 6. In the figure, the broad minima should be noted, especially for the 2D structure. This observation motivates sub-optimal schemes for input back-off optimization, which is studied next.

**E. Transmitter Input Power Optimization**

To increase the energy efficiency of the transmitter, a sub-optimal scheme, where an increased average input power is determined, should be considered. This is subject to a slight degradation in NMSE. Such an approach was introduced for a dirty 2 × 2 transmitter in [19], and is here refined for the problem at hand. Let \( \Delta \) be a user selected parameter which determines the allowable loss in performance, that is the determined average input power, for which

\[
\text{NMSE}_\ell = (1 + \Delta^2) \min[\text{NMSE}_\ell], \tag{69}
\]

where the minimum possible NMSE is determined by the set up, see (66) and (68) for the 1D and 2D scenario, respectively. For example, \( \Delta = 1 \) (or, \( \Delta \approx 0.35 \)) allows for a 3 [dB] (or, 0.5 [dB]) degradation of the NMSE. Then, the average input power \( \sigma^2_\ell \) that fulfills (69) follows as

\[
\sigma^2_\ell = \frac{\Delta \xi}{|\rho|} \sqrt{\frac{C_\ell}{6}}, \tag{70}
\]

where \( C_\ell \) denotes the number of neighbouring transmitter branches. For the example displayed in Fig. 6, an increased average input power of around 6 [dB] for the 2D scenario, given a 0.5 [dB] loss in NMSE, should be noted.

**V. Conclusion**

The contributions of the paper include a tool for analyzing the behavior of MIMO transmitters in terms of NMSE. The methodology has been applied to two different transmitter models: one physically motivated with crosstalk both before and after the nonlinearity introduced by the power amplifier, and one simplified model with linear crosstalk approximating the main behavior of the former model.

Simple analytical expressions make it straightforward to analyze the NMSE and ACPR for different values of the parameters describing the hardware impairments. It is concluded that crosstalk degrades the performance of a MIMO transmitter. Under tuned average input power conditions, the MIMO transmitter NMSE is determined by the crosstalk, with additional 3 dB loss in NMSE going from 2 × 2 MIMO to a large 1D structure of transmitters, and an additional 3 dB loss in NMSE for large 2D structures.

It is further shown that SISO-based methodologies for power amplifier back-off determination are valid for a \( M \times M \) MIMO transmitter subject to crosstalk. However, schemes taking the crosstalk into account may be favorable because they allow for the operation of the transmitter with increased energy efficiency, subject to a predefined small loss in performance.

**Appendix**

**A. 2 × 2 MIMO Transmitter With Input and Output Crosstalk**

1) **Noise Properties:** The noise covariance \( \mathbf{U} \) is given by (36). Furthermore, the matrix \( \mathbf{U} \) in (12) reads

\[
\mathbf{U} = \mathbb{E} \left[ \begin{pmatrix} u_1 u_1^* \\ u_2 u_2^* \end{pmatrix} \begin{pmatrix} u_1^* u_2^* \end{pmatrix} \right] = 2\sigma^4 \begin{pmatrix} 1 + \delta^2 & 2\delta \\ 2\delta & 1 + \delta^2 \end{pmatrix}, \tag{71}
\]
where $\mathbb{E}[u_t u_k^* | u_k^2] = 2 \mathbb{E}[u_t, u_k^*] \mathbb{E}[u_t u_k^*] \mathbb{E}[u_t u_k^2]$ was used [40]. Note from (36) and (71) that $\overline{U}$ can be expressed in terms of $U$, that is

$$\overline{U} = 2\sigma^2 (1 + \delta^2) U.$$  (72)

Finally, the matrix $\overline{U}$ in (18) is here given by

$$\overline{U} = \mathbb{E} \begin{bmatrix} (u_1^1, u_1^2, u_2^1, u_2^2) \end{bmatrix}.$$  (73)

In order to resolve (73), note that for integer $\ell$ it holds for the diagonal elements that $\mathbb{E}[(u_t u_k^*)^2] = 6(1 + \delta^2)^3 \rho \sigma^6$, which follows from (36) and the general result $\mathbb{E}[(u_t u_k^*)^n] = n! \mathbb{E}[u_t u_k^*]^n$ [40]. The off-diagonal elements of $\overline{U}$ are of the form

$$\mathbb{E}[u_1 | u_1^1 u_2^* | u_2^2] = \mathbb{E}((u_1^1 u_2^*)^2 (u_1 u_2^*))^2 = 4 \mathbb{E}[u_1 u_2^*] \mathbb{E}[u_1 u_2^1] \mathbb{E}[u_2 u_2^*] + 2 \mathbb{E}[u_1 u_2^*]^2 \mathbb{E}[u_1 u_2^2]^*,$$  (74)

using the result in Appendix V.D. Accordingly, the off-diagonal elements of $\overline{U}$ read

$$\mathbb{E}[u_1 | u_1^1 u_2^* | u_2^2] = 8\delta (1 + \delta^2)^2 \rho \sigma^6 + 16 \delta^3 \rho \sigma^6.$$  (75)

In summary, $\overline{U}$ explicitly reads

$$\overline{U} = 2\sigma^6 \begin{bmatrix} 3(1 + \delta^2)^3 & 4\delta(1 + \delta^2)^2 + 8\delta^3 & 3(1 + \delta^2)^3 \end{bmatrix}.$$  (76)

2) Bussgang Gain $A$: With $H = I$, $G = \rho I$, and the relation (72) between $\overline{U}$ and $U$, it directly follows that $A$ in (14) is given by (42).

3) Distortion Noise Properties $V$: With $G = \rho I$ and the relationship (72) between $U$ and $\overline{U}$, the expression for the covariance $V$ of the distortion noise (20) reduces to

$$V = \rho^2 (\overline{U} - 4\sigma^4 (1 + \delta^2) U),$$  (77)

where $U$ given by (36) and $\overline{U}$ by (76). Now, a straightforward calculation yields $V$ in (43).

4) Linear Distortion $\overline{U}$: To calculate $\overline{U}$ in (25), let

$$X \triangleq P A H - H_o.$$  (78)

From (42), one note that $A$ is diagonal, that is $A = a I$ with $a = 1 + 2\rho \sigma^2 (1 + \delta^2)$. Furthermore, $H = I$ according to (33), and $H_o = Q^{-1}$ according to (37), respectively. In other words, $X = a P - Q^{-1}$, or

$$\overline{U} = X U X^H = (a P - Q^{-1}) (a P - Q^{-1})^H = a^2 P U P^H - 2a \mathbb{R}[P U Q^{-1}] + Q^{-1} U Q^{-H}. \quad (79)$$

When $U = \sigma^2 Q Q^H$ according to (34), the result in (79) simplifies to

$$\overline{U} = a^2 P U P^H - 2a \sigma^2 \mathbb{R}[P Q] + \sigma^2 I.$$  (80)

Furthermore, when $U$ is given by (36) and $P$ by (40), the diagonal elements of $P U P^H$ in (80) read (for, $\ell = 1, 2$)

$$[P U P^H]_{\ell,\ell} = (1 + \delta^2) (1 + \mu^2) \sigma^2 + 4\mu \delta \sigma^2.$$  (81)

For the second term in (80), a straightforward calculation yields

$$P Q = \begin{bmatrix} 1 + \mu \delta & \delta + \mu & 1 + \mu \delta \end{bmatrix}.$$  (82)

Accordingly, the linear distortion described by (80) summarizes to

$$\frac{[\overline{U}]_t, \ell}{\sigma^2} = a^2 (1 + \delta^2) (1 + \mu^2) + 4a^2 \mu \delta - 2a (1 + \mu \delta) + 1.$$  (83)

5) Nonlinear Distortion $P V P^H$: The term $P V P^H$ corresponding to the nonlinear distortion in (24) follows from a straightforward calculation. The matrix $P$ is given by (40), and $V$ is diagonal and given by (43). Let

$$V = \begin{bmatrix} V_1 & V_2 \\ V_2 & V_1 \end{bmatrix},$$  (84)

the diagonal elements of $P V P^H$ read

$$[P V P^H]_{\ell,\ell} = V_1 (1 + \mu^2) + 2\mu V_2.$$  (85)

Inserting the elements of $V$ given by (43) into (84) yields

$$[P V P^H]_{\ell,\ell} = 2\rho^2 (1 + \mu^2) (1 + \delta^2) \sigma^4 + 32 \mu \delta \sigma^4.$$  (86)

6) NMSE and its Approximation: To calculate the NMSE (26)-(27), first note that for the 0 dB transmitter gain $\gamma^2$ in (27) for $\ell = 1, 2$ reads $\gamma^2 = \sigma^2$. Now, the NMSE requires a normalized version of $E$ in (24). Summing up the terms (82) and (85), and adding the diagonal element of $N$ in (41) (normalized with $\sigma^2$), a straightforward but tedious calculation results in the closed form NMSE, which is presented in (44).

One can note that $(a_\Delta + a \mu \delta)^2 \approx a^2 \Delta^2 \approx 4\rho^2 \sigma^4$, $2\rho^2 (1 + \mu^2) (1 + \delta^2) \sigma^4 \approx 2\rho^2 \sigma^4$, $32 \rho^2 \mu \delta \sigma^4 \approx 0$, $a^2 (\delta + \mu)^2 \approx (\delta + \mu)^2$, and $(1 + \mu^2) \sigma^2 n \approx \sigma^2 n$, which inserted in (44) results in the approximate expression (45).

B. 2 × 2 MIMO Transmitter With Linear Crosstalk

To calculate $\overline{U}$ in (25), we first note that $U = \sigma^2 I$, $P = I$, $A = I + 2\rho \sigma^2 H^{-1}$, $H_o = I$. Thus, $\overline{U} = \sigma^2 (H - (1 - 2\rho \sigma^2) I)^2 = \sigma^2 \left(2\rho \sigma^2 \xi, 2\rho \sigma^2 \xi \right)^2$. (87) Calculating the square in (86) results in (50).

C. $M \times M$ MIMO Transmitter With Linear Crosstalk

1) Noise Properties: First note that the matrix $\overline{U}$ in (12) reads

$$\overline{U} = \mathbb{E} \begin{bmatrix} u_1 | u_1^2 u_2 | u_2^2 \cdots u_M | u_M^2 \end{bmatrix} = 2\sigma^4 I.$$  (88)

With $U = \sigma^2 I$, it is observed from (87) that

$$\overline{U}^{-1} = 2U = 2\sigma^2 I.$$  (89)
In a similar vein, \( \overline{U} \) reads

\[
\overline{U} = \mathbb{E}\left\{ \begin{pmatrix} u_1 |u_1|^2 \\ \vdots \\ u_M |u_M|^2 \end{pmatrix} \begin{pmatrix} (u_1^*)^2 \cdots (u_M^*)^2 \end{pmatrix} \right\} = 6\sigma^6 \mathbf{I}.
\]  

(89)

From (87) and (89) it is observed that

\[
\overline{U} = 3\sigma^2 \mathbf{U}.
\]  

(90)

2) Bussgang Gain and Distortion Properties: By the observation (88), it directly follows that the Bussgang gain \( A \) according to (14) reads as in (57). Through this observation (90), the error covariance \( \mathbf{V} \) defined in (20) reads as in (58).

To calculate \( \overline{U} \) in (25), note that the equality reduces to

\[
\overline{U} = \sigma^2 (\mathbf{H} + \mathbf{A}_\Delta \mathbf{H} - \mathbf{I}) (\mathbf{H} + \mathbf{A}_\Delta \mathbf{H} - \mathbf{I})^H
\]  

\[
= \sigma^2 (\mathbf{H} + 2\sigma^2 \mathbf{G} - \mathbf{I}) (\mathbf{H} + 2\sigma^2 \mathbf{G} - \mathbf{I})^H
\]  

(91)

where (57) was used in the second equality. Let

\[
\mathbf{X} = \mathbf{H} + 2\sigma^2 \mathbf{G} - \mathbf{I}.
\]  

(92)

Then, \( \overline{U} = \sigma^2 \mathbf{XX}^H \) with \( \mathbf{X} \) given by

\[
\mathbf{X} = \begin{pmatrix}
2\rho_2 \sigma^2 & h_1 & h_2 & \cdots & h_{M-1} \\
h_1^* & 2\rho_2 \sigma^2 & h_1 & \cdots & h_{M-1} \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
h_{M-1} \end{pmatrix}.
\]  

(93)

Now, the diagonal elements of \( \overline{U} \) follow from a straightforward calculation, with the \( \ell \)th element given by

\[
\frac{|\overline{U}|_{\ell,\ell}}{\sigma^2} = 4\rho_2^2 \sigma^4 + \sigma^2 \sum_{m=1}^{M-\ell} |h_m|^2 + \sigma^2 \sum_{m=1}^{\ell-1} |h_m|^2.
\]  

(94)

3) 1D Transmitter Layout: Here, \( h_m = \xi^m \). Let,

\[
S_{M, \ell} = \sum_{m=1}^{M-\ell} \xi^{2m} + \sum_{m=1}^{\ell-1} \xi^{2m},
\]  

(95)

and let \( \tilde{S}_\ell = \lim_{M \to \infty} S_{M, \ell} \) as \( M \to \infty \). Then, as for \( \ell \leq M/2 \)

\[
\tilde{S}_\ell = \lim_{M \to \infty} \sum_{m=1}^{M-\ell} \xi^{2m} + \sum_{m=1}^{\ell-1} \xi^{2m} = \frac{\xi^2}{1 - \xi^2} \left[ \begin{array}{c}
\ell \\
\ell + 1 \\
\vdots \\
M/2
\end{array} \right].
\]  

(96)

4) 2D Transmitter Layout: For simplicity, the analysis is given for the centrally located transmitter. With reference to Fig. 1 it follows

\[
S_c = 4\xi^2 + 12\xi^4 + 28\xi^6 \cdots \approx 4\xi^2,
\]  

(97)

where \( c \) indicates that the transmitter is centrally located. With similar arguments, the results for the boarder and corner transmitters follow.

D. A Useful Result for Complex-Valued Gaussian Variables

The required result for the 6th order moment

\[
E\left( (u_t \xi_k^*)^2 (u_t \xi_k^*)^* \right)
\]  

of Gaussian variables is as follows. Consider

\[
E\left[ z_1 z_2 z_3 z_4^* z_5 z_6^* \right] = \sum_{t=1}^{6} T_t,
\]  

where [40]

\[
T_1 = E\left[ z_1 z_2^* \right] E\left[ z_2 z_3 \right] E\left[ z_3 z_4^* \right],
\]

\[
T_2 = E\left[ z_1 z_5^* \right] E\left[ z_2 z_6^* \right] E\left[ z_3 z_4 \right],
\]

\[
T_3 = E\left[ z_1 z_5^* \right] E\left[ z_2 z_6 \right] E\left[ z_3 z_4^* \right],
\]

\[
T_4 = E\left[ z_1 z_5^* \right] E\left[ z_2 z_6^* \right] E\left[ z_3 z_4 \right],
\]

\[
T_5 = E\left[ z_1 z_5^* \right] E\left[ z_2 z_6 \right] E\left[ z_3 z_4^* \right],
\]

\[
T_6 = E\left[ z_1 z_5^* \right] E\left[ z_2 z_6^* \right] E\left[ z_3 z_4 \right].
\]
