(Dated: November 4, 2018)

The end-to-end energy - energy correlations of random transverse-field quantum Ising spin chains are computed using a generalization of an asymptotically exact real-space renormalization group introduced previously. Away from the critical point, the average energy - energy correlations decay exponentially with a correlation length that is the same as that of the spin - spin correlations. The typical correlations, however, decay exponentially with a characteristic length proportional to the square root of the primary correlation length. At the quantum critical point, the average correlations decay sub-exponentially as $C_L \sim e^{-const \cdot L^{1/3}}$, whereas the typical correlations decay faster, as $\sim e^{-K \cdot \sqrt{L}}$, with $K$ a random variable with a universal distribution. The critical energy-energy correlations behave very similarly to the smallest gap, computed previously; this is explained in terms of the RG flow and the excitation structure of the chain. In order to obtain the energy correlations, an extension of the previously used methods was needed; here this was carried out via RG transformations that involve a sequence of unitary transformations.

I. INTRODUCTION

The random transverse field Ising model is the prototypical model of a quantum system with quenched randomness. It undergoes a novel quantum phase transition at zero-temperature, and over a wide range of parameters, exhibits unusual low temperature behavior. In one dimension, many of the low energy properties have been found exactly, initially by McCoy and Wu, and in much detail recently. The behavior in higher dimensions has been shown to be in the same general class as the one dimensional system.

In addition to its theoretical interest, models with similar behavior have been argued to be relevant for the low temperature properties of heavy fermion materials, with randomness and proximity to a quantum critical point playing key roles in producing non-fermi-liquid behavior.

In this paper we study the end-to-end energy and transverse spin correlations of long but finite random transverse field Ising chains. The average energy and transverse spin correlations are found to have rather different behavior than the order parameter correlations. Computing them introduces new difficulties which compel us to further develop the general renormalization group (RG) structure. The formulation presented here should be useful for other random quantum systems.

The organization of this paper is as follows; in the remainder of this section we review some aspects of the random Ising model and introduce the quantities of interest. In Sec. II we develop and apply a unitary-transformation approach to the real-space RG. In Sec. III and IV Laplace-transforms of the energy and transverse spin correlations are derived and used in Sec. V to obtain the average and typical correlations, and more general information about the distributions. Finally, Sec. VI presents conclusions. Some technical details are confined to an Appendix.

FIG. 1: The Hamiltonian of the transverse field Ising model. Each site is a spin-1/2 that interacts via Ising exchange with its nearest neighbors and can be flipped by the local magnetic field.

A. Random Transverse Field Ising Model

The Hamiltonian of the random quantum Ising model is

$$\mathcal{H} = -\sum_{i} \left( J_{i,i+1} \sigma_i^x \sigma_{i+1}^x + h_i \sigma_i^z \right)$$

with each site having two states, $\sigma^z = \pm 1$, with quantum fluctuations between them caused by the transverse, $\sigma^x$, fields. The system is illustrated in Fig. 1. Note that there are no magnetic fields in the $z$-direction, so that there is a global symmetry of inversion about the $xy$ spin plane. The presence of $z$ fields would break this symmetry and change the low energy physics radically.

The quantum Ising model exhibits a quantum phase transition in its ground state when the nearest neighbor interaction and the transverse field are of comparable strength. In a non-random model this occurs when $J = h$. In a random system, where the $J$'s and the $h$'s are drawn independently from some distributions, the transition occurs when $\log h = \log J$, where the over-bars denote averaging over the randomness. A convenient parametrization of the proximity to the transition is

$$\delta = \frac{\log h_J - \log J_J}{\text{var}(\log h) + \text{var}(\log J)}$$

with $\delta$ positive in the disordered phase.
B. Real Space RG

A powerful route to analytic information on this system is a real space — or energy space — RG method that is a generalization developed by one of us,\textsuperscript{4} of an RG introduced by Ma, Dasgupta and Hu.\textsuperscript{9,10} The real space RG is carried out by decimating the term in the Hamiltonian — a site ($h\sigma^z$), or a bond ($J\sigma^x\sigma^y$) — with the strongest interaction; second order perturbation theory results in new effective couplings. In the case of decimating a bond, a cluster forms with a renormalized transverse field; in the case of decimating a spin, a new Ising interaction that couples its two neighbors forms. The Hamiltonian preserves its form, with effective bonds coupling spin clusters, and the energy scale — the maximum remaining coupling — reduced. The effective bond strengths and lengths, as well as the effective transverse fields on the clusters of spins and their moments can be computed.

As the energy scale is systematically reduced, the distributions of the effective couplings become very broad for small $\delta$. Concomitantly, the averages of many quantities in the ground state are determined by rare tails of their distribution. In particular, the average order parameter correlations,

$$C^{zz}(n,n + r) \equiv \left< \sigma_n^z \sigma_{n+r}^z \right>,$$

at large separations $r$, are dominated by the rare pairs of spins that are not decimated until they join together into the same spin cluster.\textsuperscript{4}

C. Logarithmic Energy Scaling

Many properties of the random quantum Ising model can be understood in terms of the scaling behavior of the cluster sizes, bond lengths, and coupling strengths with the energy scale and the deviation from criticality, $\delta$.

At the critical point, the distributions of $h_i$ and $J_{i+1}$ become infinitely broad as the energy scale, $\Omega$, approaches zero; the random quantum critical point is thus an infinite randomness fixed point.\textsuperscript{6,11,12} At this fixed point the distribution of cluster and bond lengths, the logarithms of the interactions in units of $\Omega$,

$$\zeta \equiv \log \frac{\Omega}{\Omega_f},$$

$$\beta \equiv \log \frac{\Omega}{\Omega_0},$$

and the deviation from criticality, $\delta$, all scale with the logarithm of the energy scale,

$$\Gamma \equiv \log \frac{\Omega}{\Omega_f}.$$

Here $\Omega_f$ is the initial energy scale set by the strongest couplings, and $\Omega$ is the magnitude of the largest remaining couplings after the stronger ones have been decimated. The scaling can equivalently be given in terms of a length scale, $\ell$ — for example the length of an effective bond — the scaling of log-energies at fixed $\ell$ is of the form

$$\zeta = z\sqrt{\ell},$$

$$\Gamma = \gamma\sqrt{\ell},$$

(6)

where $\gamma$ and $z$ are scale invariant random variables.

Various basic results follow directly from this scaling. In particular, the linear number density of remaining spin-clusters at scale $\Gamma$ is

$$n \approx \frac{n_0}{\Gamma^2},$$

(7)

with $n_0$ a non-universal prefactor inversely proportional to the original bond lengths.

An example of the scaling of log-energies with length is the gap, $E_1 - E_0$, between the ground state and the first excited state of long finite chains: Analytic and numerical results show that near the critical point the logarithm of the gap is broadly distributed on the scale $\sqrt{\Omega}$. Indeed, the distribution of $-\log(E_1 - E_0)/\sqrt{\Omega}$ attains a universal scaling form in the large $L$, small $\delta$ limit.\textsuperscript{3} From the RG structure, this can be seen by noting that the gap is the energy scale of the chain when it has only one remaining cluster — and thus only one unfrozen degree of freedom. Therefore the gap is approximately $\Omega_L \sim e^{-\Gamma_L}$ with $\Gamma_L \propto \sqrt{\Omega}$ the sample-specific scale at which this last cluster is decimated.

In long finite chains of length $L$, the end-to-end spin correlations $\left< \sigma_0^z \sigma_L^z \right>$ are a useful probe of the long length scale ordering tendencies. The distributions and moments of these can be calculated exactly in the asymptotic limit of long chains and small $\delta$: these compare well with numerical results.\textsuperscript{3} The distributions can be expressed usefully in terms of

$$\Lambda_z \equiv -\log C^{zz}(0,L).$$

(8)

This logarithm of the correlations scales with $\sqrt{\Omega}$ at the critical point, with a broad distribution on the same scale. The average correlations, however, decay much more slowly: only as $C^{zz} \propto \frac{1}{L}$.

D. Ordered and Disordered Phases

When $\delta$ is non-zero but small, there are two scaling regimes. At early stages of the decimation process, clusters and interactions are not “aware” of being non critical. In this regime the critical scaling holds. At longer scales, however, there is a crossover to an off-critical regime. The crossover occurs when the typical cluster sizes and bond lengths are of order of the correlation length

$$\xi \approx \frac{1}{\delta^2}.$$
and the log-energy scale is of order
\[ \Gamma_x \sim \frac{1}{\delta}. \] (10)

At scales larger than \( \xi \), the behavior is characteristic of one of the two zero-temperature phases and thus depends on the sign of \( \delta \).

At low energies in the ordered and disordered phases, the scaling between energy and length scales is different from that at the critical point. For small \( \delta \), in both phases
\[ \Omega \sim L^{-\beta/\delta} \] (11)
with the effective dynamical exponent,
\[ z \approx \frac{1}{|\delta|} \] (12)

near the critical point.

The distributions of the log-interactions also change form. In the disordered phase, the distribution of the effective fields does not continue to broaden and \( \beta \sim \Gamma_x \sim \frac{1}{\delta} \). But the effective bonds become longer and longer and weaker and weaker with the distribution of the ln \( J \)'s broadening rapidly, with typical \( \zeta \sim \Gamma \). In the disordered phase, the average order parameter correlations decay exponentially with the correlation length \( \xi \approx \frac{1}{\xi} \). Nevertheless, the typical correlations decay much faster; for example, end-to-end correlations of almost all samples decay as \( e^{-\beta L} \). More precisely, as \( L \to \infty \), the distribution of the scaled log-correlation function, \( \Lambda_x/L \), approaches a delta function peaked at \( \Lambda_x/|L| = 2\delta \). The average correlations are thus dominated by exponentially rare samples that happen to have anomalously strong exchanges and/or anomalously weak random fields.

In the ordered phase, \( \delta < 0 \), at low energy scales the clusters become bigger and bigger, eventually encompassing the whole system. The transverse fields on these clusters — the gap between the symmetric and antisymmetric combinations of their two “ordered” states — concomitantly continues to become more and more broadly distributed. The remaining bonds, on the other hand, stay relatively short and their distribution does not continue to broaden. These fields and bonds thus play opposite roles in the two phases; as discussed below, this is a general consequence of duality.

### E. Duality

As for non-random classical and quantum Ising models, there is a dual description of the random quantum chain in terms of bond variables. Instead of using the states \( | \uparrow \rangle, | \downarrow \rangle \), on each site, one can use the states of the bonds. This is done by assigning \( | + \rangle, | - \rangle \) to the bond if the two spins surrounding the bonds are \( | \uparrow \uparrow \rangle, | \downarrow \downarrow \rangle \) or \( | \downarrow \uparrow \rangle, | \uparrow \downarrow \rangle \) respectively. These are domain-wall variables. In the new Hilbert space, if we choose the quantization axis to be \( x \) rather than \( z \), the Hamiltonian has the same form, but with \( h \) and \( J \) exchanged. The duality is summarized in the following table:

\[
\begin{align*}
\delta & \quad -\delta \\
J_{n+1} & \quad h_n \\
\sigma^z_n & \Rightarrow J_{n+1} \\
\sigma^+_n \sigma^-_{n+1} & \quad \sigma^+_n \\
\sigma^-_n \sigma^+_{n+1} & \quad \sigma^-_n 
\end{align*}
\] (13)

If the \( \delta \) dependence of the distributions of the random couplings has the form \( \rho_J(J = X, \delta) = \rho_h(h = X, -\delta) \), the random model is self dual with \( \delta \Rightarrow -\delta \). More generally, it will not be exactly self dual. But from the definition of \( \delta \) in terms of \( \rho_J \) and \( \rho_h \) (Eq. 2), and the universality at low energy scales (in particular, of the distributions of the effective couplings), we expect that the asymptotic behavior at low energies and small \( \delta \) will indeed be self-dual for any well-behaved distributions.

As we are interested in end-to-end correlations of finite chains, we must consider what happens to the ends of a chain under the duality transformation. Let \( -h_0 \sigma^z_0 \) be the energy operator on the left end site. Under duality, this site will be mapped into a bond with corresponding energy operator \( -h_0 \sigma^z_0 \sigma^z_1 \) (see Fig. 2). The bond in the dual chain implies a new site \( 0' \) that corresponds to the domain wall variable to the left of the first spin in the original chain. This new site, \( 0' \), thus carries the information about an arbitrarily fixed boundary condition, e.g., \( | \uparrow \rangle \), with respect to which the leftmost domain wall, and hence the original end spin \( \sigma^z_0 \), is defined; it thus cannot be entirely forgotten. But in the dual Hamiltonian, the operator \( \sigma^z_0 \) does not appear, so that the dual end transverse field is zero, and \( \sigma^z_0 \) is time independent. The same is true at the other end, where the extra spin is needed for the original \( \sigma^z_1 \) to be defined. Superficially, the dual chain appears to have one extra degree of freedom associated with each end. But the orientation of the
II. UNITARY TRANSFORMATION RENORMALIZATION GROUP

In this section we develop a perturbative scheme based on unitary transformations that will allow us to separate the various parts of the Hamiltonian and successively simplify the wave functions of the many-body system to a hierarchical product of simple spin wave functions. Simultaneously, we must keep track of the original operators in order to eventually compute their ground state correlations.

We begin with the first stage of decimation by constructing the eigenfunction of the highest energy part of the Hamiltonian and transforming it to take into account the low energy parts perturbatively. Specifically, the transformation gets rid of the off-diagonal parts that connect states with large energy differences between them. For the Ising chain, this can be done while preserving the form of the Hamiltonian.

Given a Hamiltonian, $H$, and a many-body ground state wave function, $|G\rangle$, with

$$H|G\rangle = E_G|G\rangle. \quad (14)$$

we can generally make a unitary transformation with a hermitian operator $S$ and write:

$$e^{iS}He^{-iS}|G\rangle = e^{iS}|G\rangle,$$

$$H_{eff} = e^{iS}He^{-iS} \quad \text{and} \quad e^{iS}|G\rangle = |H\rangle. \quad (15)$$

with the goal to make $|G\rangle$ close to a product of simple wave functions. Such transformations can be used to eliminate — or separate — low energy parts in the Hamiltonian.

Let $H = H_0 + V$, where $H_0$ is the high energy part of $H$ and $V$ is the remaining low energy parts. The effective Hamiltonian is then

$$H_{eff} = H_0 + V + i[S, H_0] + i[S, V] + \frac{i^2}{2}[S, [S, H_0]] + O(S^3). \quad (16)$$

If we are able to choose $S$ so that

$$V + i[S, H_0] = 0, \quad (17)$$

then $H_{eff}$ will contain no first order terms. The second order corrections to $H_0$ give rise to effective interactions. We may now solve for the ground state of $H_{eff}$ and hence the original $H$:

$$H_{eff}|H\rangle = E_G|H\rangle$$

$$|G\rangle = e^{-iS}|H\rangle. \quad (18)$$

Iterating this process separates the higher energy parts of the Hamiltonian from the lower energy parts. At each stage, the effective higher energy parts can be simply diagonalized. The remaining non-diagonalized Hamiltonian only has pieces with energy much lower than the gap.

---

**F. Energy-Energy Correlations**

Our goal in this paper is to understand the energy density (E-E) correlations of the random chain. These would be particularly interesting at non-equilal times, as they would then yield information on the transport of energy which is the only locally conserved quantity in this system. Unfortunately, in the bulk of the chain correlations are very hard to calculate for reasons discussed in ref. 4. Therefore we study the somewhat simpler but closely related quantities: the end-to-end correlations of the energy density in finite chains, restricting our analysis to equal time correlations.

Since the Hamiltonian involves two kinds of terms, $J\sigma_0^z\sigma_i^z$ and $ha^z$, to obtain the E-E correlations we need to calculate three quantities, $J_0\sigma_0^z\sigma_i^zJ_{L-1}\sigma_{L-1}^z$, $J_0\sigma_0^zJ_{L-1}\sigma_{L-1}^z$ and $J_0\sigma_0^z\sigma_i^zJ_{L-1}\sigma_{L-1}^z$. However, the duality transformation simplifies matters, since it maps $J_0\sigma_0^z\sigma_i^zJ_{L-1}\sigma_{L-1}^z$ at $\delta$ to $J_0\sigma_0^z\sigma_i^zJ_{L-1}\sigma_{L-1}^z$ at $-\delta$, so we only need to compute one of these quantities. Also, the mixed correlation function is dual to itself, therefore the distribution of $J_0\sigma_0^z\sigma_i^zJ_{L-1}\sigma_{L-1}^z$ must depend on $|\delta|$, and be the same in the two phases. Note that a related single-ended quantity, the imaginary time correlation function $J_0\sigma_0^z(0)\sigma_i^z(\tau)$, was considered by Iglói, Juhasz and Rieger.\textsuperscript{[14]}

The calculation of the quantities of interest requires an extension of the methods used so far. The primary reason for this is that the energy correlations are dominated by third order perturbative effects at each stage of the decimation, in contrast to the spin correlations, which are controlled by second order perturbative effects.

To be able to carry out higher order RG calculations, we develop an approach to the decimation in terms of unitary transformations; this allows one to follow precisely how operators of interest (such as $a^z$) evolve during the RG process. This approach thereby gives a systematic way to deal with higher orders perturbative effects even in problems previously analyzed using second order perturbation theory.\textsuperscript{[3]} The unitary-transformations method is developed in the next section (Sec.II).
of the high energy section, which was just diagonalized. The ground-state wave function is then constructed perturbatively from the wave-function $|H>$, which is a hierarchical wave-function simply expressible in terms of the ground states of the high energy parts of the sequence of $H_{\text{eff}}$’s. Each term in the hierarchy will be a spin-cluster pointing in the direction of the transverse field. For an example see Eq. (35) below.

Note that this method is related to the flow equation approach for interacting quantum problems developed by Kehrein and Wegner.\textsuperscript{15,16}

### A. Unitary RG for Transverse Field Ising Chain

We now apply the transformations (15) to successively reduce the maximum energy scale of the random quantum Ising Hamiltonian, thereby obtaining a series of low energy effective Hamiltonians of the system. We begin by choosing the largest energy coefficient in the Hamiltonian (1) and denote it $H_0$ (with the corresponding coupling the initial energy scale $\Omega_1$): for example, $H_0 = -J_1 \sigma_1^z$ (see Fig. 3). Let $V$ designate the part of the Hamiltonian that we would like to eliminate. For the above example we would like to eliminate the parts connecting site 1 to the rest of the chain:

$$V = -J_{01} \sigma_0^z \sigma_1^x - J_{12} \sigma_1^z \sigma_2^x.$$  \hspace{1cm} (19)

In addition to these two parts, the Hamiltonian also contains the parts involving the remainder of the chain,

$$H_1 = \ldots -J_{-10} \sigma_{-1}^z \sigma_0^x - h_0 \sigma_0^z - h_2 \sigma_2^z - J_{23} \sigma_3^z \sigma_4^z + \ldots$$  \hspace{1cm} (20)

In order to eliminate the first order couplings to spin 0, $S$ must satisfy equation (17); thus we first choose

$$S_a = - \frac{J_{01}}{2h_1} \sigma_0^x \sigma_1^y - \frac{J_{12}}{2h_1} \sigma_1^x \sigma_2^y.$$  \hspace{1cm} (21)

which yields the following terms in the effective Hamiltonian (Eq. 16):

$$H_{\text{eff}} =$$

$$\ldots - \frac{J_{-10} J_{12}}{h_1} \sigma_{-1}^z \sigma_0^x \sigma_1^y - \frac{h_0 J_{01}}{h_1} \sigma_0^y \sigma_1^x - \frac{h_2 J_{12}}{h_1} \sigma_1^y \sigma_2^x + \ldots$$  \hspace{1cm} (22)

Note that site 1 is still coupled to adjacent sites by a second order interaction. We would like to restore the Hamiltonian to its original form; thus we need to eliminate the new type of interaction. To get rid of it, we perform another transformation using

$$S_b = - \frac{h_0 J_{01}}{2h_1^2} \sigma_0^y \sigma_1^x - \frac{h_2 J_{12}}{2h_1^2} \sigma_1^y \sigma_2^x.$$  \hspace{1cm} (23)

The effective Hamiltonian now includes

$$H_{\text{eff}} = \ldots - J_{-10} \sigma_{-1}^z \sigma_0^x - h_0 \sigma_0^z$$

$$- \tilde{J}_{02} \sigma_0^x \sigma_1^y - h_2 \sigma_2^z - J_{23} \sigma_3^z \sigma_4^z + \ldots,$$  \hspace{1cm} (24)

$$- h_1 \sigma_1^x,$$
The analog of the above results for the case where an exchange interaction, e.g. $H_0 = -J_{12} \sigma^z_1 \sigma^z_2$, is eliminated is (Fig. 4)

$$H_0 = -J_{12} \sigma^z_1 \sigma^z_2$$

$$V = -h_1 \sigma^x_1 - h_2 \sigma^x_2$$

$$S_a = \frac{h_0 h_2}{2 J_{12}} \sigma^y_1 \sigma^y_2 + \frac{h_0 h_3}{2 J_{12}} \sigma^y_1 \sigma^y_2$$

$$S_b = -\frac{h_0 h_4}{2 J_{12}} \sigma^y_1 \sigma^y_0 - \frac{h_1 h_2}{2 J_{12}} \sigma^y_1 \sigma^y_2. \quad (28)$$

This could be obtained by using the duality described in the introduction (Sec. I E) and in Ref. 4, or by direct computation. The ground state of $H_0 = -J_{12} \sigma^z_1 \sigma^z_2$ is doubly degenerate with spins 1 and 2 either in the state $| \uparrow \rangle = | \uparrow \rangle_1 | \uparrow \rangle_2$ or in the state $| \downarrow \rangle = | \downarrow \rangle_1 | \downarrow \rangle_2$. Therefore in the ground state of $H_0 = \sigma^z_1 \sigma^z_2$ spin 1 and 2 form a ferromagnetic cluster, which we denote as (12). We can define cluster operators, $\sigma^z_{(12)}$, and $\sigma^z_{(12)}$, that operate on the spin cluster (12) in the following way:

$$\sigma^z_{(12)} \Rightarrow \sigma^z_{(12)}$$

$$\sigma^z_{(12)} \Rightarrow \sigma^z_{(12)}$$

$$-\sigma^x_{(12)} \sigma^y_{(12)} \Rightarrow \sigma^z_{(12)}$$

in terms of which

$$\mathcal{H}_{eff} - H_0 =$$

$$\ldots - h_0 \sigma^0_{(12)} \sigma^z_{(12)} - h_{(12)} \sigma^z_{(12)}$$

$$-J_{(12)} \sigma^z_{(12)} \sigma^z_{(12)} - h_3 \sigma^z_{(12)} - \ldots,$$

with

$$\tilde{h}_{(12)} = \frac{h_1 h_2}{J_{12}} \quad (31)$$

being the effective transverse field on the new cluster (12) that has replaced the pair of spins 1 and 2 that now only appear separately in the high energy term in $H_0$. Again, since $J_{12}$ is the strongest energy, and strong randomness is assumed, the effective transverse field obeys:

$$\tilde{h}_{(12)} \ll h_1, h_2, J_{12}. \quad (32)$$

In both the decimation cases we regain the initial form of the Hamiltonian, but with one less spin. As shown in Refs. 4, 11, with even stronger randomness. The increase in the randomness with each step justifies the iterative application of the real-space RG as described in this section. In each step we eliminate a high-energy subspace of the Hilbert space of the chain, which is gapped by $2 \Omega$ from the remaining subspace. The range of excitations in the remaining subspace is much smaller than $\Omega$. The iterative application of the decimation procedure outlined here amounts to separating the Hilbert space of the chain into a hierarchy of sequentially decreasing energy subspaces. If the coupling distributions expand

Without bounds during the flow, this method is asymptotically exact.

After applying this set of transformation rules $L$ (the original chain length) times, we are left with a single spin cluster that carries the moments of some fraction of the set of original spins. The ground state of the chain is then given by the state in which this cluster points in the $x$ direction due to the transverse field. In the same way we can also access the various excitations of the quantum Ising chain by keeping high energy subspaces in the decimation process.

At the end of the decimation process, the full effective Hamiltonian is given by

$$\mathcal{H}_{eff} = e^{iS^L} e^{iS^{L-1}} \ldots e^{iS^2} e^{iS^1} \mathcal{H} e^{-iS^1} e^{-iS^2} \ldots e^{-iS^{L-1}} e^{-iS^L}, \quad (33)$$

with $S^{(j)}$ representing the transformation of the $j$th stage of the renormalization. At the final stage the free ground-state wave-function, $|H >$, is related to the ground state of the original problem by

$$|G > = e^{-iS^1} e^{-iS^2} \ldots e^{-iS^{L-1}} e^{-iS^L} |H >. \quad (34)$$
by example, cluster points in the direction of the transverse field. For |H⟩, we neglect all the subleading contributions to the flow of

Note that the later transformations are the first to operate on |H⟩. In the end of the decimation process, |H⟩ is a product of cluster wave functions, where each cluster point is in the direction of the transverse field. For example, |H⟩ for a chain of 4 spins as in Fig. 5 is given by

\[ |H⟩ = |→(023)⟩ ⊗ |→1⟩ = (|↑0⟩ ⊗ |↑2⟩ ⊗ |↑3⟩ ⊗ |↓4⟩)(|↑1⟩ + |↓1⟩). \]  

(35)

**B. Evolution of Effective Operators**

The quantities we are interested in can be written in terms of |H⟩ and the set of unitary transformations used in the RG process. For example, let us consider

\[ \langle σ_0^x σ_L^x | G | σ_0^x σ_L^x \rangle = \langle G | G | \rangle, \]  

(36)

with |G⟩ known in terms of |H⟩. We can write

\[ \langle G | G \rangle = \langle H | e^{iS(L)} ... e^{iS(1)} e^{-iS(1)} e^{-iS(2)} ... e^{-iS(L)} | H \rangle \]

\[ = \langle H | e^{iS(L)} ... e^{iS(2)} e^{iS(1)} e^{-iS(1)} e^{-iS(2)} ... e^{-iS(L)} | H \rangle \]

\[ = \langle H | e^{iS(L)} ... e^{iS(2)} e^{iS(1)} e^{-iS(1)} e^{-iS(2)} ... e^{-iS(L)} | H \rangle \]

(37)

Thus we see that calculating expectation values of an operator A with respect to the ground state |G⟩ is equivalent to calculating the expectation value of the effective operator \( \hat{A} \) with respect to |H⟩:

\[ \langle G | A | G \rangle = \langle H | \hat{A} | H \rangle, \]

\[ \hat{A} = e^{iS(L)} ... e^{iS(2)} e^{iS(1)} A e^{-iS(1)} e^{-iS(2)} ... e^{-iS(L)}. \]

(38)

**III. TRANSVERSE FIELD CORRELATIONS**

**A. Renormalization of End Spin Operators**

In order to obtain the transverse field part of the end-to-end energy correlations, \( < h_0 σ_0^x h_L σ_L^x > \), we must consider the effects of the two types of renormalization steps (decimation of a site or a bond) on the end operators \( σ_0^x \) and \( σ_L^x \). In this section we show that the decimation of the first bond makes the operator \( σ_0^x \) evolve to the effective operator \( σ_0^x = \frac{h_0}{J_{01}} σ_0^x \). We also show that the decimation of the end site yields \( σ_0^x = \frac{J_{01} h_1}{h_0} σ_1^x \), which is third order in the off-diagonal terms that couple high and low energies in the Hamiltonian. In this derivation we neglect all the subleading contributions to the flow of the edge operators; we show in Appendix A that this is indeed justified.

**Decimations away from the ends.** A renormalization step that does not involve the end spin will generally leave the end operators unchanged, since the generator of the unitary transformation of this RG step, \( S \), commutes with \( σ_0^x \). The exception to this is when the decimation involves spins adjacent to the end, for which \( [S, σ_0^x] \neq 0 \); however, it can be shown that to all orders in perturbation theory, there is no contribution to the dominant parts of the correlation function from the resulting corrections to \( σ_0^x \).

**Decimation of an end bond.** If \( J_{01} \) is decimated, sites 0 and 1 will form a cluster (01) (see Fig. 6). The dominant contribution to the correlation function comes from the effective operator \( σ_{01}^x \). This contribution is obtained...
from the first order transformation, $S_a$ in Eq. (28):

$$\sigma_0^x = e^{iS_a} \sigma_0^x e^{-iS_a} = \sigma_0^x + i\frac{J_{01}}{2h_0} \sigma_0^y \sigma_1^z + i\frac{J_{01}}{2h_0} \sigma_0^y \sigma_0^z \sigma_1^z$$

(39)

The first two terms in (39) will not evolve under the continuing renormalization. Their expectation values are

$$< H | \sigma_0^x | H > = 0,$$
$$< H | \sigma_0^y | H > = 1.$$  (40)

The only piece of (39) relevant to us is the third piece. As indicated in Eq. (39), when the operator $-\sigma_0^z \sigma_0^y$ is restricted to the low energy subspace in which sites 0 and 1 form a cluster, it is equivalent to the cluster operator $\sigma_{01}^z$. Therefore when the end spin forms a cluster with its neighbor via a bond decimation, the flow of the transverse spin is given by

$$\sigma_0^z \Rightarrow \frac{h_3}{J_{01}} \sigma_{01}^z.$$  (41)

**End site decimation.** If $h_0$ is the strongest interaction in the chain, site 0 will be decimated. Applying the first order transformation $S_a$ from Eq. (21) to $\sigma_0^x$ yields

$$S_a = -\frac{J_{01}}{2h_0} \sigma_0^y \sigma_1^z$$

(42)

Applying the second order transformation yields

$$S_b = -\frac{h_1J_0}{h_0^3} \sigma_0^y \sigma_1^z,$$

$$\sigma_0^x = \sigma_0^x + i\frac{h_1J_0}{2h_0^2} \sigma_0^y \sigma_1^z + i\frac{h_1J_0}{2h_0} \sigma_1^z \sigma_0^z.$$  (43)

Once again, the first two terms in Eq. (43) do not contribute to truncated correlation functions since $< \sigma_0^x > = 1$, $< \sigma_0^y > = 0$. The flow of $\sigma_0^x$ in this case is

$$\sigma_0^x \Rightarrow \frac{h_1J_0^2}{h_0^3} \sigma_1^z.$$  (44)

**B. Evolution of the Correlation Function**

As the renormalization proceeds, the effective operators $\sigma_0^x$ and $\sigma_1^z$ accrue multiplicative factors that will eventually combine to form the end-to-end correlation function. The evolution of these prefactors is obtained from Eqs. (41) and (44) by the method outlined in Ref. 3.

At log-energy scale $\Gamma$, we write the effective operator of the end spin as

$$\sigma_0^x \Rightarrow \sigma_0^x(\Gamma) e^{-\Lambda(\Gamma)},$$  (45)

where $\sigma_0^x(\Gamma)$ operates on the first spin cluster of the renormalized chain at the scale $\Gamma$. Using the logarithmic variables $\beta = \ln \frac{\Omega}{h}, \zeta = \ln \frac{\Omega}{\beta}$, we can rewrite Eqs. (41, 44) and the results described in Figs. (6) and (7) in terms of $\Lambda$:

**bond-decimation:** $\Lambda \Rightarrow \Lambda + \beta_0$,

**spin-decimation:** $\Lambda \Rightarrow \Lambda + \beta_1 + 2\zeta_{01}$.

The quantities $\Lambda$, $\beta_0$, and $h_0^0$ (length of the cluster containing the end spin) are correlated at all stages of the renormalization. Therefore we must keep track of their joint distribution, which we define as

$$\text{Prob}[d\lambda_0, d\beta_0, d\lambda] = \omega(\beta_0, \lambda_0, \xi) d\beta_0 d\lambda d\lambda.$$  (47)

Using the results of ref. 4 and Eqs. (28) and (46), we can write the evolution equation for $\omega(\beta, I, \xi)$:
in terms of the distributions \(P\) and \(R\) of the log-couplings and lengths of the bonds and spin-clusters at scale \(\Gamma\). Employing the notation for convolutions introduced in Ref. 4, \(f(x_1) \otimes g(x_2) = \int f(x_1)g(x_2)\delta(x - x_1 - x_2)dx_1dx_2\), we can write the above equation in a more compact way:

\[
\frac{d\omega(\beta, l, \Lambda)}{dt} = \frac{\partial\omega(\beta, l, \Lambda)}{\partial \beta} + \int \omega(\beta = 0, l_0, \Lambda') R(\beta_1, l_1) \delta(\Lambda - \Lambda' - 2\zeta_0 - \beta_1) \delta(l - l_0 - l_1) \delta(\beta - \beta_1) dl_0 dl_1 d\Lambda' d\beta_1 \\
+ \int \omega(\beta_0, l_0, \Lambda') R(\beta_1, l_1) P(\zeta_0 = 0, l_0) \delta(\Lambda - \Lambda' - \beta_1) \delta(l - l_0 - l_1) \delta(\beta - \beta_1 - \beta_2) dl_0 dl_1 d\Lambda' d\beta_1 \\
- \int P(0, l') dl' \omega(\beta, l, \Lambda). 
\]

By Laplace transforming \(\omega(\beta, l, \Lambda)\) with respect to both \(l\) and \(\Lambda\),

\[
\omega(\beta, y, \lambda) = \int dl \int d\Lambda e^{-yl} e^{-\lambda \Lambda} \omega(\beta, l, \Lambda),
\]

we obtain

\[
\frac{d\omega(\beta, y, \lambda)}{dt} = \frac{\partial\omega(\beta, y, \lambda)}{\partial \beta} + \omega(\beta_0 = 0, y, \lambda) \int e^{-2\zeta y} \Phi(\zeta_y) d\zeta R(\beta, y) \\
+ \int \omega(\beta_0, y, \lambda) \otimes R(\beta_1, y) P(\zeta_0 = 0, y) \\
- P(0, y = 0) \omega(\beta, y, \lambda).
\]

In Ref. 4 the scaling limits of the functions \(R(\beta, y)\), \(P(\beta, y)\) are derived:

\[
P(\zeta, \Gamma) = \Upsilon(y) e^{-\xi y} \Gamma, \\
R(\beta, y) = T(y, \Gamma) e^{-\beta \tau(y, \Gamma)}, \\
T(y, \Gamma) = \frac{\Delta(y)}{\sinh \Delta(y) \Gamma} e^{-\beta \Gamma}, \\
\Upsilon(y, \Gamma) = \frac{\Delta(y)}{\sinh \Delta(y) \Gamma} e^{-\beta \Gamma}, \\
\tau(y, \Gamma) = \delta + \Delta(y) \coth(\Delta(y) \Gamma), \\
u(y, \Gamma) = -\delta + \Delta(y) \coth(\Delta(y) \Gamma), \\
\Delta(y) = \sqrt{y + \delta^2}.
\]

Using these results and the corresponding notations, we get

\[
\frac{d\omega(\beta, y, \lambda)}{dt} = \frac{\partial\omega(\beta, y, \lambda)}{\partial \beta} + \omega(0, y, \lambda) T(y, \Gamma) T(y, \Gamma) \frac{\Delta(y)}{2\zeta + u} \\
+ \Upsilon(y, \Gamma) \int \omega(\beta_0, y, \lambda) e^{-\beta \tau(y, \Gamma)} T(y, \Gamma) \\
- \delta(\beta - \beta_0 - \beta_1) d\beta_0 d\beta_1 \\
- \Upsilon(0, \Gamma) \omega(\beta, y, \lambda).
\]

To solve this we write \(\omega(\beta, y, \lambda)\) in the following form:

\[
\omega(\beta, y, \lambda) = W(y, \lambda) e^{-\beta \lambda - \beta \tau},
\]

under which (53) becomes

\[
\frac{dW}{dt} = -(\tau + \lambda) W + \frac{\Upsilon(y, \Gamma) T(y, \Gamma)}{2\lambda + u} W - \Upsilon(0, \Gamma) W.
\]

Using the definitions of the functions \(\Upsilon, T, u,\) and \(\tau\), we can integrate Eq. (55) and find

\[
W = W_0 e^{(\lambda + \delta)(\Gamma - \Gamma_0)} \\
\frac{\sinh(\Delta(y) \Gamma_0)}{\sinh(\Delta(y) \Gamma)} \left(\frac{2\lambda + u(y, \Gamma_0)}{2\lambda + u(y, \Gamma)}\right)^{\tau(0, \Gamma_0)}
\]

The value of \(W_0\) can be found from the normalization condition on the distribution \(\omega(\beta, l, \Lambda)\). To be a properly normalized, \(\omega(\beta, l, \Lambda)\) has to obey

\[
\int_0^\infty d\beta \omega(\beta, y = 0, \lambda = 0) = 1.
\]

This implies \(W_0 = \tau(0, \Gamma_0)\).

Before proceeding, we should check what initial conditions this distribution satisfies. Setting \(\Gamma = \Gamma_0\) and \(y = 0\) we see:

\[
\omega(\beta, 0, \lambda | \Gamma_0) = \tau(0, \Gamma_0) e^{-\tau(y, \Gamma_0) \beta} e^{-\lambda \beta}
\]

The inverse Laplace Transform in \(\lambda\) yields

\[
\omega(\beta, 0, \lambda | \Gamma_0 = \tau(0, \Gamma_0) e^{-\gamma(0, \Gamma_0) \beta} \delta(\lambda - \beta). 
\]

The delta function in Eq. (59) shows that the initial value of the correlation variable is the same as the transverse field, as it should be for this part of the energy - energy correlations.
C. Last Decimation Step

After carrying out the decimation process \( L - 1 \) times and following the flow of the edge energy operators, we end up with two clusters. The remaining clusters correspond to the left and right edges of the chain, and each has a distribution \( \omega(\beta, l, \Lambda|\Gamma) \) associated with it. In the next decimation step one of these clusters is decimated, and a single cluster forms. At this stage we can compute the distribution of the energy correlations from the flow of edge operators and the remaining couplings. Note that the \( \Gamma \) at which a single cluster forms is logarithm of the gap between the first and second excited states (as was also noted in Ref. 14).

The computation of the truncated correlation function is as follows:

\[
C_{\ell, r}^{xx} = \langle G | h_0 \sigma^z_0 h_L \sigma^z_L | G \rangle - \langle G | h_0 \sigma^z_0 | G \rangle \langle h_L \sigma^z_L | G \rangle \\
= \langle H | e^{- \Lambda_r \sigma^z_r} e^{- \Lambda_\ell \sigma^z_\ell} | H \rangle \\
= e^{- \Lambda_r \sum_{\psi \neq G} \langle H | \sigma^z_r | \psi \rangle \langle \psi | \sigma^z_\ell | H \rangle},
\]

where \( \Lambda_r \) and \( \Lambda_\ell \) are the correlation factors picked up in the RG process, Eq. (46), for the left end and right end transverse spins respectively, and we have labeled the last remaining spin clusters \( \ell \) and \( r \). The correlation function can also be written as a sum over excited states:

\[
C_{\ell, r}^{xx} = \langle G | (h_0 \sigma^z_0 - \langle h_0 \sigma^z_0 \rangle)(h_L \sigma^z_L - \langle h_L \sigma^z_L \rangle) | G \rangle \\
= \sum_{\psi \neq G} \langle G | h_0 \sigma^z_0 | \psi \rangle \langle \psi | h_L \sigma^z_L | G \rangle \\
= e^{- \Lambda_r \sum_{\psi \neq G} \langle H | \sigma^z_r | \psi \rangle \langle \psi | \sigma^z_\ell | H \rangle},
\]

where \( \Lambda \) is the desired log of the energy-correlations.

**Site Decimation.** In the case of a site decimation it is unimportant which of the last surviving clusters gets decimated. Let us assume that it is the left cluster, \( \ell \). This involves the unitary transformation (dropping the tildes) \( S_a = -\frac{i}{\hbar} \sigma^z_\ell \), and makes the ground state \( |H \rangle \) be

\[
|H(L) \rangle = | \downarrow \rangle \rightarrow | \downarrow \rangle \rightarrow = \frac{1}{\sqrt{2}}(| \uparrow \rangle + | \downarrow \rangle)(| \uparrow \rangle + | \downarrow \rangle).
\]

By using the sum form in Eq. (61) and applying \( S_a \) we get

\[
C_{\ell, r}^{xx} e^{\Lambda_r + \Lambda_\ell} \approx \sum_{\psi \neq G} \langle H | e^{i S_a \sigma_\ell^z} e^{-i S_a} | \psi \rangle \langle \psi | e^{i S_a \sigma_\ell^z} e^{-i S_a} | H \rangle \\
\approx \sum_{\psi \neq G} \langle H | \frac{d}{d \psi} \sigma_\ell^z \sigma_\ell^z | \psi \rangle \langle \psi | \frac{d}{d \psi} \sigma_\ell^z \sigma_\ell^z | H \rangle = \frac{J_{\ell}^2}{\hbar^2}.
\]

This yields

\[
\Lambda = \Lambda_r + \Lambda_\ell + 2 \xi_{\ell r}.
\]
with:
\[
\frac{1}{a_T} \frac{d a_T}{d \Gamma} = \int_0^\infty (P(0, l) + R(0, l)) dl.
\] (69)

Let us now define the function \(J(\Lambda, \Gamma|L)\) as
\[
d\text{Prob}[\text{chain of length } L \text{ becomes a single cluster at } \Gamma \text{ with } \log(C_L) = \Lambda] = J(\Lambda, \Gamma|L)d\Gamma d\Lambda.
\] (70)

The probability distribution of \(\log(C_L)\) is then given by
\[
f(\Lambda, L) = \int_0^\infty J(\Lambda, \Gamma|L)d\Gamma.
\] (71)

The function \(J(\Lambda, \Gamma|L)\) has two contributions, the first contribution comes from the case of the penultimate decimation being a bond decimation (Eq. 64). The second contribution comes from the case of a site-decimation (Eq. 67). The combination of the two contribution yields:
\[
J(\Lambda, \Gamma|L) = a_T \int P(0, l_0^b) \omega(\beta, \lambda, l_0^b) \omega(\beta, \lambda, l_r) \delta(l_0^b + l_r + l_0 - L) \delta(\Lambda - \Lambda_0 - \lambda_r) d\Lambda d\lambda_r dl_0^b dl_r d\beta d\beta_r \nonumber
\]
\[
+ 2a_T \int P(\zeta, l_1) \omega(0, \lambda, l_1) \omega(\beta, \lambda, l_0^b) \delta(l_1 + l_0^b + l_0^b - L) \delta(\Lambda - \Lambda_0 - \lambda_1 - 2\zeta) d\Lambda d\lambda d\lambda_0^b dl_1 d\beta d\zeta
\] (72)

where \(l_0^b, l_r\) is the length of the effective bond connecting the last two clusters.

The Laplace transform of \(J\) is considerably simpler to write:
\[
J(\Lambda, \Gamma, y) = a_T \left[ P(0, y) \left( \int \omega(\beta, \lambda, y) d\beta \right)^2 + 2 \int e^{-2\lambda y} P(\zeta, y) d\zeta \omega(0, \lambda, l_0) \int \omega(\beta, \lambda, y) d\beta \right] = a_T P(0, y) \frac{\omega(\Lambda, \Gamma)^2}{(\tau(y)^2 + \lambda y)^2} \left( \frac{1}{\tau(y)^2 + \lambda y} + 2 \frac{1}{(\tau(y)^2 + \lambda y)^2} \right).
\] (73)

Eq. (73) is one of the main results of this paper; from it we will derive the typical and average correlation functions, as well as information on the distribution of \(C_L\).

**IV. EXCHANGE ENERGY AND CROSS CORRELATIONS**

**A. Boundaries and Duality**

The calculation of the \(h \sigma_0^z - h \sigma_L^z\) correlations in the previous section simplified greatly because the operators \(\sigma_{\Omega, L}^z\) considered were end operators. In this section we calculate expressions for the end-to-end correlations of the exchange energy density, \(J \sigma^z \sigma^z\). We consider the special case for which one or both end-transverse-fields, \(h_0\) and \(h_L\), are zero, which simplifies the calculation considerably. We will argue that the universal features of the correlations will be the same as in the general case with non-zero end-fields.

The simplifications with vanishing end transverse-fields arise because this makes the exchange energy be an edge operator in the sense that it is the first and last energy operator in the Hamiltonian:
\[
\mathcal{H} = -J_{01} \sigma_0^z \sigma_1^z - h_1 \sigma_1^z - \ldots - h_{L-1} \sigma_{L-1}^z - J_{L-1} \sigma_{L-1}^z \sigma_L^z.
\] (74)

And edge bond is the dual of an edge site, and therefore the edge-to-edge exchange-energy correlations of the ground state of the Hamiltonian in Eq. (74) are duals to the transverse-spin correlations calculated in Sec. III. This is explained below.

As was explained in the introduction (IE), the duality transforms a bond to a spin and vice versa. In the previous section we considered a chain that terminates with a site that has a finite transverse field on it, \(h_0 > 0\). The dual of this edge is a chain edge that terminates with a nonzero bond, \(J_{01} = h_0\). The site 1’ is the dual of the bond \(J_{01}\) and therefore experiences a field \(h_{1’} = J_{01}\). Since there is no bond \(J_{-1} 0\), i.e., \(J_{-1} 0 = 0\), the field on site 0’ is zero as well (see Fig. 2).

In what follows we calculate the end-to-end correlations of the exchange energy and the cross-correlations between the transverse spin and the exchange energy. In both cases we will assume that the chain terminates with the energy operators whose correlations we calculate (as in Eq. (74) for the exchange-energy correlations). In the
case of exchange energy correlations both edges of the chain we consider will terminate with a vanishing transverse field, \( h_0 = h_L = 0 \). Similarly, when we calculate the edge correlations between the exchange energy of sites 0 and 1, and the transverse spin on site \( L \), the edge transverse field \( h_0 \) is set to 0. These rules allow us to use the dual of the function \( \omega(\beta, l, \Lambda|\Gamma) \) which was derived in Sec. III.B. We define the function \( \phi(\zeta, l, \Lambda|\Gamma) \) as the dual of \( \omega(\beta, l, \Lambda|\Gamma) \). This function will keep track of the correlations and evolution of the operator \( J_0 \sigma_0^z \sigma_1^z \) in the same way that \( \omega(\beta, l, \Lambda|\Gamma) \) was used to keep track of the correlations and evolution of the operator \( h_0 \sigma_0^z \).

The calculations carried out in this section assume that one or both edge transverse fields are zero, but this does not limit the generality of our results for universal quantities. We expect that when the edge transverse-fields are non-zero, the correlations of the last bond in a chain will only be modified by a non-universal multiplicative factor from the correlations in the special case with no transverse-field on the end spin.

B. Evolution of Edge Exchange-Energy Operator

As discussed above, the edge exchange-energy \( J_0 \sigma_0^z \sigma_1^z \) is dual to the and edge transverse field operator \( h_0 \sigma_1^z \). Therefore we can obtain the distribution function for the evolution of the edge exchange energy operator from the results of Sec. III.

By making use of the duality (Sec. I.E), we can transform all the results obtained in Sec. III to the dual chain. As stated above, we define the analog of \( \omega(\beta, l, \Lambda|\Gamma) \) to be \( \phi(\zeta, l, \Lambda|\Gamma) \): \( \phi(\zeta, l, \Lambda|\Gamma) \) keeps track of the bond strength of the end bond, its length (including the length of the \( h = 0 \) end site), and the log contribution to the correlation, \( \Lambda \). \( \phi(\zeta, l, \Lambda|\Gamma) \) is obtained from the dual of (56):

\[
\phi(\zeta, \mu, \Lambda) = \Phi(\mu, \Lambda) \cdot e^{-\Lambda - \zeta u(y, \Gamma)}
\]

\[
\phi(\mu, \Lambda) = e^{(\Lambda - \delta)(\Gamma - \Gamma_1)} \frac{\sinh(\Lambda(y')\Gamma_1)}{\sinh(\Lambda(y')\Gamma)} \frac{1}{2} \frac{1}{(1 + u(y, \Gamma))} u(0, \Gamma).
\]

C. Exchange Energy Correlations

The results for the exchange energy correlations are given, by duality, by Eq. (73), with \( \delta \rightarrow -\delta \). This yields

\[
J(\Lambda, \Gamma|y) = a_{1} R(0, y) \frac{\phi(y, \Lambda)^2}{u(y, \Gamma)} \left( \frac{1}{u(y^1, \Gamma)} + \Lambda \right) \left( \frac{1}{u(y^1, \Gamma)} + 2 \tau(\Gamma + 2\Lambda) \right).
\]

Since the results for the exchange-energy correlations are identical to that of the transverse correlations, we will only analyze the later.

D. Cross-Correlations — Last Decimation Step and Final Expression

In order to obtain the cross correlations we need to combine the results for the edge transverse-spin flow and exchange-energy flow. In analogy to Sec. III, putting together the two flows happens in the penultimate step of the RG flow. The accumulated multiplicative factors, along with the couplings of the renormalized chain just before it is completely decimated, will determine the total correlations between the transverse-spin and exchange energy.

In contrast to Sec. III, the last needed step of the RG to obtain the cross correlations involves the transverse spin of one of the two clusters, and the bond between them:

\[
C^B_{\ell} = <G[h_0 \sigma_0^z J_{L-1} \sigma_1^z | G] >
\]

\[
- <G[h_0 \sigma_0^z G > <G[J_{L-1} \sigma_1^z | G] >
\]

\[
= <H[e^{-\Lambda} \sigma_0^z \sigma_1^z e^{-\Lambda} | H] >
\]

\[
- <H[e^{-\Lambda} \sigma_1^z | H] > <H[\sigma_1^z \sigma_1^z e^{-\Lambda} | H] >
\]

where \( B \) stands for bond. The two possibilities for the last step of the decimation process are the decimation of the bond (\( J_{\ell} \)), or of the \( \ell \) cluster (\( h_{\ell} \)). These two processes are dual to each other; hence we only need to consider one of them. Let us consider the site decimation.

As before, the ground state will be

\[
|H> = |\rightarrow_{\ell} >= |\rightarrow_{\ell} >= \frac{1}{2} (|\uparrow_{\ell} > + |\downarrow_{\ell} >)(|\uparrow_{\ell} > + |\downarrow_{\ell} >).
\]

From the transformation \( S_a = -\frac{\mu_{\ell}}{h_{\ell}} \sigma_0^z \sigma_1^y \) that induces this decimation, the correlations are found to be:

\[
C^B_{\ell} e^{i2 \lambda + \Lambda} = <H[e^{i2 \lambda} \sigma_0^z e^{-i2 \lambda} e^{i2 \lambda} \sigma_1^y e^{-i2 \lambda} | H] >
\]

\[
- <H[e^{i2 \lambda} \sigma_0^z e^{-i2 \lambda} | H] > <H[\sigma_1^y e^{i2 \lambda} e^{-i2 \lambda} | H] >
\]

\[
= <\Lambda = \beta_{\ell} > \frac{\mu_{\ell}}{h_{\ell}} \sigma_0^z \sigma_1^y | H] >
\]

Thus the cluster decimation process yields

\[
\Lambda = \Lambda_{\ell} + \Lambda_{\tau} + \zeta_{\ell}.
\]

By duality, the bond decimation process yields

\[
\Lambda = \Lambda_{\ell} + \Lambda_{\tau} + \beta_{\ell}.
\]

Following the reasoning that led to Eqs. (72, 73) we get:

\[
J(\lambda, \Gamma|y) = a_{1} \omega(\lambda, \Gamma) \phi(\lambda, \Gamma) \left( \frac{1}{\tau(\Gamma + 2\Lambda)} + \frac{1}{u(y, \Gamma) + \lambda} \right).
\]
This is the second main result in this paper, and it is analogous to Eq. (73). Here we must bear in mind that the correlations obtained here are negative (see Eq. 79). This is to be expected, since the two operators, $\sigma^x$ and $\sigma^z\sigma^z$, try to impose competing orders: One tends to disorder the system and the other to order it.

V. RESULTS

The above results (73, 82) in principal allow the calculation of the distribution function for the log-correlations, $\Lambda = -\log(C_L)$, of long finite chains. In the following sections we calculate the average correlations, $C_L$, and the distribution, $f(\Lambda | L)$, for all $\delta$.

A. Average $h_\sigma^x - h_\sigma^x$ and $J_\sigma^z\sigma^z - J_\sigma^z\sigma^z$

Correlations

Derivation of the Average. In this section we derive the average x-x correlations. The BB correlations of the exchange energy are obtained from the x-x correlations upon the transformation $\delta \rightarrow -\delta$.

In order to obtain $C_L^{xx}$, we begin with Eq. (73) in the following form:

$$J(\lambda, \Gamma | y) = \frac{\tau^{(0, \Gamma)} \sinh^2(\Delta \Gamma)}{\sinh(\Delta \Gamma)} \frac{(2\lambda - \delta + \Delta \cosh(\Delta \Gamma))}{(2\lambda + \delta)^2} e^{-(2\lambda + \delta)\Gamma + 2(\lambda + \delta)\Gamma_i}$$

$$\left[ \frac{1}{[(\delta + \lambda) \sinh(\Delta \Gamma) + \Delta \cosh(\Delta \Gamma)]^2} + \frac{2(2\lambda - \lambda) \sinh(\Delta \Gamma)}{[(\delta - \lambda) \sinh(\Delta \Gamma) + \Delta \cosh(\Delta \Gamma)]^2} \right].$$

First, we perform an inverse Laplace transform in $y$ to recover the length dependence:

$$J(\lambda, \Gamma | L) = \sum_{n=1}^{\infty} (-1)^n \frac{\tau^{(0, \Gamma)} ((2\lambda - \delta) + 1) (2\lambda - \delta) L}{(2\lambda + \delta)^2} e^{-(2\lambda + \delta)\Gamma + 2(\lambda + \delta)\Gamma_i}$$

$$e^{-\frac{1}{2\lambda + \delta} (\frac{\delta^2}{2\lambda + \delta}) L} \frac{4L(n\pi)^2}{\Gamma(\lambda + \delta)} \left( \frac{2L(n\pi)^2}{\Gamma^3(\lambda + \delta)} \right)$$

$$\left( \frac{2L(n\pi)^2}{\Gamma^3(\lambda + \delta)} \right) - \frac{4L(n\pi)^2}{\Gamma^3(\lambda + \delta)} e^{-\frac{1}{2\lambda + \delta} (\frac{\delta^2}{2\lambda + \delta}) L}.$$

This is obtained by approximating the roots of

$$a \sinh(\Delta \Gamma) + \Delta \cosh(\Delta \Gamma)$$

with $a \approx 1$, by $y_n = -\delta^2 - \left(\frac{n\pi}{2}\right)^2 \left(1 - \frac{\delta^2}{2^2}\right)$ and expanding (83) around these roots:

$$a \sinh(\Delta \Gamma) + \Delta \cosh(\Delta \Gamma) \approx \sum_{n=1}^{\infty} (-1)^{n+1} i(y - y_n) \frac{\delta^2}{2n\pi}$$

The roots in Eq. (86) are given as an expansion in powers of $1/\Gamma$. Since we are interested in $\Gamma \gg 1$ we are content with two terms only; in fact, as can be seen by the following Eq. (87), only the first non vanishing power of $1/\Gamma$ contributes to the average correlations. In addition, Eq. (86) is only valid for $y_n \ll 1$, i.e., for $n\pi \ll \Gamma$. But since we are interested in the large length behavior of the correlations, we can restrict our calculation to small values of $n$, as they give the slowest decaying term in the correlations.

The desired result is obtained by performing the integral. This integral is dominated by the large exponent in

$$e^{-\frac{1}{2\lambda + \delta} L} e^{O(\log(\Gamma))} O(\Gamma^{-1/3}) = \xi \varphi(\Gamma)$$

which has a saddle point at $\Gamma_S = \left(\frac{2(n\pi)^3 L}{3\lambda + \delta}\right)^{1/3}$. The exponential dependence then becomes

$$e^{\varphi(\Gamma)} \approx e^{\varphi(\Gamma_S) - \frac{1}{2}\left(\frac{2(n\pi)^3 L}{3\lambda + \delta}\right)^{1/3}} (\Gamma - \Gamma_S)^2$$

and the saddle point integration yields

$$J(\lambda, L) \approx \sum_{n=1}^{\infty} (-1)^{n+1} 2^{2/3} \sqrt{n\pi} (n\pi)^{1/3} \frac{1}{T(n\pi)^{2/3}} e^{-\frac{1}{2\lambda + \delta} (\frac{\delta^2}{2\lambda + \delta}) L}$$

$$\times e^{2\Gamma_i(\lambda + \delta)} \left( \frac{2\Gamma_i + 1}{\lambda - 2\lambda} \right)^{1/3} \frac{1}{(2\lambda + \delta)^{2/3}}$$

$$\times \left( e^{-\frac{1}{2\lambda + \delta} (\frac{\delta^2}{2\lambda + \delta}) L} + e^{-\frac{1}{2\lambda + \delta} (\frac{\delta^2}{2\lambda + \delta}) L} - e^{-\frac{1}{2\lambda + \delta} (\frac{\delta^2}{2\lambda + \delta}) L} \right).$$
This result is valid for the critical regime \((\frac{1}{\Delta} \gg L)\) when \(\frac{1}{\Delta} \ll \lambda \ll L\), and away from the critical regime \((\frac{1}{\Delta} \ll \frac{1}{L})\) away from \(\lambda = 0\). To get the equivalent expression for \(\lambda \gg 1\), we need to be more careful with the third term of equation (89) and get the next order corrections. Note that there is no singularity in this expression at \(\lambda = 2\delta\); this will have implications for the off-critical large \(L\) behavior.

Result. To get the final result for \(C^{xx}_L\), all that remains is to set \(\lambda \to 1\). Neglecting terms suppressed by factors of \(\delta \ll 1\) we obtain

\[
C^{xx}_L \approx A^x_0 \frac{1}{L^{5/6}} e^{-\delta^2 L - 3L^{1/3}(\pi/2)^2(1+\delta/2)^{2/3}}, \tag{90}
\]

Also, for the exchange-energy correlations we obtain

\[
C^{BB}_L \approx A^x_0 \frac{1}{L^{5/6}} e^{-\delta^2 L - 3L^{1/3}(\pi/2)^2(1-\delta/2)^{2/3}}, \tag{91}
\]

where \(A^x_0\) and \(A^z_0\) are non-universal coefficients.

When the chain is not critical, we notice that the exponential decay is controlled by the same correlation length, \(\xi = \frac{1}{\delta}\), as the order parameter correlation function.

**B. Average Cross Correlations**

Derivation of the Average. In complete analogy with the derivation of the previous section, we proceed from Eq. (82) in the following form:

\[
J(y, \Gamma|y) \approx \frac{(2\Gamma_0+1)^2}{\lambda} e^{-2\lambda y} e^{-\Gamma \sinh(\Delta)} \cdot \frac{\Delta^2}{\sinh(\Delta)}
\]
\[
\times \left( \frac{1}{(\lambda-2\delta) (\lambda-2\delta) \sinh(\Delta)} + \frac{1}{(\lambda+2\delta) (\lambda+2\delta) \sinh(\Delta)} \right)
\]
\[
+ \left( \frac{\lambda-2\delta}{(\lambda-2\delta) \sinh(\Delta)} + \frac{\lambda+2\delta}{(\lambda+2\delta) \sinh(\Delta)} \right).
\]

Performing an inverse Laplace transform in \(y\) and then performing a saddle point integration in \(\Gamma\), we find:

\[
J(\lambda|L) \approx \sum_{n=1}^{\infty} e^{2\Gamma_0} \frac{(2\Gamma_0+1)^2}{\lambda} e^{-\Gamma \sinh(\Delta)} \cdot \frac{\Delta^2}{\sinh(\Delta)} \cdot \frac{1}{\lambda^{5/6}} e^{-\delta^2 L - 3L^{1/3}(\pi/2)^2(1+\delta/2)^{2/3}}.
\]

This result, as well as Eq. (90), is valid for \(\frac{1}{L^{5/6}} \ll \lambda \ll L\) for all small or zero \(\delta\).

Result. The average \(x-B\) correlation is obtained from the above by setting \(\lambda = 1\):

\[
C^{x-B}_L \approx -A^{x-B}_0 \frac{1}{L^{5/6}} e^{-\delta^2 L - 3L^{1/3}(\pi/2)^2(1+\delta/2)^{2/3}}, \tag{94}
\]

which is almost the same as Eq. (90) but the \(\delta\) dependence of the above result is strictly symmetric with respect to \(\delta\), as expected for an object that is self-dual.

**C. Typical Correlations**

One of the striking features of random quantum systems is that typical correlations are usually very different from average correlations. Average correlation functions can be, as here, dominated by samples (or spatial regions) with anomalously strong correlations. The typical correlations are much smaller and decay faster with distance. Indeed, for the random Ising chain, the typical correlations hold for almost all long-but-finite samples.

The average end-to-end correlations are dominated by extremely rare samples.

In the off-critical regime the typical correlations are well characterized by the average log-correlations

\[
C_{typical} = e^{-\log(C)} = e^{-\overline{L}}.
\]

However, at the critical point \(-\log(C) = -\overline{L}\) is of the same order as the logarithm of the typical correlations, but the typical correlations will also have a very wide spread. More precisely, there is a random proportionality constant relating the log of the correlations to its average; this constant is random and widely varying. We will first investigate the typical correlations at the critical point, and then consider the off critical regime.

Typical Correlations at the critical point. The average log-correlations \(\overline{L}\) are easily found at the critical point. Going back to Eq. (73) and setting \(\delta = 0\), we see that the Laplace transform in \(L\) of the \(x\)-\(x\) log-correlations is given by
The typical correlations decay as
\[ \sim \left( \frac{\lambda}{y} \right)^3 \]
for long critical chains.

The distribution of \( \frac{\Lambda}{\sqrt{2L}} \) is thus indeed non-trivial for
ing very long critical chains.

For the cross correlation function, \( J \sigma^2 \sigma^- h \sigma^z \), the result we get for the average log-correlation is (by a similar calculation)

\[
\bar{\Lambda}_{\sim B}^x \approx \frac{16}{3\sqrt{n}} \sqrt{2L} + O(1)
\]
\[
\sqrt{(\Lambda_{x-B}^x)^2 - \Lambda_{\sim B}^x} \approx 5.4 \sqrt{2L}.
\]

Note the similar — but not identical — behavior of the two results (99) and (96).

**Off Critical x-x Correlations.** To investigate the x-x energy correlations in the off-critical regime, we pursue a different course of action. Instead of setting \( \lambda \) to 1, we invert the Laplace transform with respect to \( \lambda \) in expression (73) and obtain \( I(\lambda, \Gamma/y) \) in terms of \( \Lambda \).

Equation (73) can be written in the following form:

\[
J(\lambda, \Gamma/y) = \frac{x(0, \Gamma)}{\sinh(\Delta \Gamma)} \Delta(2\lambda - \delta + \Delta \coth(\Delta \Gamma)) \left(e^{2\lambda(\Gamma - \Gamma_f)} + e^{23\Gamma - 3\Delta \Gamma}ight)
\]
\[
\cdot \left[ \frac{1}{(3\delta + \Delta \coth(\Delta \Gamma))^2(\delta + \lambda + \Delta \coth(\Delta \Gamma))} + \frac{2}{(3\delta + \Delta \coth(\Delta \Gamma))^2(\delta + \lambda + \Delta \coth(\Delta \Gamma))} \right] \cdot
\]
\[
+ \frac{4}{(3\delta + \Delta \coth(\Delta \Gamma))(2\lambda - \delta + \Delta \coth(\Delta \Gamma))^3} - \frac{4}{(3\delta + \Delta \coth(\Delta \Gamma))^3(2\lambda - \delta + \Delta \coth(\Delta \Gamma))}.
\]

This form of \( J(\lambda, \Gamma/y) \) lends itself to inverting the Laplace transform and recovering the \( \Lambda \) dependence. This gives (neglecting \( \Gamma_f \), as before)

\[
J(\lambda, \Gamma/y) \approx \frac{\pi(0, \Gamma)}{\sinh(\Delta \Gamma)} \Delta^3 e^{23\Gamma - 3\Delta \Gamma} \Theta(\lambda - 2(\Gamma - \Gamma_f))
\]
\[
\left[ \left( \frac{4(2\lambda - \delta + \Delta \coth(\Delta \Gamma))}{(3\delta + \Delta \coth(\Delta \Gamma))^3} - \frac{4}{(3\delta + \Delta \coth(\Delta \Gamma))^3} \right) e^{-(2\lambda -2(\Gamma - \Gamma_f))(\delta + \Delta \coth(\Delta \Gamma))} \right.
\]
\[
+ \left( \frac{2(2\lambda - \delta + \Delta \coth(\Delta \Gamma))^2}{(3\delta + \Delta \coth(\Delta \Gamma))^3} - \frac{4}{(3\delta + \Delta \coth(\Delta \Gamma))^3} \right) e^{-(2(\lambda - \Gamma_f)(\delta + \Delta \coth(\Delta \Gamma))} \right].
\]

By performing the inverse Laplace transform we get

\[
\bar{\Lambda}_{\sim B}^x \approx \frac{7\sqrt{2}}{3} \bar{\Lambda} + O(1)
\]
\[
\approx 3.1 \sqrt{2L}.
\]

The result in Eq. (96) should be compared with the critical behavior of the average correlation:

\[
\log \left( e^{-\Lambda} \right) \approx -3\pi^{2/3} L^{1/3}.
\]

The typical correlations decay as \( \sim e^{-k\sqrt{2L}} \) with \( k \) of order unity but random with a computable universal distribution. But the average correlation function is \( \sim e^{-cL^{1/3}} \), which decays much more slowly. As claimed above, this means that realizations of the quenched randomness that have an exponentially low probability dominate the average.

By differentiating (95) once more with respect to \( \lambda \), we get

\[
\left( \frac{\bar{\Lambda}_{\sim B}^x}{\lambda} \right)^2.
\]

Using that we get for the standard deviation of \( \Lambda_{\sim B}^x \):

\[
\sqrt{(\Lambda_{\sim B}^x)^2 - \bar{\Lambda}_{\sim B}^x} \approx 5.6 \sqrt{2L}.
\]
with $\Theta$ the Heaviside step function. Off critical, for long enough chains, specifically with, $L \gg \xi \approx \frac{1}{\lambda}$ and the concomitant log-energy scale $\Gamma \delta \gg 1$, one can expand

$$\Delta \approx \delta + \frac{y}{2\delta}$$

and hence obtain

$$J(\Lambda, \Gamma | y) \approx |\delta|^3 e^{+2\delta \Gamma_1 -(\delta + 3|\delta|)\Gamma} \Theta(\Lambda - 2\Gamma)$$

$$+ \left( \frac{2(\Lambda - 2(\Gamma - \Gamma_1))^2}{(4\delta)} - \frac{4}{(4\delta)} \right) e^{-\frac{1}{2}(\Lambda - 2(\Gamma - \Gamma_1))(-\delta + |\delta|)} e^{-\frac{1}{4\delta}(\Lambda - 2(\Gamma - \Gamma_1))}\right].$$

From the simple form of the $y$ dependence in this limit, one can invert the Laplace transform by inspection to obtain the $L$ dependence.

In the paramagnetic phase ($\delta > 0$), $J(\Lambda, \Gamma | L)$ is sharply peaked for long chains at $2(\Gamma - \Gamma_1) + 4\delta L$. In the ferromagnetic phase ($\delta < 0$), it is instead sharply peaked at $2(\Gamma - \Gamma_1) + 2|\delta| L$. Integrating over $\Gamma$ gives exponential decay in $L$. Thus the distributions of the end-to-end transverse field log-correlations of long off-critical samples will have the form:

$$f^{xx}(\Lambda, L) = \int_{\Gamma_1}^{\infty} J(\Lambda, \Gamma | L) d\Gamma \sim \begin{cases} e^{-2\delta(\Lambda - 4|\delta|)\Theta(\Lambda - 4\delta L)} & \delta > 0 \\ e^{-|\delta|(\Lambda - 2|\delta|)\Theta(\Lambda - 2|\delta| L)} & \delta < 0 \end{cases}.$$  

[Recall that $\eta$ is the Heaviside step function.] This behavior, with exponential decay of almost all samples with a characteristic length that is much shorter than the correlation length is similar to that of the order parameter correlations in the paramagnetic phase as discussed in Sec. I C of the Introduction.

**Off Critical $x$-B Correlations.** The same analysis can be applied to the $x$-B correlation function. The mathematical expressions are simpler, but the result is more interesting. Since this correlation function is symmetric with respect to $\delta$, we can choose to carry out the analysis in the paramagnetic phase, $\delta > 0$. Using the same simplifying limit as before ($\Gamma_1 \gg 0$, $\Gamma \delta \gg 1$, $y \ll \delta^2$), and keeping only the dominating terms in the disordered phase, Eq. (82) becomes

$$J(\lambda, \Gamma | y) \approx e^{-2\lambda(\Gamma - \Gamma_1) - 2\delta \lambda} \left( \frac{1/y}{\lambda - \frac{y}{4\delta}} - \frac{1/y}{\lambda - \frac{y}{2\delta}} \right).$$

The inverse Laplace transform in $\lambda$ and $y$ of this leads to

$$J(\lambda, \Gamma | y) \approx e^{-2\delta \lambda^2} \left( \Theta(\Lambda - 2(\Gamma - \Gamma_1) - 2\delta L) - \Theta(\Lambda - 2(\Gamma - \Gamma_1) - 4\delta L) \right).$$

By integrating over $\Gamma$ we get for the distribution of the end-to-end log cross-correlations, $\Lambda = \Lambda_{x-B}^\pm$, of long off-critical chains,

$$f_{\Lambda,L}^{x-B}(\Lambda, L) = \int_{\Gamma_1}^{\infty} J(\Lambda, \Gamma | L) d\Gamma \sim \begin{cases} 0 & \Lambda < 2|\delta|L \\ 1 - e^{-\delta(\Lambda - 2|\delta|L)} & 2|\delta|L < \Lambda < 4|\delta|L \\ (1 - e^{-2\delta^2 L})e^{-|\delta|(\Lambda - 4|\delta|L)} & \Lambda > 4|\delta|L \end{cases}.$$  

Most long samples will have $2\delta L < \Lambda < 4\delta L$; remembering that this expression is valid only for $L \delta^2 \gg 1$, we see that the distribution will be roughly constant in this range. For larger $\Lambda$, the distribution decays exponentially.

In the ferromagnetic phase, the same result for the cross correlations will obtain with $\delta$ replaced by $|\delta|$. The behavior in this phase contrasts with that of the $x$-$x$ correlations whose distribution of $\Lambda$ is peaked near $2|\delta|L$ and thus are typically stronger than the cross correlations.
D. Energy - Energy Correlations and the Energy Gap

Looking at the earlier results for the average of the energy gap, $\Delta E$, of finite chains, we observe a strong resemblance to the results obtained here for the average $E - E$ correlations. In particular Eq. (60) in Ref. [3],

$$\Delta E \sim L^{1/6} e^{-\frac{2}{3}(\frac{\alpha^* h}{\Delta})^{1/3}},$$

(108)
gives the average gap at the critical point $\delta = 0$. We see that

$$2 \log \Delta E \approx \log C^E_E,$$

(109)

Some relation between the gap and the energy correlations is to be expected, but the behavior of the two quantities is surprising in the degree of the similarity. We will see that this relationship between the gap and the energy correlations arises in the structure of the RG flow.

In Eq. (103), the Heaviside function $\Theta(\Lambda - 4(\Gamma - \Gamma_I))$ implies that $-\log(C^E_{Lz}) > 2(\Gamma - \Gamma_I)$. Since the appropriate $\Gamma$ at which the decimation establishing this correlation occurs is $\Gamma = -\log \Delta E$, this implies that

$$C^E_{Lz} \leq \left(\frac{\Delta E}{\Omega_I}\right)^2.$$ (110)

To understand this inequality, consider the correlation coefficient $e^{-\Lambda}$ associated with an end site, and compare this to the transverse field $h$ on the end spin cluster. The strongest correlations will occur if the chain undergoes a series of bond decimations. Looking at Fig. (6) one can see that in this case the evolution of $e^{-\Lambda}$ and $h$ are exactly the same; in each end-bond decimation they acquire a factor of the $\frac{h_{\Lambda_{\text{dec}}}}{h_{\Lambda_{\text{init}}}}$ at that scale. The strongest correlations dominate the average correlations. Therefore chains in which the energy-correlations and the gap are strongly correlated also dominate the average correlations.

VI. CONCLUSIONS

In this paper we have investigated the various contributions to the end-to-end energy correlations of random quantum Ising chains in the universal regime of long chains near the quantum phase transition. In principal, the main result obtained here, the Laplace transform of the logarithm of the correlation functions (73, 82), can be used to obtain the complete distributions in the scaling limit. We have explicitly computed the average and typical correlations, as well as some other aspects of the distributions, in various limits. The average correlations are dominated by exponentially (in the chain length) rare samples. Nevertheless, they still decay as $e^{-CL^{1/3}}$ at the critical point. This is in contrast to the power law decay of the average order parameter correlations. The various components of the energy correlations are qualitatively similar, although their distributions differ. The cross correlations between the ordering operator, $J\sigma^z\sigma^z$, and disordering transverse-field operator, $h\sigma^z$, are negative because of their competing effects; they are also self-dual.

The average correlations in the off-critical regime decay with the same correlation length: $\xi \sim \frac{1}{\sqrt{\delta}}$, as the order parameter correlations. The typical correlations, however, decay much faster, and have the same correlation-length exponent, $\nu = 1$, as the pure system. In Sec. (VC) it was shown that the distribution of $\sigma_0^x\sigma_L^x$ is strongly peaked near $\exp(-4\delta L)$ for $\delta > 0$ and near $\exp(-2\delta L)$ for $\delta < 0$, indicating a surprising asymmetry between the two phases. This asymmetry is a result of the difference between the ordering and disordering components of the energy density and their behavior in the corresponding phases. At the critical point, the typical correlations decay as $\sim e^{-KL^{1/2}}$ with $K$ a random variable; this is similar to the typical order parameter correlations.

The behavior of the end-to-end energy correlations turn out to be similar to that of the energy gap. We explain this in terms of the rare realizations of the quenched randomness that dominate the averages: these are such that the gap and the correlation function involve essentially the same product of ratios of $J$’s to $h$’s.

Unlike previous RG calculations of properties of the random transverse-field Ising model, the energy correlations required the development of a formalism that goes beyond second order perturbation theory. Performing the RG transformation by unitary transformations proved to be a useful tool that allows one to follow readily the evolution of effective operators. Here we have focussed on end-to-end correlations because these are far simpler to handle analytically: correlations in the bulk of the chain involve effective operators on both sides of the objects of interest and are much harder to deal with. Nevertheless, they could be computed by keeping track of the needed distributions numerically.

The unitary transformation RG method can also be applied to the calculation of correlations in imaginary time. In this case, primarily average quantities have been calculated thus far (for instance, see Refs. [14,17,18]) but progress on distributions should be possible utilizing the procedure described here (Sec. II). The present method may also be applied to other models both in one dimension, and, numerically, in higher dimensions.

APPENDIX A: EFFECTS OF END OPERATORS

When calculating the energy correlation functions we kept terms that were third order or higher in the per-
turbation expansion. A concern to the validity of our treatment is that terms that were produced as fourth or fifth order terms at an early stage of the RG flow, $\Gamma_1$, become more relevant than terms that we kept that are produced at a later stage of the RG flow, $\Gamma_2 > \Gamma_1$. In this Appendix we verify that end operator effects that we excluded in the text can not give rise to leading order contributions to the various computed energy correlations.

In addition, The flow of the operator $\sigma_0^y$ when the end spin is decimated, will include a term $\sigma_0^y \sigma_1^x$. Naively, as this is an order — rather than a disorder — energy operator, it may make the disordered and ordered phases look indistinguishable as far as the transverse spin correlations are concerned. We will show here that this is not the case, and although these extraneous operators do appear, their contribution is at best subdominant.

1. End Site Decimation

In order to prove the above claims, we need to investigate the additional operators that arise when decimating ends. Revisiting the process of decimating an end-site, we consider the flow of the operator $h_0 \sigma_0^y$. The following table describes the series of transformation, and the effective operators that contribute to $h_0 \sigma_0^y$:

The fourth line and the second line contain the terms that are most likely to give a leading contribution to the correlations; these operators have a non-vanishing expectation value in the ground state of the decimated part. Keeping them all we have

$$ h_0 \sigma_0^y \Rightarrow \frac{J_{01}^2 h_1}{h_0^2} \sigma_1^x + \frac{J_{01}^2}{h_0^2} J_{12} h_1^2 \sigma_1^z \sigma_2^z + \frac{J_{02}^2}{h_0^2} J_{12} h_1^2 \sigma_2^y \sigma_0^y. \tag{A2} $$

Another process that we need to consider is a bond decimation close to the end. If we decimate the first bond, $-J_0 \sigma_0^y \sigma_1^x$, then $h_0 \sigma_0^y$ becomes

$$ h_0 \sigma_0^x \Rightarrow -\frac{h_0 h_2}{h_{01}} \sigma_0^y \sigma_1^y + \frac{h_0 h_2}{h_{01}} J_{12} h_1^2 \sigma_0^y \sigma_1^y \sigma_2^y = h_{0(01)} \sigma_{0(01)}^x + \frac{1}{h_{01}} h_{01} J_{01} h_{2} \sigma_{0(01)}^y \sigma_2^y, \tag{A3} $$

where the parentheses signify effective spin clusters. Going further away from the end, a decimation of the second site in the chain, $-h_1 \sigma_1^x$, will give

$$ h_0 \sigma_0^x \Rightarrow h_0 \sigma_0^x + \frac{1}{h_{01}} \frac{J_{01}}{h_1} J_{01} h_{02} \sigma_0^y \sigma_1^y \sigma_2^y = h_0 \sigma_0^x + \frac{1}{h_{01}} J_{02} h_{02} \sigma_0^y \sigma_1^y \sigma_2^y. \tag{A4} $$

with site 1 eliminated. Note that site 0 is still the first site but site 2 is now the next.

From the above processes a pattern emerges. The fifth-order perturbation calculation above produces two dangerous operators:

$$ \sigma_0^x \sigma_1^y, \sigma_0^y \sigma_1^y. \tag{A5} $$

We need to verify that these operators do not produce leading-order correlations. The first step is to observe that instead of seeing the bare operators, $\sigma_0^y, \sigma_0^x \sigma_1^y, \sigma_0^y \sigma_1^y$, appearing with varying prefactors, we see them appearing in the combinations

$$ h_0 \sigma_0^y, \frac{1}{h_{01}} h_{01} \sigma_0^y \sigma_1^y, \frac{1}{h_{01}} h_{01} h_{1} \sigma_0^y \sigma_1^y, $$

where $\Omega$ is the energy scale at which the operator appeared. There may be additional prefactors, which we will consider shortly, but first let us establish that these forms have an invariant structure.

2. Invariant Operators

In this section we will show that the form of the operators defined as follows:

$$ h_0 \sigma_0^y, \frac{1}{h_{01}} J_{01} \sigma_0^y \sigma_1^y \tag{A6} $$

$$ h_0 J_{01} h_1 \sigma_0^y \sigma_1^y $$

is preserved during the RG flow. The coefficients $h_0, h_0 J_{01}$, and $h_0 J_{01} h_1$ will only be replaced by their renormalized counterparts every time that a decimation affects them. This is demonstrated in the following examples.

The simplest example is the operator $h_0 \sigma_0^y$. Under the decimation of $-J_{01} \sigma_0^y \sigma_1^y$.
Another example is the operator $\frac{1}{J_{01}} h_{01}^2 J_{01} \sigma_0^y \sigma_1^z$. The decimation of the second bond, $-J_{12} \sigma_1^z \sigma_2^z$, modifies this operator as follows:

$$h_{01}^2 J_{01} \sigma_0^y \sigma_1^z \Rightarrow h_{01}^2 J_{01} \sigma_0^y \sigma_1^z = h_{01}^{\text{eff}}(\sigma_{01}).$$ (A7)

In the case of the operator $\frac{1}{J_{01}} h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y$, the corresponding transformation $S_a = \frac{h_{2}}{J_{12}} \sigma_1^y \sigma_2^y$ yields

$$h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y \Rightarrow h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y = h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y.$$ (A8)

Decimating the second site in the chain, $-h_1 \sigma_1^z$ involves the transformation $S_a = \frac{h_{12}}{h_1} \sigma_1^z \sigma_2^z$, yielding the following flow for the two operators $\frac{1}{J_{12}} h_{01}^2 J_{01} \sigma_1^z$, $\frac{1}{J_{12}} h_{01} J_{01} h_{12} \sigma_1^y$:

$$h_{01}^2 J_{01} \sigma_0^y \sigma_1^z \Rightarrow h_{01}^2 J_{01} \sigma_0^y \sigma_1^z = h_{01}^2 J_{01} \sigma_0^y \sigma_1^z = h_{01}^{\text{eff}} \sigma_0^y \sigma_1^z.$$ (A9)

The second transformation in this same decimation process is $S_b = \frac{J_{12} h_{12}}{h_1} \sigma_1^z \sigma_2^z$, which gives rise to:

$$h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y \Rightarrow h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y = h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^y.$$ (A10)

In all cases the flow due to decimations leaves the three forms of the end operators invariant. We excluded here the cases of a decimation of the first site or bonds; these are considered below.

3. Displacement Prefactors

As mentioned before and seen from the results of (A1), there are still multiplicative prefactors coming before the invariant operator forms. In Eq. (A2), for instance, all three operators from Eq. (A6) have the prefactor $\left(\frac{dn}{h_0}\right)^2$. This suppression can be associated with the displacement of the edge to the next undecimated site. With the help of (A1) it can be easily shown that an end site ($-h_0 \sigma_0^y$) decimation leads to the following flows:

$$h_0 \sigma_0^y \Rightarrow \left(\frac{dn}{h_0}\right)^2 h_{(011)} \sigma_0^y$$

$$h_0^2 J_{01} \sigma_0^y \sigma_1^z \Rightarrow \left(\frac{dn}{h_0}\right)^2 h_{12} J_{12} \sigma_1^y \sigma_2^y$$

$$h_0 J_{01} h_{12} \sigma_1^y \sigma_1^y \Rightarrow \left(\frac{dn}{h_0}\right)^2 h_{01}^2 J_{01} \sigma_1^y \sigma_1^z.$$ (A12)

From the above equation we see that there is a factor $\left(\frac{dn}{h_0}\right)^2$ associated with the displacement into the chain of the $\sigma_0^y \sigma_1^z$, $\sigma_0^y \sigma_1^y$ operators. This is repeated partially in the case of a bond decimation of the $-J_{01} \sigma_0^z \sigma_1^z$:

$$h_0^2 J_{01} \sigma_0^y \sigma_1^z \Rightarrow h_{01}^2 J_{01} \sigma_0^y \sigma_1^z$$

$$h_0 J_{01} h_{12} \sigma_1^y \sigma_1^y \Rightarrow \left(\frac{dn}{h_0}\right)^2 h_{01} J_{01} h_{12} \sigma_1^y \sigma_1^z.$$ (A13)

4. Leading Order Correlations

Now that we know how the end operators neglected in the text evolve and discovered that their forms are invariant, we can show that these operators do not change the leading order contributions to the correlation functions of interest. The $xx$ correlation function is

$$C^{xx}_L = \langle \psi | h_{00} \sigma_0^x h_L \sigma_L^x \psi \rangle = \langle \psi | \sigma_0^x \psi \rangle$$

$$= \sum_{\psi \neq G} \langle \psi | h_{00} \sigma_0^x \psi \rangle = \langle \psi | \psi \rangle G | G \rangle.$$ (A14)

with the sum over all excited states, $\psi$.

As the RG process progresses, all the end operators will be generated several times. However, we need only concern ourselves with the last set of these generated. Previously generated edge operators will have a larger suppression due to the more times they underwent edge displacement.

Considering the last decimation step which is needed to obtain the x-x correlations and changing notation so that the remaining effective sites are $\ell, r$ as in the text, we have:
\[ C_{\ell}^{xx} \approx \frac{e^{-\lambda_{\ell} - \lambda_{\ell'}}}{h_{\ell}h_{\ell'}} \sum_{\psi \neq G} <H| h_{\ell}\sigma_{\ell}^x + \frac{1}{112_r} h_{\ell}^2 J_{\ell}, \sigma_{\ell}^x \sigma_{\ell}^x + \frac{1}{112_r} h_{\ell} J_{\ell}, \sigma_{\ell}, \sigma_{\ell'}^y \sigma_{\ell'}^y |\psi > <\psi|h_{\ell}\sigma_{\ell}^x + \frac{1}{112_r} h_{\ell}^2 J_{\ell}, \sigma_{\ell}^x \sigma_{\ell}^x + \frac{1}{112_r} h_{\ell} J_{\ell}, \sigma_{\ell}, \sigma_{\ell'}^y \sigma_{\ell'}^y |H > . \] (A15)

The remaining low energy parts of the hamiltonian are
\[ \mathcal{H} = -h_{\ell}\sigma_{\ell}^x - J_{\ell} \sigma_{\ell}^z \sigma_{\ell}^z - h_{\ell'}\sigma_{\ell'}^x. \] (A16)

Two cases need to be considered: a site decimation and a bond decimation. In the case of a bond decimation, the ground state of the system is

\[ |H^{(L)} > = \frac{1}{\sqrt{2}}(|\downarrow_r > |\downarrow_{r'} > + |\uparrow_r > |\uparrow_{r'} > ) \] (A17)

and we immediately see that the only excitation that contributes in the sum (A15) is the \( \sigma_{\ell}^x \sigma_{\ell'}^z \) term:

\[ C_{\ell}^{xx} \approx e^{-\lambda_{\ell} - \lambda_{\ell'}} h_{\ell}h_{\ell'}, \] (A18)

which shows that in this case the dangerous operators (Eq. A5) do not contribute to the correlations.

The second case involves a site decimation. Let us assume that the dominant piece in (A16) is \(-h_{\ell}\sigma_{\ell}^x\):

\[ |H^{(L)} > = \frac{1}{2}(|\downarrow_r > + |\uparrow_r > )(|\downarrow_{r'} > + |\uparrow_{r'} > ) \] (A19)

In this case the contribution of the \( \sigma_{\ell}^x \sigma_{\ell'}^z \) product is only second order, and we need to consider the unitary transformation that induces this decimation. To lowest order, this is \( S_a = -\frac{J_{\ell}}{h_{\ell}} \sigma_{\ell}^x \sigma_{\ell'}^z \). Applying this to (A15) we get

\[ C_{\ell}^{xx} e^{\lambda_{\ell} + \lambda_{\ell'} h_{\ell}h_{\ell'}} \]

\[ \approx \sum_{\psi \neq G} <H| h_{\ell} e^{iS_a} \sigma_{\ell}^x e^{-iS_a} + \frac{1}{112_r} h_{\ell}^2 J_{\ell}, \sigma_{\ell}^x \sigma_{\ell}^x + \frac{1}{112_r} h_{\ell} J_{\ell}, \sigma_{\ell}, \sigma_{\ell'}^y \sigma_{\ell'}^y |\psi > <\psi|h_{\ell} e^{iS_a} \sigma_{\ell}^x e^{-iS_a} + \frac{1}{112_r} h_{\ell}^2 J_{\ell}, \sigma_{\ell}^x \sigma_{\ell}^x + \frac{1}{112_r} h_{\ell} J_{\ell}, \sigma_{\ell}, \sigma_{\ell'}^y \sigma_{\ell'}^y |H > \]

\[ \approx \sum_{\psi \neq G} <H| -h_{\ell} \frac{J_{\ell}}{h_{\ell}} \sigma_{\ell}^x \sigma_{\ell'}^z + \frac{1}{112_r} h_{\ell}^2 J_{\ell}, \sigma_{\ell}^x \sigma_{\ell}^x + \frac{1}{112_r} h_{\ell} J_{\ell}, \sigma_{\ell}, \sigma_{\ell'}^y \sigma_{\ell'}^y |H > \]

\[ = h_{\ell}h_{\ell'} \frac{J_{\ell}}{h_{\ell}} + (h_{\ell} - h_{\ell'}) \frac{J_{\ell}}{h_{\ell}h_{\ell'}} \approx h_{\ell}h_{\ell'} \frac{J_{\ell}}{h_{\ell}}, \]

which is the same result as was derived in the text while ignoring the additional edge operators from Eq. (A5). In the above we used \( \frac{J_{\ell}^2}{h_{\ell}} \ll 1 \).

This demonstration can be repeated for the xx-z correlations and also carried to higher order with the same conclusions. We have thus verified that the energy correlations can be obtained from the leading contributions to the flow of the edge energy operators in each step of the RG.
