Abstract

Background

Ankle joint equinus, or restricted dorsiflexion range of motion (ROM), has been linked to a range of pathologies of relevance to clinical practitioners. This systematic review and meta-analysis investigated the effects of conservative interventions on ankle joint ROM in healthy individuals and athletic populations.

Methods

Keyword searches of Embase Medline Cochrane and CINAHL databases were performed with the final search being run in August 2013. Studies were eligible for inclusion if they assessed the effect of a non-surgical intervention on ankle joint dorsiflexion in healthy populations. Studies were quality rated using a standard quality assessment scale. Standardised mean differences (SMDs) and 95% confidence intervals (CIs) were calculated and results were pooled where study methods were homogenous.
Results

Twenty-three studies met eligibility criteria, with a total of 734 study participants. Results suggest that there is some evidence to support the efficacy of static stretching alone (SMDs: range 0.70 to 1.69) and static stretching in combination with ultrasound (SMDs: range 0.91 to 0.95), diathermy (SMD 1.12), diathermy and ice (SMD 1.16), heel raise exercises (SMDs: range 0.70 to 0.77), superficial moist heat (SMDs: range 0.65 to 0.84) and warm up (SMD 0.87) in improving ankle joint dorsiflexion ROM.

Conclusions

Some evidence exists to support the efficacy of stretching alone and stretching in combination with other therapies in increasing ankle joint ROM in healthy individuals. There is a paucity of quality evidence to support the efficacy of other non-surgical interventions, thus further research in this area is warranted.

Keywords

Ankle joint, Range of motion, Non-surgical intervention, Stretching, Biomechanics

Background

Ankle joint equinus occurs when there is reduced dorsiflexion range of motion (ROM) available at the ankle. Studies have shown that the presence of equinus deformity may cause healthy individuals to adopt compensatory gait patterns such as genu recurvatum, early heel lift and excessive subtalar joint pronation [1,2] in addition to altering their biomechanical function in gait. Altered biomechanics may predispose individuals to the development of pathologies such as metatarsalgia, ankle sprain and medial tibial traction periostitis as well as Achilles tendinopathy, plantar fasciopathy and gastrocnemius strain in sporting populations [1-4]. Restricted ROM at the ankle joint has been associated with poor balance and an increase in falls risk in the elderly [5] and furthermore, as equinus increases total plantar pressure acting on the forefoot, it has been linked to a prolongation of the healing time of plantar forefoot ulcers in diabetic patients [6].

There is lack of consensus within the literature regarding the degree of restriction that defines an equinus deformity [7]. Traditionally, less than 10 degrees of dorsiflexion has been cited as an indicator of ankle equinus [8], however, less than zero degrees and less than five degrees are also commonly used markers in biomechanics and sports medicine studies [9,10]. Equinus may result from shortening or contracture of the gastrocnemius or soleus muscles, bony restriction, structural abnormalities of the forefoot, or pathologies causing joint stiffness [7]. Methods of assessment for ankle joint equinus are inconsistent in the literature. Ankle joint ROM has been assessed in weight-bearing and non-weightbearing positions with the knee flexed or extended [11]. Various instruments such as goniometers, inclinometers and dynamometers, as well as different anatomical landmarks have been used to quantify the ROM available [7].

Clinicians screen for ankle joint equinus routinely as part of a lower limb biomechanical assessment and treat equinus conservatively, regardless of ankle joint pathology, to improve
biomechanical function of the lower limb [10,11]. A variety of interventions have been proposed to increase actual or functional dorsiflexion ROM at the ankle joint, including stretching, warm up and use of ultrasound [1-6,9,12-32]. Previous systematic reviews have investigated the effects of such interventions in increasing ankle joint dorsiflexion ROM in the context of ankle injuries [33] or neuromuscular disease [34]. However, there has been no synthesis of the literature investigating the efficacy of a range of interventions to increase ankle joint dorsiflexion in otherwise healthy individuals with an incidental finding of ankle equinus. Therefore, the purpose of this systematic review and meta-analysis was to investigate the effects of conservative interventions on increasing ankle joint dorsiflexion range of motion in healthy individuals.

**Methods**

**Search strategy and study inclusion**

Electronic databases were searched without date or language delimiters (Embase, Medline, Cochrane and CINAHL) using keyword searches, as follows:

- (Ankle AND equinus) OR (ankle AND joint AND range AND motion) OR (ankle AND dorsiflex* AND range AND motion) OR (ankle AND rocker)
- AND
- (dorsiflex* AND lunge AND test) OR treat* OR assess* OR measure* OR interven* OR clinical OR apparatus OR tool OR device OR instrument

The only search parameter applied was the human delimiter. Titles and abstracts were screened for relevance to the research question, and full text evaluations were performed on potentially relevant studies using predetermined criteria. A hand search of the reference lists of all relevant studies was undertaken to identify further eligible studies. Studies were selected for inclusion in this review based on the following criteria:

- Included a sample of healthy, human participants;
- Assessed a conservative (non-surgical) intervention for increasing ankle joint dorsiflexion; and
- Measured and reported passive ankle joint dorsiflexion values before and after intervention.

Studies were excluded based on the following criteria:

- Included participants with spastic equinus, talipes equinovarus or other pathology;
- Included participants with a history of ankle joint injury;
- Assessed surgical interventions.

**Quality assessment**

Two authors (RY, AW) independently assessed the included studies against a modified PEDro scale (Table 1) [35]. The two authors met to discuss the PEDro scale rating system prior to undertaking quality assessments in order to ensure clear understanding of assessment criteria. A consensus meeting resolved disagreements between assessors and a third party was
available to provide mediation if required. Consensus on all criteria was reached without need for third party mediation.

1. Eligibility criteria were specified.
2. Subjects were randomly allocated to groups.
3. Allocation was concealed.
4. The groups were similar at baseline regarding the most important prognostic indicators.
5. There was blinding of all subjects.
6. There was blinding of all therapists who administered the therapy.
7. There was blinding of all assessors who measured at least one key outcome.
8. Measures of at least one key outcome were obtained from more than 85% of the subjects initially allocated to groups.
9. All subjects for whom outcome measures were available received the treatment or control condition as allocated.
10. The results of between group statistical comparisons are reported for at least one key outcome.
11. The study provides both point measures and measures of variability for at least one key outcome.
12. Was the sample size justified?
13. Were the outcome measures reliable?
14. Were the outcome measures valid?

The modified PEDro scale featured three additional assessment criteria taken from Law et al. [36]. The additional criteria assessed whether the sample size was justified and whether the outcome measures used were both reliable and valid. The assessment scale featured 14 criterion designed to assess the methodological quality of randomised and non-randomised trials. Trials were awarded a ‘yes’ or ‘no’ rating for each criteria and ‘yes’ responses were then summed to produce an overall quality score for each trial assessed. For consistency, any criteria not directly reported by the authors of each trial were considered to have been unfulfilled and subsequently were awarded a ‘no’ rating.
**Data extraction and analysis**

Data extraction was performed by a single investigator (RY), who recorded details regarding study design, sample characteristics, outcome measures, interventions and follow-up periods. In order to calculate effect sizes, means and standard deviations (SD) were obtained wherever possible for each study group. In two studies [15,25] a smaller reported value for ankle ROM indicated greater dorsiflexion, so in these cases the means were subtracted from 90 degrees prior to analysis to allow for standardisation against other presented results. Standardised mean differences (SMDs) and 95% confidence intervals (CIs) were calculated, based on the difference between treatment and control groups at the longest period of follow-up. Where studies did not include a comparison group, SMDs were not calculated. SMDs were considered statistically significant if the 95% CI did not contain zero, and interpretation of the magnitude of SMDs was based on previous guidelines [37]: small effect ≥ 0.2, medium effect ≥ 0.5, large effect ≥ 0.8. Positive effect sizes indicated greater increases in ankle joint dorsiflexion in the treatment group compared to the control group. Where more than one intervention group was compared, intervention group A was designated to be the reference group for analysis. Random effects meta-analysis methods were used to pool data where study methods were considered to be homogenous. Sensitivity analyses were performed to investigate the influence of differing intervention or assessment techniques. Heterogeneity was quantified using Chi-squared tests (p < 0.10) and the I² statistic described by Higgins et al. [38], which represents the percentage of total variation across studies due to heterogeneity. To investigate potential bias across studies included in the meta-analysis, effect sizes were plotted against study quality score and sample size, and symmetry of these plots was assessed visually. All statistical analyses were performed using Stata version 10 (StataCorp LP, College Station, TX).

**Results**

**Included studies**

The search strategy returned 3,362 studies total from five databases (Figure 1). A further two potentially relevant studies were sourced through expert consultation. After initial screening to exclude irrelevant studies and to remove duplicates, 541 studies remained for detailed evaluation. The abstracts were read in order to select those that were directly relevant to this review. Three hundred and fifty-six studies were excluded based on abstract screening, and full text evaluations were performed on the remaining 185 studies. Twenty-three studies including a total of 734 participants satisfied the inclusion criteria for this review. Selected characteristics of included studies are presented in Additional File 1.

**Figure 1 Selection process for study inclusion.**

**Methodological quality**

The 23 included studies received overall quality scores ranging from 1/14 to 11/14 on the modified PEDro scale. Results from quality assessment are presented in Table 1. Of the studies selected for inclusion, 13 featured a control group [2,3,5,12,16,18,19,21,23,25,29,31,32,38]. Sixteen of the included studies randomly assigned participants to treatment groups [1-3,5,12,14-16,18,19,21,23,25,29,31,32], nine studies featured blinding of the participants, assessors or therapists [1,2,12,13,16,19,21,31,38] and 13
studies reported on the reliability of the measures used [1,3,5,12,14,16,23,25,27,29-32]. No studies reported on the validity of measures employed.

**Effects of interventions**

Eighteen studies investigated stretching interventions [1,3,5,6,12,14,15,18,19,21-23,25,27,29-32] and six of the 18 studies investigated the effects of combining stretching with interventions such as ultrasound therapy or strengthening exercises [14,19,21-23,30]. Two studies investigated manipulation therapy [13,16], two studies investigated mobilisation therapy [38,39] and one investigated soleal trigger point therapy [2]. Four studies did not include a comparison group [6,13,27,39] and a further four studies [19,31,32,39] reported insufficient data for SMDs to be calculated. Data comparing the effectiveness of various interventions, including SMDs and 95% CIs, is presented in Table 2. Table 3 provides a synthesis of the body of evidence for each intervention.

**Table 2 Comparison of conservative interventions for increasing ankle joint dorsiflexion range of motion**

### Stretching

Of the 18 studies that investigated stretching interventions, seven studies did not compare to a control group [1,6,14,15,22,27,30] and two studies presented insufficient data [19,31]. Another study investigating proprioceptive neuromuscular facilitation stretching was excluded from the meta-analysis due to differing stretching technique [25]. The results of eight remaining studies [3,5,12,18,21,23,29,32] investigating static stretching interventions were combined by meta-analysis methods. The combined effect size indicated that stretching had a statistically significant effect on increasing ankle joint dorsiflexion (SMD 0.68, CI: 0.40 to 0.97) (Figure 2). There was no statistically significant heterogeneity between pooled studies (Chi-squared 4.32, p = 0.74) (Figure 2). Visual inspection of funnel plots revealed that study quality score and sample size did not appear to bias the findings of studies included in the meta-analysis. Further analyses showed that removing studies from the meta-analysis that had used a non-weight bearing stretching technique, or used a different assessment technique (active versus passive ROM or knee flexed versus knee extended) did not substantially alter the findings of the meta-analysis.

![Figure 2](image.png)

**Figure 2 Pooled effect size (SMD, 95% CI) for studies investigating stretching compared to control group.** Positive effect sizes indicate greater increases in ankle joint dorsiflexion in the treatment group compared to the control group.

One study demonstrated that proprioceptive neuromuscular facilitation stretching was associated with greater increases in ankle dorsiflexion ROM than static stretching (SMD 1.90, 95% CI: 0.92 to 2.88) [15]. Stretching in combination with warming up (SMD 0.87, 95% CI: 0.18 to 1.55) [30], superficial moist heat (SMD 0.84, 95% CI: 0.18 to 1.50) [21], diathermy (SMD 1.12, 95% CI: 0.05 to 2.18) [23], diathermy and ice (SMD 1.16, 95% CI: 0.12 to 2.20) [23] and heel raise exercises (SMD 0.70, 95% CI: 0.04 to 1.37) [21] were also found to be associated with greater increases in ankle dorsiflexion when compared to
controls. In contrast, 12 studies showed no significant differences in ankle joint dorsiflexion between the stretching and comparison groups (SMDs: range –0.84 to 1.19) [1,5,6,14,18,19,22,25,27,29,31,32].

Two studies investigated the use of ultrasound prior to stretching compared to stretching alone. One reported significantly greater overall gains in ankle joint dorsiflexion ROM compared to stretching alone (SMD 0.95, 95% CI: 0.27 to 1.58) [21]. The second study found that there was no statistically significant difference between these two interventions. (SMD 0.0, 95% CI: -0.62 to 0.62) [14].

**Manual therapy**

Two studies eligible for inclusion in this review assessed the effect of manipulation therapy on ankle joint ROM. One study found that talocrural joint manipulation did not produce a statistically significant increase in dorsiflexion ROM in asymptomatic ankles when compared with a control group (SMD 0.0, 95% CI: -0.44 to 0.44) [16]. The second study reported insufficient data and was not included in the meta-analysis [13].

Two studies eligible for inclusion in this review assessed the effects of mobilisation therapy on ankle joint dorsiflexion ROM [39,40]. One study assessing the effects of mobilisation therapy did not report sufficient data to be included in the meta-analysis [40]. The second study found that talocrural joint mobilisation did not produce a statistically significant increase in dorsiflexion ROM when compared to a control group (SMD 0.19, 95% CI: -0.37 to 0.75) [39]. The second study assessing mobilisation therapy reported insufficient data and was not included in the meta-analysis [40].

**Soleus trigger point release**

One included study investigated the effect of trigger point therapy on ankle joint dorsiflexion ROM and reported no statistically significant difference between the intervention and control groups (SMD 0.72, 95% CI: -0.18 to 1.63) [2].

**Discussion**

This systematic review investigated the effects of conservative interventions on ankle joint dorsiflexion ROM in healthy individuals. Effect sizes calculated from individual studies revealed that stretching alone and the use of stretching in conjunction with ultrasound therapy, superficial moist heat, warm up and heel raise exercises were associated with statistically significant gains in ankle joint dorsiflexion ROM in the intervention groups compared to controls. There is currently insufficient evidence to suggest that soleal trigger point therapy, ankle joint mobilisation or manipulation are associated with statistically significant gains in ankle dorsiflexion ROM in healthy individuals.

Only five of the studies assessing the effects of stretching reported statistically significant gains in ankle ROM [3,12,21,30,31] however, the combined effect size from eight studies included in the meta-analysis showed a statistically significant positive effect of stretching compared to a control condition (pooled SMD 0.68, CI: 0.40 to 0.97) (Figure 2). Whilst the majority of studies investigating the efficacy of stretching programs reported non-significant results, it may be that this was due to small sample size or methodological weakness rather
than genuine inefficacy of the intervention. Only three of the 18 studies investigating the efficacy of stretching on ankle dorsiflexion ROM reported conducting power calculations to determine necessary sample size [1,29,30].

There is some evidence to suggest that interventions such as stretching and the combined use of stretching with ultrasound, warm up, superficial moist heat and heel raise exercises are effective in the short term. As such, they may be considered suitable for use in patients where even short term increases in ankle dorsiflexion would clinically be considered beneficial. The minimal clinically important difference for ankle dorsiflexion ROM has not been established; however, studies included in this review reported differences of two [29] to eight [18] degrees between intervention and control groups at follow up.

With respect to study quality, of the 23 trials included for detailed analysis in this review, 13 included a control group [2,3,5,12,16,18,19,21,25,29,31,32,39] whilst four studies did not include any comparison group [6,13,27,40]. Six compared interventions to each other without including a non-intervention control group [1,14,15,19,22,30]. Without comparing interventions to a control group, it cannot be known whether observed changes in ankle ROM may be attributed to real change or to the effects of individual variation at different points in time. Similarly, studies that compared two interventions to each other without comparing them to a control group, may only conclude that one intervention may be more beneficial than another. It can be noted that in this review, the ten non-controlled studies presented results which were similar to those reported in the 13 controlled studies.

All of the studies included for evaluation in this review assessed the effects of conservative interventions on ankle joint ROM in healthy individuals. The scope of this review did not include patients with neurologically-associated equinus deformity due to the current sound body of research pertaining to equinus deformity in individuals with neurological disease. A recent Cochrane review published by Rose et al. [34] investigated the efficacy of a range of conservative and surgical interventions in patients with neurologically-linked equinus deformity and reported that the use of night splints, prednisone and surgery were not associated with statistically significant increases in ankle joint dorsiflexion ROM in this sample population. The scope of this review also did not include individuals with active pathology such as acute metatarsalgia, plantar fasciopathy, Achilles tendinopathy, medial tibial traction periostitis or muscle strain. Consequently, future systematic reviews are warranted to determine the efficacy of conservative interventions in symptomatic populations such as these.

The majority of studies evaluated within this review reported on the short-term effects of conservative interventions on ankle joint dorsiflexion. The longest study period was eight weeks [5,6,12] and fewer than half of the included studies followed up their study participants for longer than four weeks. Due to the relative brevity of study periods, it is difficult to ascertain for how long conservative treatments may remain effective. As such, future research investigating the long term effects of conservative interventions to better inform clinical practice.

A review by Gatt et al. [41], investigated the reliability of a range of measurement techniques used to assess ankle dorsiflexion ROM. The review emphasized that the reliability and validity of goniometric measurements of ankle ROM have been shown to be poor and thus the use of goniometry in clinical trials calls into question the quality of the results obtained. The seven studies included in this review that presented reliability data for goniometry,
reported ICCs between 0.80 and 1.00 [1,3,12,25,29,39,40]. It must be noted however, that none of the included studies reported on the validity of measures used.

In this review, change in ankle dorsiflexion ROM was used as the main outcome measure to assess the efficacy of conservative interventions. There are a number of potential limitations associated with using measures of ankle joint dorsiflexion in this way. Firstly, it has been suggested that conventional measures of ankle joint dorsiflexion actually assess combined dorsiflexion range of motion at the ankle and midtarsal joints rather than at the ankle alone [41,42]. Secondly, it is possible that ankle range of motion is not directly indicative of functional performance. Turner et al. [43] studied cohorts of diabetic patients and healthy adults in order to assess the correlation between passive and functional ROM measures at the ankle joint. It was reported that there was a lack of correlation between the two measures and thus concluded that passive ankle joint ROM may not accurately reflect functional limitations in joint mobility at the ankle joint.

Foot posture has a profound effect on the measurement of dorsiflexion range of motion at the ankle joint. A study by Tiberio et al. [44] concluded that measuring ankle joint dorsiflexion with the foot in a pronated position increases recorded ROM by up to 10 degrees when compared with measuring dorsiflexion in a subtalar joint neutral position. Of the 23 studies included in this review, seven studies reported that ankle joint range of motion was measured in subtalar joint neutral position to minimise the effects of foot posture on ROM [1,3,6,13,29,31,39]. The remaining 16 studies however, did not report any standardisation of foot posture during ROM measurements and consequently, there is question as to the validity and consistency of measures obtained.

Although clinicians often prescribe interventions to increase ankle joint dorsiflexion in patients with clinically diagnosed ankle equinus (less than 10 or 15 degrees of ankle dorsiflexion), seven of the studies included in this review sampled study participants who had an initial ankle dorsiflexion ROM greater than 10 to 15 degrees [14,22,27,30,32,39,40]. In light of this, there is some question as to the generalizability of the findings presented in this review to patients with equinus deformity.

Further research needs to be undertaken in the future to investigate the functional, as well as the statistical significance of conservative interventions. Rees et al. [25] reported that the increases in musculotendinous stiffness and ankle joint range of motion associated with PNF stretching would be beneficial for athletes participating in sports such as sprinting, and cycling. Gadjosik et al. [5] and Christiansen et al. [12] both reported that stretching of the ankle plantarflexors may be associated with significant functional improvements in older populations. None of these studies however report the magnitude of increase in ankle dorsiflexion necessary to produce clinically significant improvements in function. Until further high quality research is published therefore, clinicians must continue to incorporate their own clinical expertise and knowledge of individual patient needs with research-based evidence when developing treatment plans.

**Conclusion**

There is some evidence to support the efficacy of stretching with or without the concurrent use of ultrasound, diathermy, diathermy and ice, heel raise exercises or warm up in increasing dorsiflexion range of motion at the ankle joint in healthy individuals. However, there is
insufficient evidence to suggest that soleal trigger point therapy, ankle joint mobilisation or
manipulation therapy are associated with statistically significant gains in ankle dorsiflexion
range of motion. Current evidence is limited by inconsistent assessment methods and
definitions of ankle equinus, as well as poor methodological rigor. Further research is
required to investigate which conservative interventions are most effective for managing
healthy individuals with ankle restricted ankle dorsiflexion range of motion.

Titles and abstracts screened for relevance to the question ‘does the article appear to discuss ankle equinus or non-surgical interventions to increase ankle dorsiflexion?’

2,821 excluded based on the following criteria
  - duplication with another retrieved study
  - no relation to equinus
  - discussion of equinus in relation to neurological conditions
  - combination of deformities featuring equinus
  - discussion of equinus in relation to particular disease states
  - investigation of equinus in patients with previous injury
  - surgical intervention

541 retrieved for detailed evaluation and review against inclusion and exclusion criteria
  356 abstract screening
  185 full text

520 excluded based on the following criteria
  - 145 neurological causes of equinus
  - 78 surgical interventions
  - 7 equinovarus deformity
  - 28 ankle injury
  - 25 diabetes and equinus
  - 33 other pathology
  - 204 irrelevant to research question

2 additional, relevant studies retrieved by hand searching and expert consultation

23 articles included for review
Figure 2 - Pooled effect size (SMD, 95% CI) for studies investigating stretching compared to control group. Positive effect sizes indicate greater increases in ankle joint dorsiflexion in the treatment group compared to the control group.
| Study ID  | Reference number | Study design                  | Sample                                                                 | Intervention                                                                 |
|----------|------------------|--------------------------------|------------------------------------------------------------------------|----------------------------------------------------------------------------|
| Bohannon (1994) | [31]              | Randomised control trial       | 36 female volunteers randomly assigned to experimental or control groups. | Control group: nil intervention. Intervention group: 5 minutes of weight bearing triceps surae stretching. |
| Christiansen (2008) | [12]             | Randomised control trial       | 40 participants were recruited for the study and randomly assigned to an intervention. Only 37 completed the study. | Control group: nil intervention. Intervention group: 8 week stretching program. Hip and ankle stretches were performed twice a day for 8 weeks. Each stretch was held for 45 seconds and repeated 3 times during each session. |
| Dananberg (2000) | [13]             | Non-randomised experimental trial. | 22 patients between the ages of 20 and 69 with gastrocnemius equinus. Recruited from the Bedford Podiatry Group. | Manipulation of the proximal fibular head and talus. |
| De Souza (2008) | [38]             | Non-randomised experimental trial. | 25 asymptomatic subjects between the ages of 18 and 35. | Maitland grades III and IV mobilisation of the right ankle. |
| Dinh (2010) | [1]              | Experimental trial.            | A convenience sample of 36 volunteers with less than 10 degrees of passive ankle dorsiflexion was recruited and 28 subjects completed the study. | Group 1: Non-weight bearing gastrocnemius stretching performed 5 times for 30 seconds each, twice a day for 21 days. Group 2: Weight bearing gastrocnemius stretching performed 5 times for 30 seconds each, twice a day for 21 days. |
| Draper (1998) | [14]             | Non-randomised experimental trial. | 40 healthy college students volunteered for participation. | Stretching alone: Static gastrocnemius and soleus stretches held for 20 seconds and repeated 4 times in total. Stretching and ultrasound: 3MHz, 1.5 W/cm² for 7 minutes applied to the musculotendinous junction of the right triceps surae. Immediately after ultrasound, subjects performed a gastrocnemius stretch for 20 seconds followed by a soleus stretch for 20 seconds. The stretching cycle was repeated three more times. |
| Etnyre (1986) | [15]             | Non-randomised experimental trial. | 12 males aged between 21 and 33 were randomly assigned to a treatment order group. | Static stretching group: Passive soleal stretch held for 9 seconds. Contract relax stretching group: passive lengthening of soleus, then isometric plantarflexion for 6 seconds, then a further 3 sec of passive soleal stretching. Contract-relax-agonist-contract stretching group: Same as contract-relax except that pt assisted post-contraction dorsiflexion. |
| Fryer (2002) | [16]             | Randomised control trial       | 41 healthy volunteers aged between 18 and 40. | Control group: nil intervention. Treatment group: a single manipulation of the talocrural joint administered by an osteopath. High velocity, low amplitude thrust technique was used. |
| Gajdosik (2005) | [5]              | Randomised control trial       | 19 older women with active ankle dorsiflexion range of motion <10 degrees were recruited from the community. | Control group: nil intervention. Stretching group: Gastrocnemius stretching performed with Kin-com system for 10 repetitions of 15 seconds stretching. Repeated three times/week for 8 weeks. |
| Gajdosik (2007) | [18]             | Randomised control trial       | 12 unconditioned women between 18 and 31 years volunteered for participation. | Control group: nil intervention. Stretching group: ten static wall stretches for gastrocnemius held for 15 seconds each and repeated 5 times each week for 6 weeks. |
| Grieve (2011) | [2]              | Randomised control trial       | 28 healthy physiotherapy and sports therapy students with unilateral restriction in active ankle dorsiflexion (<10 degrees) and at least one identifiable myofascial trigger point in the soleus muscle. | Control group: nil intervention. Intervention group: Trigger point release performed on myofascial trigger points within the soleus. Barrier release technique was used. |
| Johanson (2009) | [3]              | Randomised control trial       | 9 men and 7 women with less than 5 deg of passive ankle dorsiflexion with knee extended. | Experimental group: gastrocnemius stretches held for 30 seconds, repeated three times, twice each day for five weeks. Control group: nil intervention. |
| Study ID | Reference number | Study design | Sample | Intervention |
|----------|------------------|--------------|--------|--------------|
| Kasser (2009) | [19] | Randomised control trial. | 27 patients between 20 and 45 years with less than 20 degrees of active ankle dorsiflexion. | Control group: nil intervention. Stretching group: gastrocnemius stretching performed with the ProStretch device. Stretches were held for 30 seconds and repeated three times on 5 days of each week for 6 weeks. Strengthening group: tibialis anterior strengthening performed with a 10-lb ankle weight for three sets of 10 reps, 5 days each week for 6 weeks. |
| Knight (2001) | [21] | Randomised Control Trial. | 97 subjects from the local community volunteered for participation. | Group 1: control Group 2: Static stretching Group 3: Active heel raises prior to static stretching Group 4: Superficial moist heat prior to stretching Group 5: 7 minutes of continuous ultrasound prior to static stretching. Static stretching involved 4 sets of 20 second gastrocnemius stretches performed three times each week for 6 weeks. |
| Macklin (2012) | [6] | Non-randomised experimental trial. | 13 runners with less than 6 deg of ankle joint dorsiflexion with the knee extended, but no bony block. | 4 minutes of calf stretching twice each day for 8 weeks using a Flexeramp device. |
| McNair (1996) | [22] | Experimental trial. | 24 recreational athletes with no musculoskeletal problems. | Stretching group: 5, 30 second static soleal stretches. Aerobic exercise group: 10 min of treadmill running at 60% of maximum. Combined protocol: aerobic exercise followed by stretches. |
| Pratt (2003) | [32] | Randomised Control Trial | 24 healthy volunteers randomly assigned to experimental or control groups. | Control group: nil intervention Intervention group: 3 minutes of passive triceps surae stretching performed on three consecutive days with heels suspended from the edge of a platform. |
| Peres (2002) | [23] | Randomised Control Trial. | 44 healthy college students. | Control 1: nil intervention. Control 2: nil intervention. Treatment 1: Stretching. Treatment 2: diathermy and stretching. Treatment 3: diathermy, stretching and ice. |
| Rees (2007) | [25] | Randomised Control Trial. | 20 healthy, active women. | Proprioceptive neuromuscular facilitation stretching program. 3 sessions per week for 4 weeks of contract-relax agonist-contract PNF. |
| Samukawa (2011) | [27] | Non-randomised experimental trial. | 20 healthy male university students. | Dynamic plantarflexor muscle stretches. 5 repetitions of 30 seconds performed on right leg only. |
| Venturini (2007) | [39] | Experimental trial. | 35 healthy university students. | Maitland grade III anteroposterior joint mobilisation of the talus. |
| Youdas (2003) | [29] | Randomised control trial. | 101 volunteers. | Group 1: control Group 2: 1 repetition of a static stretch of the right calf MTU once per day for 30 seconds Group 3: 1 repetition of a static stretch of the right calf MTU once per day for 1 minute Group 4: 1 repetition of a static stretch of the right calf MTU once per day for 2 minutes. Stretches were repeated 5 days a week for 6 weeks. |
| Zakas (2006) | [30] | Non-randomised experimental trial. | 18 adolescent team soccer players. | Treatment control: active warm up (continuous jogging for 20 minutes) Treatment 1: active warm up followed by stretching adductors, hamstrings, quadriceps, soleus, hip flexors and spinal extensors for 15 sec each repeated 3 times. Treatment 2: Stretching alone |
