Detection of entanglement in bipartite states is a fundamental task in quantum information. The first method to verify entanglement in mixed states was the partial-transpose criterion. Subsequently, numerous quantifiers for bipartite entanglement were introduced, among them concurrence and negativity. Surprisingly, these quantities are often treated as distinct or independent of each other. The aim of this contribution is to highlight the close relations between these concepts, to show the connections between seemingly independent results, and to present various estimates for the mixed-state concurrence within the same framework.

I. INTRODUCTION

In quantitative entanglement theory, considerable effort has been spent in developing many different entanglement measures [1,3], while much less is known regarding the relations between these measures and, in particular, their connection to the resources they quantify. This has lead to a situation that parts of quantitative entanglement theory have the fame of a certain arbitrariness, if not a lack of meaning. As opposed to this, we believe that—given a well-defined entanglement measure—there is a physical resource (defined through a protocol) that is quantified by this measure.

At present, there are only few well-established links between entanglement-related resources and their quantifiers [4,10]. However, many more mathematical ways of characterizing and quantifying entanglement are known than corresponding protocols using that entanglement. Therefore we think it is important to investigate and reveal the relations between different concepts, their possible common origins and essential differences, in order to introduce more structure in the world of entanglement measures where it is possible.

The subject of this article exemplifies the coexistence and apparent independence of different concepts in entanglement characterization. The partial-transpose criterion [11,12] provided the first possibility to detect entanglement in arbitrary mixed states. Later, numerous tools based on the partial transpose were developed, such as decomposable entanglement witnesses [13], negativity (and logarithmic negativity) as an entanglement measure [14,17], combinations of the latter in detection of multipartite entanglement [18,19], and others. On the other hand, the concurrence was first introduced by Bennett et al. [20] as an auxiliary tool to compute the entanglement of formation for Bell-diagonal two-qubit states and then developed further by Wootters and co-workers [21,22] who established concurrence as an entanglement measure in its own right. Subsequently, generalizations to the higher-dimensional case $d \times d$ ($d > 2$) as well as for multipartite systems (e.g., Refs. [22,30]) were proposed.

There have been comparative studies of concurrence and negativity (e.g., Refs. [15,31–35], however, as far as we can see they continue to exist in separate research lines. Therefore, we find it useful to present a discussion showing that both negativity and concurrence can be directly related to the partial transpose, and that both essentially determine the same type of entanglement deriving from the Schmidt rank of a Bell state which results in various mathematical relations linking all these quantities.

Our paper is organized as follows. In Sec. II, we introduce the most important concepts and notation. In Sec. III, we discuss the links between partial transpose, concurrence, and negativity for pure states. Finally, in Sec. IV, we extend this discussion to mixed states. In particular we study a family of symmetric bipartite mixed states—the axisymmetric states—for which the quantitative concepts of interest can be derived exactly thus providing both an illuminating illustration as well as a powerful tool for further investigation.

II. DEFINITIONS

Throughout this article we study bipartite quantum systems with $d$-dimensional local parties (often termed $d \times d$ systems). For their pure states $\psi \in \mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B = \mathbb{C}^d \otimes \mathbb{C}^d$. Given orthonormal bases $\{|j\rangle_A\}, \{|k\rangle_B\}$ for the
two parties a state $\psi$ can be written
\[ |\psi\rangle = \sum_{j,k=1}^d \psi_{jk} |j\rangle_A \otimes |k\rangle_B \equiv \sum_{j,k=1}^d \psi_{jk} |j k\rangle . \] (1)

The mixed states $\rho$ are bounded positive operators acting on $\mathcal{H}$ and can be represented as convex combinations of pure-state projectors $\pi_\psi \equiv |\psi\rangle \langle \psi|$ (with $\text{tr} \pi_\psi = 1$)
\[ \rho = \sum_j p_j \pi_\psi, \] (2)
where $p_j \geq 0$, $\sum_j p_j = 1$. Importantly, such decomposition of a mixed state is not unique, that is, there are infinitely many pure-state ensembles representing a given state.

For each pure state $\psi$, there is a so-called Schmidt decomposition (see, e.g., Ref. [37])
\[ |\psi\rangle = \sum_{j=1}^{r(\psi)} \sqrt{\lambda_j} |\alpha_j \beta_j\rangle \] (3)
with $\lambda_j \geq 0$ and $r(\psi) \leq d$. The local Schmidt bases $\{|\alpha_j\rangle_A, |\beta_j\rangle_B\}$ can be obtained be suitable local unitary transformations from given local bases $\{|k\rangle_A\}$, $\{|l\rangle_B\}$. The Schmidt rank $r(\psi)$ is the number of nonvanishing Schmidt coefficients $\lambda_j$.

For mixed states, the generalization of the Schmidt rank is the Schmidt number [38], defined as the smallest maximum Schmidt rank occurring in any decomposition $\{(p_j, \psi_j)\}$ of $\rho$
\[ r(\rho) = \min_{\{(p_j, \psi_j)\}} \max_j r(\psi_j). \] (4)

Given a state $\rho$, we may trace out one of the parties and obtain the reduced state of the other party $\rho_A \equiv \text{tr}_B \rho$ (and analogously for $\rho_B$). A well-known quantifier for the entanglement of the pure state $\psi$ is the concurrence
\[ C(\psi) = \sqrt{2(1 - \text{tr} \rho^{2}_A)} = \sqrt{2(1 - \text{tr} \rho^{2}_B)}. \] (5)

Note that sometimes the factor 2 is replaced by $d/(d-1)$, however, this difference in normalization is not essential. Interestingly it was shown [24, 25] that
\[ C(\psi) = \sqrt{\sum_{jklm} |c_{jk}^{lm}|^2} \] (6)
where $c_{jk}^{lm} \equiv \psi_{jk} \psi_{lm}^\ast - \psi_{jl} \psi_{km}^\ast$ are the concurrence vector components [24, 31].

For mixed states $\rho$ the concurrence is given by the minimum average concurrence taken over all decompositions of $\rho$, the so-called convex roof
\[ C(\rho) = \min_{\{(p_j, \psi_j)\}} \sum_j p_j C(\psi_j). \] (7)
The convex roof is notoriously hard to evaluate, therefore it is difficult to determine whether or not an arbitrary state is entangled.

The partial transpose of a bipartite state $\rho$ (with respect to party $B$) is given by
\[ \rho^{T_B} = \sum_{jk,lm} \rho_{jk,lm} |j k\rangle \langle l m| \equiv \sum_{jk,lm} \rho_{jk,lm} |jm\rangle \langle lk|. \] (8)
The partial transpose indicates entanglement of $\rho$ if $\rho^{T_B}$ has negative eigenvalues. The corresponding quantifier is the negativity [14, 17]
\[ N(\rho) = \frac{1}{2} (||\rho^{T_B}||_1 - 1), \] (9)
where $||M||_1 \equiv \text{tr} \sqrt{M^\dagger M}$ is the trace norm of the matrix $M$. The huge advantage of the negativity is that it can easily be computed for any mixed state, however, at the price that entanglement in states with a positive partial transpose (PPT) is not detected.

A related quantity which detects PPT entanglement but, again, is hard to compute is the convex-roof extended negativity [40, 41]
\[ N^{\text{CREN}}(\rho) = \min_{\{(p_j, \psi_j)\}} \sum_j p_j N(\psi_j). \] (10)

It is the largest convex function that coincides with $N(\psi)$ on the pure states, that is, $N^{\text{CREN}}(\rho) \geq N(\rho)$.

An important property of concurrence and negativity is that they are both invariant under local unitary transformations. The Schmidt rank does not change under arbitrary invertible local operations.

III. PURE STATES

The relation between pure-state concurrence and the partial transpose was studied before (e.g., [31, 35]) but we find it important to make it very explicit here, because this will directly connect to the negativity and show what is actually quantified by these measures. Moreover, we discuss how concurrence and negativity can be viewed as $\ell_p$ norms of the concurrence vector.

A. Partial transpose and concurrence

Assume the pure state $\phi$ is a tensor product
\[ |\phi\rangle = \sum_{jk} \phi_{jk} |j k\rangle \] (11)
so that the corresponding projector can be written
\[
\pi_\phi = \sum_{jklm} \phi_{jk} \phi^*_{lm} |jk\rangle \langle lm| = \sum_{jklm} a_{j} b_{k} a_{l}^* b_{m}^* |jk\rangle \langle lm| .
\] (12)

The matrix elements of the partial transpose of \(\pi_\phi\) instead read
\[
\left(\pi_{\phi}^{T_B}\right)_{jk,lm} = \phi_{jm} \phi^*_{lk} = a_{j} b_{k} a_{l}^* b_{m} .
\] (13)

Therefore, for any product state \(\phi\) we have
\[
\left|\left(\pi_{\phi}^{T_B}\right)_{jk,lm}\right|^2 - \left|\left(\pi_{\phi}^{T_B}\right)_{jk,jk}\left(\pi_{\phi}^{T_B}\right)_{lm,lm}\right|^2 = \left|\phi_{jm} \phi_{lk}\right|^2 - \left|\phi_{jk} \phi_{km}\right|^2 = 0 .
\] (14)

A state that does not fulfill condition (14) cannot be a product state. Since violation of Eq. (14) may occur for any combination of level pairs \((j,k)\) for party \(A\) and \((k,m)\) for \(B\), we define
\[
{\tilde{C}}(\psi)^2 = \sum_{jklm} \left|\psi_{jm} \psi_{lk} - \psi_{jk} \psi_{lm}\right|^2
\] (15)
as a quantifier for the violation of the product-state condition for the state \(\psi\). By comparing Eqs. (10) and (15) we see that \({\tilde{C}}(\psi)\) coincides with the \(d \times d\) concurrence \(C(\psi)\). That is, for a pure state \(\psi\) the squared concurrence is simply a measure for the total violation of the PPT-type condition (14).

Because of the local unitary invariance of \(C(\psi)\) (see Sec. III C) it suffices to compute the concurrence for the Schmidt decomposition \(|\psi\rangle = \sum \sqrt{\lambda_j} |\alpha_j \beta_j\rangle\) of \(\psi\), one obtains
\[
C(\psi) = \sqrt{2 \left| \sum_{j<k} \sqrt{\lambda_j \lambda_k} \delta_{jk} - \sqrt{\lambda_j \lambda_k} \right|^2}
= 2 \sqrt{\sum_{j<k} \lambda_j \lambda_k} ,
\] (16)
that is, the concurrence is identical with the case \(k = 2\) of the \(k\)-concurrence defined by Gour [42], the \(k\)th elementary symmetric function of the Schmidt coefficients taken to a power so that it is homogeneous of degree 2 in the state coefficients (note the different normalization of \(C_2(\psi)\) in Ref. [42]).

Consider now the (maximally entangled) Bell state of rank \(r\)
\[
|\Phi_r\rangle = \frac{1}{\sqrt{r}} \sum_{j=1}^{r} |jj\rangle .
\] (17)
The corresponding concurrence equals
\[
C(\Phi_r) = \sqrt{\frac{2(r-1)}{r}} .
\] (18)

We see that the concurrence grows monotonically with the Schmidt rank of \(\Phi_r\). For rank-\(r\) states which are not maximally entangled the concurrence clearly is smaller than \(C(\Phi_r)\), in a sense it attributes an ‘effective rank’ \(r_{\text{eff}} = \frac{1}{1-\frac{2}{r^2}} < r\) to the state.

**B. Negativity**

Again, because of the local unitary invariance, we can compute the negativity \(N(\psi)\) from the Schmidt decomposition \(|\psi\rangle = \sum \sqrt{\lambda_j} |\alpha_j \beta_j\rangle\)
\[
N(\psi) = \sum_{j<k} \sqrt{\lambda_j \lambda_k} .
\] (19)

In particular, we find for the Bell states \(\Phi_r\)
\[
N(\Phi_r) = \frac{1}{2} \left( 2 \frac{r(r-1)}{2} \right) = \frac{r-1}{2} .
\] (20)

That is, in analogy with the concurrence the negativity ‘counts’ the Schmidt rank, if the state is maximally entangled. The word ‘counting’ can be taken literally here due to the linear dependence of \(N(\Phi_r)\) on \(r\) (cf. Ref. [43]).

Thus, we see that both concurrence and negativity quantify the Schmidt rank, albeit in a mathematically different manner. If a state \(\psi\) is not maximally entangled, both measures attribute a kind of ‘effective rank’ to it which is smaller than that of the maximally entangled state locally equivalent to \(\psi\) (that is, equivalent under stochastic local operations and communication (SLOCC)).

From Eqs. (18) and (20) it is evident that the negativity gives equal weight to each Schmidt rank increment while the concurrence favors increments at lower Schmidt ranks. It is not difficult to track down the origin of this difference by comparing the squared equations (16) and (19). The squared concurrence contains only the products of two different Schmidt coefficients while the squared negativity has contributions also from products of up to four Schmidt coefficients.

Moreover, the negativity keeps increasing linearly with the Schmidt rank while the concurrence converges to a finite value. This means that adding more dimensions to a state which already has high Schmidt rank does practically not augment the concurrence. This hints at the fact that concurrence and negativity, both being related to the Schmidt rank of the state, quantify qualitatively different resources: The resource quantified by the concurrence is present to a high degree already in a state with relatively low Schmidt rank, and can be improved beyond that only marginally. On the other hand, the negativity can grow without a limit on increasing the Schmidt rank, and this should apply also to the corresponding resource.
C. Concurrence, negativity, and $\ell_1$ norms

From Eq. (6) and also form the derivation of condition (14) leading to the total violation of the PPT condition, we see that the concurrence formally looks like the length of a Euclidean vector, i.e., it can be regarded as the $\ell_2$ norm of the concurrence vector. However, in our derivation of condition (14) it was by no means necessary to use the square of $|\psi_j m \psi_{lk} - \psi_j k \psi_{lm}|$. The last line of Eq. (14) is correct also without squaring it. Hence, we could have introduced a total violation of the PPT condition also as

$$\tilde{N}(\psi) = \frac{1}{4} \sum_{jklm} |\psi_j m \psi_{lk} - \psi_j k \psi_{lm}| \quad . (21)$$

Now, comparing Eq. (21) with the negativity calculated from the Schmidt decomposition, Eq. (19), it is tempting to conclude that the pure-state negativity actually equals the $\ell_1$ norm of the concurrence vector (14), i.e., $N(\psi) = \tilde{N}(\psi)$. Unfortunately this is not correct in general. The reason is that the right-hand side in Eq. (21) may increase under local unitaries, and thus cannot represent an entanglement monotone.

To put it in different words: The negativity of a pure state $\psi$ equals the $\ell_1$ norm (21) of the concurrence vector $c_{jklm} = (\psi_j m \psi_{lk} - \psi_j k \psi_{lm})$ if $\psi$ is given in the Schmidt basis. Then, this $\ell_1$ norm assumes its minimum

$$N(\psi) = \min_{\text{local bases}} \tilde{N}(\psi) \quad , (22)$$

while for other local bases it is larger. Clearly, since the minimum of the $\ell_1$ norm (22) equals the negativity it is an entanglement monotone, however, the $\ell_1$ norm written in a different basis is not (it is not even invariant under local unitaries).

Now we will prove that $\tilde{N}(\psi)$ is minimized for $\psi$ given in the Schmidt basis, Eq. (8). To this end, consider local unitaries $U$ and $V$ applied to the parties of $\psi$ written in the Schmidt basis

$$\psi_{ab} = \sum_{mn} U_{am} V_{bn} \psi_{mn} = \sum_{mn} U_{am} V_{bn} \sqrt{\lambda_m \delta_{mn}} \quad (23)$$

and use this in Eq. (21) to express $\tilde{N}(\tilde{\psi})$ as

$$\tilde{N}(\tilde{\psi}) = \frac{1}{4} \sum_{a'b'bb'} |\tilde{\psi}_{a'b} \tilde{\psi}_{a'b'} - \tilde{\psi}_{a'b'} \tilde{\psi}_{a'b}|$$

$$= \frac{1}{4} \sum_{a'b'bb'} \left| \sum_{mn} U_{am} U_{a'n} (V_{bm} V_{b'n} - V_{bn} V_{b'm}) \sqrt{\lambda_m \lambda_n} \right|. \quad (24)$$

In order to proceed, we note that

$$\sum_{a'b'bb'} \left| \sum_{mn} U_{am} U_{a'n} (V_{bm} V_{b'n} - V_{bn} V_{b'm}) x_{mn} \right|^2 = 2 \sum_{mn} |x_{mn}|^2 , \quad (24)$$

which is easily seen by expanding $|y|^2 = yy^*$. This relation also implies local unitary invariance of the concurrence.

By substituting $x_{mn} = (\sqrt{\lambda_m \lambda_n} - 1)$ in Eq. (24) and applying the triangle inequalities $|a - b| \geq |a| - |b| \geq |a| - |b|$ we obtain

$$2 \sum_{mn} \sqrt{\lambda_m \lambda_n}$$

$$\leq \sum_{a'b'bb'} \left| \sum_{mn} U_{am} U_{a'n} (V_{bm} V_{b'n} - V_{bn} V_{b'm}) \sqrt{\lambda_m \lambda_n} \times \right|$$

$$\times \sum_{mn} |U_{am} U_{a'n} (V_{bm} V_{b'n} - V_{bn} V_{b'm})| \quad . (25)$$

The last factor on the right-hand side is $\leq 1$, by virtue of the Cauchy-Schwarz inequality and the normalization of columns of unitary matrices. Hence we have

$$\tilde{N}(\psi) = \tilde{N}(\tilde{\psi}) = \sum_{m>n} \sqrt{\lambda_m \lambda_n} \leq \tilde{N}(\tilde{\psi}) \quad , (26)$$

where, as defined above, $\psi$ is a state given in the Schmidt basis, while $\tilde{\psi}$ is obtained from $\psi$ by applying local unitaries.

Finally, it is easy to construct an example showing that indeed $\tilde{N}$ can increase under local unitaries, consider, e.g., $\Phi_3$ and apply a Hadamard transform in the subspace $\{|1\rangle, |2\rangle\}$. This concludes the proof.

D. Inequalities for concurrence and negativity

By using the results of the previous section, a number of interesting inequalities connecting concurrence, negativity and Schmidt rank can be proven.

We have already mentioned that for a pure state $\psi \in \mathbb{C}^d \times \mathbb{C}^d$ of Schmidt rank $r$

$$C(\psi) \leq \sqrt{\frac{2(r-1)}{r}} ,$$

$$\tilde{N}(\psi) \leq \frac{r-1}{2} .$$

Furthermore, we see that

$$2\tilde{N}(\psi) \geq C(\psi) \geq 2 \sqrt{\frac{2}{r(r-1)}} \tilde{N}(\psi) . \quad (27)$$

The first of these inequalities can be readily deduced from Eqs. (10) and (11) while the second is a consequence of the fact that the quadratic is larger than the arithmetic mean. Obviously, for pure states of two qubits the negativity equals the concurrence divided by two.

In Fig. 1 we illustrate the bounds of Eq. (27) by plotting the concurrence and negativity for many randomly chosen pure states. Clearly, those linear estimates are not the best ones possible. In fact, the evident (curved) boundaries for the concurrence values can be obtained by analytically maximizing/minimizing the concurrence for given negativity and rank of the state.
IV. MIXED STATES

The estimation of the Schmidt number and the concurrence for arbitrary mixed states is an important problem, both for theory and experiment. By combining the results for pure states and some recent ideas, one obtains an interesting toolbox for practical applications.

A. Concurrence, negativity, and Schmidt number

The great advantage of the negativity is that it can be evaluated also for arbitrary mixed states, as opposed to the Schmidt number or the concurrence. We will now discuss some relations connecting the negativity to the other two quantities.

It has been shown only recently \cite{43} that the negativity can actually be used as a lower bound on the Schmidt number. Let us assume that we are given a mixed state \( \rho \) of a \( d \times d \) system and a decomposition \( \{ (p_j, \psi_j) \} \) that optimizes the Schmidt number \( r(\rho) \). Then we have

\[
\mathcal{N}(\rho) \leq \sum_j p_j \mathcal{N}(\psi_j) \leq \sum_j p_j \frac{r(\rho) - 1}{2} \leq \frac{r(\rho) - 1}{2}
\]

from which follows

\[
r(\rho) \geq 2\mathcal{N}(\rho) + 1 \quad . \tag{28}
\]

Here we have used Eq. (20) and the convexity of negativity. An analogous inequality can be derived for the concurrence

\[
C(\rho) \leq \sum_j p_j C(\psi_j) \leq \sqrt{\frac{2(r(\rho) - 1)}{r(\rho)}} \quad , \tag{29}
\]

from which we arrive at

\[
r(\rho) \geq \frac{1}{1 - \frac{1}{2}C(\rho)^2} \quad . \tag{30}
\]

This relation is essentially different from Eq. (28). On the other hand, finding a useful lower bound for the concurrence might be more difficult than calculating the negativity. On the other hand, for PPT-entangled states Eq. (28) is not useful.

We can also find inequalities for the concurrence and the negativity. From the first inequality in Eq. (27) it follows that

\[
2\mathcal{N}^{\text{CREN}}(\rho) \geq C(\rho) \quad , \tag{31}
\]

while from the second inequality of Eq. (27) we get for an optimal decomposition \( \{ (p_j, \psi_j) \} \) of the concurrence (cf. \cite{31, 33})

\[
C(\rho) = \sum_j p_j C(\psi_j) \geq 2 \sum_j p_j \sqrt{\frac{2}{r_j(r_j - 1)}} \mathcal{N}(\psi_j) 
\]

\[
\geq 2 \sqrt{\frac{2}{r(r - 1)}} \mathcal{N}^{\text{CREN}}(\rho) 
\]

\[
\geq 2 \sqrt{\frac{2}{r(r - 1)}} \mathcal{N}(\rho) \quad , \tag{32}
\]

where \( r_j = r(\psi_j) \) and \( r = \max r_j \). If \( r \) is not known it can be replaced by the dimension \( d \).

We mention that the two-qubit concurrence divided by two \textit{equals} the convex-roof extended negativity \( \mathcal{N}^{\text{CREN}} \) [cf. Eq. (27)], and the negativity \( \mathcal{N} \) is a lower bound to the latter. Therefore, the \( 2 \times 2 \) negativity never exceeds the concurrence divided by two, as noted in Ref. \cite{31}. In contrast, for higher local dimension \( d > 2 \) the negativity may be larger than half the concurrence (e.g., Bell states), but it may also be smaller (e.g., PPT-entangled states).

B. Systematic lower bounds for concurrence

Already from the discussion in the preceding section it can be seen that it is desirable to have systematic ways for estimating the mixed-state concurrence. However, this has proven difficult over the years. Only recently, an elegant method was devised by Huber and co-workers (based on earlier ideas \cite{46, 47}) to lower bound concurrence-type entanglement measures, see, e.g., Ref. \cite{29, 30}. While in those references the focus is on multipartite states, we apply it here in the simpler case of bipartite states.

The method proceeds in two steps. First, we estimate the pure-state concurrence directly from Eq. (13). Subsequently we show that the resulting inequality applies to mixed states. We select a set \( \mathcal{M} \) of \( \mu \) pairs \( \{ jk, lm \} \) \((j < l, k < m)\) and estimate the corresponding terms in

Figure 1. (color online). Concurrence vs. negativity for 1000 random pure states \cite{15} (blue dots) with \( d = 4 \) and \( r \leq 3 \). The green lines represent the upper and lower bounds in Eq. (27).
Eq. (6) using the triangle inequality and the inequality between arithmetic and quadratic mean

\[ C(\psi) \geq \frac{2}{\sqrt{\mu}} \sum_{jk \in M} |\psi_{jk} - \psi_{jm}| \geq \frac{2}{\sqrt{\mu}} \sum_{jk \in M} |\psi_{jk}| - \sqrt{|\psi_{jm}|^2 |\psi_{lk}|^2} . \tag{33} \]

The convex-roof construction for the concurrence and the convexity of the functions on the right-hand side of Eq. (33) guarantee that we can replace all state components by the corresponding density matrix elements so that

\[ C(\rho) \geq \frac{2}{\sqrt{d-1}} \sum_{j<k=1}^d \left( \rho_{jj,kk} + \rho_{kk,jj} - \rho_{jj,kk} - \rho_{kk,jj} \right) \]

Because of the local unitary invariance of the concurrence, one can maximize this lower bound simply by changing local bases.

A nice application of this inequality results if we choose \( M \) such that it specifies the off-diagonal matrix elements \( \rho_{jj,kk} \) of the Bell-state projector \( \pi_{\Phi,j} \), i.e., \( \mu = \frac{1}{2}d(d-1) \). For simplicity we replace the square root terms by \( \frac{1}{2}(\rho_{jj,kk} + \rho_{kk,jj}) \geq \sqrt{\rho_{jj,kk}\rho_{kk,jj}} \) and obtain

\[ C(\rho) \geq \sqrt{\frac{2}{d(d-1)}} \left[ \sum_{j<k} (\rho_{jj,kk} + \rho_{kk,jj} - \rho_{jj,kk} - \rho_{kk,jj}) \right] \]

\[ \geq \sqrt{\frac{2}{d(d-1)}} \left[ -1 + \sum_{j<k} (\rho_{jj,kk} + \rho_{kk,jj}) + \sum_{j} \rho_{jj,jj} \right] \]

\[ \geq \sqrt{\frac{2d}{d-1}} \left[ \langle \Phi_A | \rho | \Phi_A \rangle - \frac{1}{d} \right] \] \hspace{1cm} \tag{35a}

\[ \geq \sqrt{\frac{2d}{d-1}} \text{tr} \left( \rho \left[ | \Phi_A \rangle \langle \Phi_A | - \frac{1}{d} \mathbb{1}_d \right] \right) \] \hspace{1cm} \tag{35b}

which is a concurrence estimate from the optimal Schmidt number witness [45] (for Schmidt number 2).

We can even improve this bound by optimization over local unitaries. This way we encounter another well-known quantity, namely the fully entangled fraction \( F _{\text{REF}} \)

\[ F(\rho) = \max_{U_A,U_B} \langle \Phi_A | (U_A \otimes U_B) \rho (U_A \otimes U_B)^\dagger | \Phi_A \rangle \] \hspace{1cm} \tag{36}

and Eq. (35a) then reads

\[ C(\rho) \geq \max \left( 0, \sqrt{\frac{2d}{d-1}} \left[ F(\rho) - \frac{1}{d} \right] \right) \] \hspace{1cm} \tag{37}

a result found in Ref. [49].

C. Axisymmetric states

We conclude our survey by considering a nontrivial family of mixed states for which the quantitative concepts we have discussed can be evaluated exactly for all finite dimensions \( d \). This family is called axisymmetric states [43]. In \( d \) dimensions it includes all states that have the same symmetries as the Bell state \( \Phi_d \), Eq. (17), namely

\begin{itemize}
  \item[(i)] permutation symmetry of the two qudits,
  \item[(ii)] symmetry with respect to simultaneously exchanging two levels for both qudits, e.g., \( |1\rangle_A \leftrightarrow |2\rangle_A \) and \( |1\rangle_B \leftrightarrow |2\rangle_B \),
  \item[(iii)] simultaneous (local) phase rotations of the form \( V(\varphi_1, \varphi_2, \ldots, \varphi_{n-1}) = e^{i \sum \varphi_{j} \theta_j} \otimes e^{-i \sum \varphi_{j} \theta_j} \), \hspace{1cm} \tag{38}
\end{itemize}

where \( \varphi_j \) are the \( (d-1) \) diagonal generators of SU(\( d \)). Note that the period of the phase angles \( \varphi_j \) depends on the normalization of the generators \( g_j \). For axisymmetric states, qubit permutation symmetry is implied by the requirements (ii) and (iii).

After discussing the symmetries of axisymmetric states, we will show how to parametrize them. In any dimension \( d \) the \( d \times d \) axisymmetric states are parametrized by two real numbers. This can be seen as follows. The phase rotation symmetry eliminates all off-diagonal components which are not of the form \( \rho_{jj,kk} \). Qudit permutation and simultaneous level exchange symmetry are possible only if all off-diagonal elements are real and equal (one parameter) and there are only two different types of diagonal elements \( \rho_{jj,kk} \) for \( j = k \) and \( j \neq k \) which give one more parameter, due to the normalization constraint \( \text{tr} \rho = 1 \). Based on the ideas above, we have the following parametrization

\[ \rho_{jj,jj}^{\text{axi}} = \frac{1}{d^2} + a , \quad \rho_{jk,jk}^{\text{axi}} = \frac{1}{d^2} - \frac{a}{d-1} \] \hspace{1cm} (j \neq k) \hspace{1cm} \tag{39}

\( (j,k = 1, \ldots, d) \) and off-diagonal entries

\[ \rho_{jk,jk}^{\text{axi}} = \begin{cases} b & \text{for } l = j , m = k \\ 0 & \text{otherwise} \end{cases} \] \hspace{1cm} \tag{40}

Let us now determine the limits for the parameters for physical states. We are free to choose the length scales \( a \) and \( b \) in such a way that in a graphical representation the lengths are the same as in state space, hence geometrical intuition can be directly applied to the figures. Here the length in state space \( D_{\text{HS}}(A,B) \) is defined via the Hilbert-Schmidt scalar product \( D_{\text{HS}}(A,B) = \text{tr}(A - B)(A - B)^\dagger \). The appropriate scaling factors for the coordinates \( x \) and \( y \) are

\[ a = y \sqrt{\frac{d-1}{d}} , \quad b = \frac{x}{\sqrt{d(d-1)}} \] \hspace{1cm} \tag{41}

from which we can compute the boundary of the axisymmetric states

\begin{align}
- \frac{1}{d \sqrt{d-1}} & \leq y \leq \frac{\sqrt{d-1}}{d} , \tag{42a} \\
- \frac{1}{\sqrt{d(d-1)}} & \leq x \leq \sqrt{\frac{d-1}{d}} \tag{42b}
\end{align}
obtained by averaging metrics \[51\]. Correspondingly, isotropic states can be divided by the Schmidt number regions in the axesymmetric states. This is not a surprise because the symmetry group of the isotropic states is \(\Phi_1\) and form a subgroup of \(\Phi_0\) (and analogously for isotropic states) because neither permutations nor local unitaries or mixing can increase entanglement.

The procedure for performing the average in Eq. (46) is easy: Given an arbitrary \(d \times d\) state \(\rho\) the matrix elements of its projection \(\rho_{axi}(\rho)\) are

\[
\rho_{jj,jj}^{axi} = \frac{1}{d} \sum_m \rho_{mm,mm},
\]

\[
\rho_{jk,kk}^{axi} = \frac{1}{d(d-1)} \sum_{m \neq n} \rho_{mn,mn} (j \neq k),
\]

with \(j, k = 1, \ldots, d\), and off-diagonal elements

\[
\rho_{jk,lm}^{axi} = 0 \quad \text{for } k \neq j \text{ or } l \neq m.
\]

D. Entanglement of axisymmetric states

The optimal Schmidt number witness \[48\]

\[
\mathcal{W} = \frac{k-1}{d} \mathbb{I}_{d^2} - |\Phi_d\rangle\langle\Phi_d|
\]

for Schmidt number \(k\) can be used to detect the exact boundaries of the different SLOCC classes (for \(x > 0\)), that is, the regions of different Schmidt number (see Fig. 2). While for \(x < 0\) the witness cannot be applied, one can check that the projection \(\rho_{axi}(\psi_0)\) of the product state \(|\psi_0\rangle = \frac{1}{2} (|1\rangle + |2\rangle \otimes (|1\rangle - |2\rangle))\) is the endpoint of the border for separable states. It is also easy to verify that above the line connecting this point with the separable state at \((x = 0, y = \sqrt{d^2-1})\) the negativity becomes nonzero, but does not exceed 1. The state at the upper left corner is a state of at most \(r = 2\) since it is the projection of \(\frac{1}{2} (|1\rangle - |2\rangle)\), therefore the entangled states for \(x < 0\) must have \(r = 2\).

The states with Schmidt number \(k \leq d\) belong to convex sets \(S_k\) and form a hierarchy \(S_1 \subset S_2 \subset \ldots \subset S_d\). Schmidt number \(k = 1\) corresponds to separable states
We can maximize the state and obtain exact solutions for the convex-roof extended negativity and concurrence we obtain (see Fig. 3). Notably, all the boundaries are represented by straight lines. In fact, this is a hint that the bipartite case—even for large states with concurrence—can be treated as the result of a projection to a bipartite state is contained in its fidelity with the maximum lower bound.

Let us now consider the entanglement quantitatively. The formula for the negativity is readily applied to \( \rho^{\text{axi}} \) and gives

\[
N(\rho^{\text{axi}}(x, y)) = \max \{0, \frac{1}{2} \left[ \sqrt{d(d-1)}|x| + \sqrt{d-1}y - \frac{d-1}{d} \right] \}. 
\]

On the other hand, by using the lower bound for the concurrence we obtain

\[
C(\rho^{\text{axi}}(x, y)) \geq \max \{0, \sqrt{\frac{2}{d(d-1)}} \left[ \sqrt{d(d-1)}|x| + \sqrt{d-1}y - \frac{d-1}{d} \right] \}. 
\]

These results (see Fig. 3) are remarkable for several reasons. Both concurrence and fidelity estimates depend linearly on \(|x|\) and \(y\) coordinates. Since Eqs. (50) and (51) include the exact values for the pure state \(\Phi_d\), and their graphs are planes, there cannot be a larger convex function containing \(N(\Phi_d)\) and \(C(\Phi_d)\) than these graphs. Hence, the formulas (50) and (51) represent the exact solutions for the convex-roof extended negativity and the concurrence of axisymmetric states, respectively. Moreover, it follows that all PPT axisymmetric states are separable. We mention that the concurrence result restricted to the isotropic states was found in Ref. [20].

Another immediate consequence is that the integer part of \((2N(\rho^{\text{axi}}) + 1)\) changes by 1 whenever a border between SLOCC classes, i.e., Schmidt numbers for \(\rho^{\text{axi}}\), is crossed. That is, for axisymmetric states Eq. (28) can be written

\[
r(\rho^{\text{axi}}) = \lceil 2N(\rho^{\text{axi}}) \rceil + 1 
\]

with the ceiling function \(\lceil x \rceil\) denoting the smallest integer greater than or equal to \(x\).

Concluding this section we discuss yet another procedure to determine a lower bound for the convex-roof extended negativity and the concurrence of arbitrary \(d \times d\) states \(\rho\). As we have mentioned before, the symmetrization Eqs. (48)-(49) does not increase the entanglement

\[
N^{\text{CREN}}(\rho^{\text{axi}}) \leq N^{\text{CREN}}(\rho) \quad C(\rho^{\text{axi}}) \leq C(\rho) 
\]

so that after symmetrizing \(\rho\) we can simply read off the value for \(N^{\text{CREN}}(\rho^{\text{axi}})\) or \(C(\rho^{\text{axi}})\) from Fig. 3. As discussed in Sec. [IVB] we can maximize the state \(\rho\) over local unitaries before projecting it and thus obtain an optimized lower bound.

It is interesting to note that for the concurrence this bound coincides with the one obtained from Eq. (37). The latter can be regarded as the result of a projection of the optimized state onto the isotropic states. Thus we see that one does not lose entanglement information projecting directly onto the isotropic rather than the axisymmetric states. This is a direct consequence of the fact that essential entanglement-related information of a bipartite state is contained in its fidelity with the maximally entangled state \(\Phi_d\), i.e., the fully entangled fraction.

\[\text{V. CONCLUSION}\]

We have pointed out and made explicit that not only negativity, but also concurrence is closely related to the partial transposition of a \(d \times d\) density matrix. In fact, both measures may be understood and derived as quantifiers for the violation of the PPT criterion in pure states. We have discussed that both negativity and concurrence quantify the Schmidt rank of a pure state, however, in different mathematical ways which hints at the fact that they quantify different resources. Finally we have shown that, while the concurrence equals the \(\ell_2\) norm of the concurrence vector of a pure state, the negativity is in general larger than the \(\ell_1\) norm of the concurrence vector. The negativity equals that \(\ell_1\) norm if the pure state is written in the Schmidt decomposition.

These relations between negativity and concurrence lead to various estimates for those measures (as well as
for the Schmidt number) in mixed states. A particularly nice result is that the negativity represents a direct lower bound to the Schmidt number of a state, Eq. (25). In the last section, we have provided an extensive discussion of the axisymmetric states, a nontrivial family of highly symmetric $d \times d$ states for which all the entanglement properties studied in this article can be calculated exactly.

[45] The random states were obtained as follows. First random states of a given Schmidt-rank were generated in the computational basis as the Schmidt basis. Then, a ran-
dom unitary rotation was applied. The algorithm provided unitaries distributed uniformly according to the Haar measure. The 1000 points were selected from the results of 100000 random states such that they uniformly fill the area on the plot. Concerning generating random unitaries, see for example G. Tóth, Comput. Phys. Comm. 179, 430 (2008).
