ABSTRACT
We present optical ccd images of the large supernova remnant (SNR) G132.71.3 (HB3) covering its full extent for the first time, in the emission lines of Hα, [N ii], [S ii] and [O iii], where new and known filamentary and diffuse structures are detected. These observations are supplemented by new low-resolution long-slit spectra and higher-resolution images in the same emission lines. Both the flux-calibrated images and spectra confirm that the optical emission originates from shock-heated gas since the [S ii]/Hα > 0.4. Our findings are also consistent with the recently developed emission line ratio diagnostics for distinguishing SNRs from H ii regions. A multi-wavelength comparison among our optical data and relevant observations in radio, X-rays, γ-rays and CO bands, provided additional evidence on the interaction of HB3 with the surrounding clouds and clarified the borders of the SNR and the adjacent cloud. We discuss the supernova (SN) properties and evolution that led to the current observables of HB3 and we show that the remnant has most likely passed at the pressure driven snowplow phase. The estimated SN energy was found to be (3.7 ± 1.5) × 10^51 erg and the current SNR age (5.1 ± 2.1) × 10^4 yrs. We present an alternative scenario according to which the SNR evolved in the wind bubble cavity excavated by the progenitor star and currently is interacting with its density walls. We show that the overall mixed morphology properties of HB3 can be explained if the SN resulted by a Wolf-Rayet progenitor star with mass ∼ 34 M☉.

Key words: ISM: general – ISM: supernova remnants – ISM: individual objects: G 132.71.3

1 INTRODUCTION
Supernova remnants (SNRs) are the aftermath of supernova (SN) explosions, that result from the interaction of the supersonically moving stellar ejecta with the ambient medium. The resultant nebula is an excellent celestial lab from which we can infer the mechanisms responsible for the explosive death of certain stars, the shock wave physics and the local ambient medium properties. In addition, SNRs are considered one of the most efficient cosmic-ray accelerators while they substantially contribute on the chemical and dynamical evolution of their host galaxies. For these reasons several targeted, multiwavelength observational campaigns have been conducted aiming to decipher the formation and evolution processes of these nebulae. While most SNRs have been detected in radio wavelengths (see Dubner & Giacani 2015; Green 2017), optical observation of SNRs allow us to inspect the SNR properties such as the filamentary morphology, the chemical abundances and thermo-dynamical properties of the shocked gas, the remnant’s expansion velocities and the density of the ambient medium (e.g. Boumis et al. 2008, 2009; Alikakos et al. 2012; Stupar & Parker 2012; Sabin et al. 2013; Stupar et al. 2018; How et al. 2018; Fesen et al. 2020, 2021).

The SNRs in our Galaxy can be very extended structures depending on their distance, their evolutionary stage, the characteristics of their parent stars and the properties of the ISM that encloses them (see e.g. Asvarov 2014). G132.71.3 (also known as HB3 radio

© 2022 The Authors
source) is among the largest Galactic SNRs observed so far with an angular size of 90° × 123° in 408 MHz radio maps (Caswell 1967) which implies a physical size of 52 × 72 d2 pc, where d2 is the distance of the remnant in units of 2 kpc. The distance of HB3 has been considered to be within the range of 1.6 – 2.4 kpc (Routledge et al. 1991; Fesen et al. 1995; Xu et al. 2006) and up to date it has been determined by the distance of the adjacent Hii region/molecular cloud complex W3.

HB3, was primarily detected in radio wavelengths by Brown & Hazard (1953) during a 158.5 MHz survey for radio sources in the Milky Way. Further radio observations (e.g. Williams et al. 1966; Caswell 1967) revealed the SNR nature of this radio source distinguishing it from the adjacent Hii region W3. In the radio band the remnant reveals a shell like morphology while its radio spectral index has been determined to be between – 0.64 and – 0.56 (Landecker et al. 1987; Fesen et al. 1995; Reich et al. 2003; Tian & Leahy 2005; Green 2007; Shi et al. 2008). One pulsar discovered close to the SNR’s boundaries seems not to be a part of it due to its large characteristic age (Lorimer et al. 1998) and six masers detected in the line-of-sight of HB3 is most probably associated with the adjacent W3 complex and not with the SNR (Koralesky et al. 1998).

Optical emission associated with HB3 was first found in the western portion of the remnant where a few filamentary structures were discovered (van den Bergh et al. 1973; D’Odorico & Sabbadin 1977). Low dispersion spectra of these filaments exposed the shock heated origin of this emission and revealed a filament’s density of ≤ 100 cm−3 and velocity of 35 – 40 km s−1 (D’Odorico & Sabbadin 1977; Lozinskaya & Sitnik 1980, respectively), Fesen & Gull (1983) and Fesen et al. (1995) presented new Hα images of HB3 covering the western two-thirds of the remnant. The optical morphology of the remnant was found to be strongly spatially correlated with the radio band. Optical follow-up spectroscopy on the western limb filaments was also performed by Fesen et al. (1995), indicating a shock velocity of ≤ 100 km s−1, an electron density of ≤ 150 cm−3 and an E(B−V) = 0.71 ± 0.04.

The large size of HB3 in conjunction with the strong radio to optical correlation and the multi-shell appearance of the remnant, indicate a SNR of advanced age that most likely has passed beyond the adiabatic phases of evolution. However, the remnant is characterised by a centrally peaked thermal X-ray emission (Venkatesan et al. 1984; Leahy et al. 1985; Rho & Petre 1998; Lazendic & Slane 2006). Such an evidence cannot be explained by the canonical theories for SNR evolution, as in mature SNR such as HB3, the reverse shock is expected to have been ceased long ago. Thus, the remnant’s interior is expected to be characterised by a cold and low density gas. For this reason, Rho & Petre (1998) classified HB3 as a mixed morphology (or thermal composite) SNR (MMSNR). X-ray spectroscopy revealed that the central emitting gas is close to ionization equilibrium characterised by a single temperature (Lazendic & Slane 2006). The element abundances of the X-ray emitting plasma are still ambiguous. Lazendic & Slane (2006) suggested that either it is characterised by enhanced abundances of O, Ne, Mg or it has marginally enhanced abundances of Mg and under-abundant Fe. Extended γ-ray emission is also discovered in the vicinity of the remnant (Tsypganov et al. 2016; Katagiri et al. 2016). This emission has been correlated to HB3 and it has been attributed to the decay of π0 produced by the interaction of hadrons accelerated at the remnant’s shock waves- with the surrounding interstellar gas (Katagiri et al. 2016).

Regarding the environment of the remnant, HB3 has been found to evolve within and a rather complex medium where its eastern part is adjacent to the Hii region / molecular complex W3 (e.g. Digel et al. 1996). Routledge et al. (1991) presented radio observations on the 21 cm Hii emission covering the whole region of the remnants and 12CO spectra in the southern portion of HB3. A shell shaped structure superimposed on HB3 was found indicating an atomic neutral gas acceleration by the SNR blast wave. In addition, a bright 12CO emission near ~ 43 km s−1 was detected overlapping with the radio emission of HB3 and they interpreted this evidence as a SNR interaction with molecular gas, in essence with W3. This evidence was verified by multimeter observations of CO lines, conducted by Zhou et al. (2016) which revealed a substantial amount of molecular gas around ~ 43 km s−1, being morphologically and dynamically correlated with HB3. Finally, shocked molecular hydrogen (H2) and broad CO was recently detected in the near/mid infrared and millimeter bands, respectively, whose morphological and kinematic properties provide an additional evidence on the interaction of the SNR with the surrounding clouds (Rho et al. 2021).

The origin and age of HB3 are still not well-determined. Lazendic & Slane (2006) assuming that the SNR is in the adiabatic phase and adopting an evaporating clouds model for MMSNRs, estimated the SN explosion energy to be 7 × 1050 erg and the age of the SNR between 25 – 30 kyrs. On the other hand, Zhou et al. (2016) considered that the remnant of HB3 has passed into the radiative phase and came to the conclusion that it is approximately 21 ± 2 kyrs old and the explosion energy E = (1.6 ± 0.9) × 1051 erg. Regarding the progenitor mass, Zhou et al. (2016) estimated a lower limit of 28 M⊙ by applying the linear relationship between the size of the wind-blown and the progenitor mass suggested by Chen et al. (2013).

In this paper, we explore the optical emission of the SNR G132.71.3 in its full extent. In particular, Hα,[N ii], [S ii] and [O iii] emission line images are presented, which show, for the first time, the complete structure of this large SNR in the optical band. Moreover, we present optical higher resolution imaging and long-slit spectroscopy at multiple areas of the SNR. HB3’s optical emission is also compared with the radio, X–ray, γ–ray and molecular emission. In Section 2, we describe our imaging and spectroscopic observations, with the results and multi-wavelength comparison presented in Section 3. We discuss the SNR’s properties, origin and evolution in Section 4, while in Section 5, we summarize the conclusions acquired from this work.

2 OBSERVATIONS

A brief summary and log of our observations are given in Table 1. In the following sections, we describe the observations of HB3 in more detail.

2.1 Imaging

2.1.1 Wide-field imaging

The wide-field imagery of HB3 was obtained with the 0.3 m Schmidt-Cassegrain (f/3.2) telescope at Skinakas Observatory, Crete, Greece in two different runs. The first was on the nights from 19th to 23th and 25th of August 2009, as well as, on the 29th

---

1 Only recently optical SNRs were found with a few degrees sizes at high Galactic latitudes; (Fesen et al. 2020, 2021)

^a Numbers in parentheses represent the number of individual frames.

^b Numbers in brackets represent the number of different fields in each filter.

^c The exposure time for all spectra is 3600 s.

^d Spatial offset from the slit center in arcsec: N (=North), S (=South).

^e Aperture lengths for each area in arcsec.

and 30th of August 2010. The camera used was a 2048 × 2048 Andor DW436 CCD, which has a pixel size of 13.5 µm that results in a 101′ × 101′ field of view and an image scale of 2′′.96 pixel⁻¹. In this run, the remnant was observed with the [N II], [S II] and [O II] filters with exposure times of 2400 s each and of 180 s for the continuum blue and red filters. Multiple exposures were taken in the first two filters, resulting to a total observing time of 16800 s for the [N II] and 12000 s for the [S II]. The second run was on the nights 7th, 8th, 11th and 17th of August and on the 5th and 15th of September 2018, as well as, on the 27th – 29th of July, 30th of September and 1st – 2nd October 2019. The camera was the same with the first run, resulting to the same FOV and scaling.
The filters used in this run were a new set of Hα[N ii] and [S ii], the same [O iii], all with sets of exposure times of 600 s and the continuum SDSS-r and V with exposure time of 20 s (see Table 1 for details). As in the first run, multiple exposures were taken for all filters, resulting to a total observing time of 13200 s for the Hα[N ii], 10200 s for the [S ii], 15000 s for the [O iii] and 400 s for the continuum filters. During all the observations, the “seeing” varied between 0″.8 and 1″.2.

For the data reduction the IRAF and Montage packages were used and all frames were bias-subtracted and flat-field corrected using a series of twilight flat-fields, and they were all airmass extinction corrected. For the absolute flux calibration the spectrophotometric standard stars HR 7596, HR 7950, HR 8634, HR 9087, and HR 0718 (Hamuy et al. 1992, 1994) were used. The Hubble Space Telescope (HST) Guide Star Catalogue (Lasker et al. 1999) was used for the calculation of the astrometric solution for all data frames and all the equatorial coordinates quoted in this work refer to epoch 2000. The Hα[N ii], [S ii] and [O iii] continuum subtracted mosaic images are shown in Fig. 1, while in Fig. 2, we present the flux-calibrated [S ii] image. In the latter image the blue lines indicate the positions of the slits, and the cyan and magenta rectangles indicate the position of the higher resolution images shown in Fig. 4. For a better comparison between the three emission line images presented in Fig. 1, we created a colour RGB image shown in Fig. 3. In this figure, it is clear that most of the Hα[N ii] filaments coincide with the [S ii] ones, while there is a number of [O iii] filaments which appear bright in this emission line and do not show any low ionization emission.

2.1.2 Higher-resolution imaging

Follow-up, higher resolution images where obtained with the 2.3m (f/8) Aristarchos telescope at Helmos Observatory in Peloponnese, Greece, on 18th and 19th of October 2017 and with the 1.3m
Figure 3. The continuum–subtracted RGB image of G132.71.3, combining the Hα[N ii] (red), [S ii] (green) and [O iii] (blue) emission line images. The yellow colour produced in regions where both Hα[N ii] and [S ii] exist.

(17.64) Ritchey-Chretien telescope at Skinakas Observatory on 13th to 15th of July 2021. These images cover the regions of interest (hereafter areas S1 to S6) where spectroscopic observations were performed (centered at slit positions 1-6). In particular, S1–S6 were observed with the Hα[N ii] and [S ii] filters with Aristarchos telescope (cyan rectangles in Fig. 2), while areas S1, S2, S5, S6 and S1, S2, S3 were observed with the [O iii] filter with the Aristarchos (cyan rectangles in Fig. 2) and Skinakas (magenta rectangles in Fig. 2) telescopes, respectively.

The detector at Aristarchos telescope was a 2048×2048, 13.5 μm pixels CCD, with a field of view of 5′.5×5′.5 (0″′.16 pixel−1 in 2×2 binning), while at Skinakas Observatory a 2048×2048, 13.5 μm pixels Andor CCD was used which has a 9′.5×9′.5 field of view and an image scale of 0″′.28 pixel−1. All information about the used Hα[N ii], [S ii] and [O iii] filters as well as the exposure times of all higher-resolution images are shown in Table 1. The data reduction was carried out using standard IRAF routine packages for the bias subtraction and flat-field correction, while the same catalogue of stars was used for the astrometric calculations. Seeing conditions were between 1″′ to 1″′.5.

The higher-resolution images are shown in Figs. 4, with two of them (S1 and S6) being also presented in RGB colour images (Fig. 5). Details of all imaging observations are given in Table 1.
Figure 4: Higher resolution images of G132.71.3 in Hα, [N II], [S II] and [O III] emission of the regions where slit positions 1-6 were taken (see Fig. 2). The North-East orientation is the same for Hα, [N II] and [S II] images and it can be seen on the top left image. The [O III] images have a larger FOV (Sect. 2.1.2), so the position of the Hα, [N II], [S II] images are indicated with a dash rectangle. The faint ring which appears to the north-east of all bright stars is a ghost due to the filter.

Figure 4: Continued.
Figure 5. Higher resolution RGB image of Areas S1 and S6, combining the Hα[N α](red), [S α](green) and [O III](blue) emission line images. The yellow colour produced in regions where both Hα[N α] and [S α] exist. North is to the top, East to the left.
2.2 Spectroscopy

Low-dispersion, long-slit spectra where obtained with the 1.3 m Ritchey-Cretien telescope (O/7.7), at Skinkas Observatory, on August 20, 22-23, 2009 and September 3, 5, 7-10, 2010. For these observations, the 1302 line mm$^{-1}$ grating was employed with the 2000 $\times$ 800 (13 $\mu$m) SITe CCD covering the wavelength range from 4750 to 6815Å, while the exposure time for each frame was 3600 s. The spectral resolution being $\sim$8 Å and $\sim$11 Å for the red and blue part of the spectra, respectively. The slit has a width of 7.7 arcsec and a length of 7.9 arcmin and it was oriented in the north-south direction for all the positions. The coordinates of each slit are given in Table 1. For the data reduction the IRAF package was used, while the spectrophotometric standards stars HR 0718, HR 7596, HR 7950, HR 8634, and HR 9087 were used for the flux calibration of the spectra (Hamuy et al. 1992, 1994).

3 RESULTS

3.1 The optical emission line images

The optical emission of HB3 is detected for the first time in its full extent. Both bright and faint, diffuse and filamentary structures spread along the entire remnant are revealed, while the H$\alpha$ region W3 is also found at the southeast region of the remnant. The [S$\alpha$] emission of HB3, though fainter, displays a similar morphology to that of the H$\alpha$[N$\alpha$] emission-line image, tracing all the filamentary structures. The [O$\alpha$] emission line, displays a different filamentary morphology compared to the former line images, indicating different shock velocities and physical conditions.

H$\alpha$[N$\alpha$], [S$\alpha$] and [O$\alpha$] fluxes are calculated from areas with 40×40 arcsec$^2$ dimensions over the brightest filaments where the low resolution spectra were taken (see Table 2). The errors of the integrated fluxes are estimated between 10 and 20 percent. All selected slit areas but one (area S7) and area A (where a known H$\alpha$ region exists) exhibit [S$\alpha$]/H$\alpha$ > 0.4, as expected for shock-heated regions.

The most interesting regions lie in the west, south-west and east directions, where bright filamentary and faint diffuse structures are present (Figs. 1, 4, between $\alpha \simeq 02^h18^m30^s$, $\delta \simeq 62^\circ15^\prime$, $\alpha \simeq 02^h24^m00^s$, $\delta \simeq 63^\circ30^\prime$, and $\alpha \simeq 02^h11^m10^s$, $\delta \simeq 62^\circ23^\prime$; $\alpha \simeq 02^h14^m30^s$, $\delta \simeq 63^\circ13^\prime$), which all are very well correlated with the radio emission. The bright H$\alpha$[N$\alpha$] filaments cover most of the emission found at radio wavelengths. In contrast to the above results, diffuse emission was mainly detected in the south, centre and north with only a few small filamentary structures are present (i.e. those at $\alpha \simeq 02^h18^m40^s$, $\delta \simeq 63^\circ09^\prime0^\prime$ and $\alpha \simeq 02^h19^m15^s$, $\delta \simeq 63^\circ09^\prime20^\prime$; $\sim$2′ long). We also detected [S$\alpha$] emission where most of the H$\alpha$[N$\alpha$] emission was found with filamentary bright structures and diffuse emission in the same regions (Figs. 1, 2, 4). Both the H$\alpha$[N$\alpha$] and [S$\alpha$] higher–resolution images (Fig. 4 show clearly filamentary and diffuse emission in all slit positions 1–6, which have similar structures. Furthermore, very thin (less than 2–3′′ wide), as well as wider (~10′) filaments are present, while the shock front region can be clearly seen (i.e. in S1 and S4 areas). Note that the detected [O$\alpha$] emission (Figs. 1, 4) appears more filamentary and less diffuse than in the H$\alpha$[N$\alpha$] and [S$\alpha$] images. In Table 2 upper limit fluxes are listed for the [O$\alpha$] and [S$\alpha$] images. Significant differences between the H$\alpha$[N$\alpha$] and [O$\alpha$] images are present for many of the filaments. In particular, most of the bright H$\alpha$[N$\alpha$] and [S$\alpha$] complex filamentary structures to the east, south-east are not present to the [O$\alpha$] image, while there are other bright filaments only to the [O$\alpha$] emission. However, some thin filaments (of the order of 8-10′ long), coincide with the H$\alpha$[N$\alpha$] and [S$\alpha$] emission (see Fig. 1). These are at slit positions 5 and 6 and to the north at $\alpha \simeq 02^h22^m55^s$, $\delta \simeq 03^\circ25^\prime25^\prime$ and $\alpha \simeq 02^h22^m20^s$, $\delta \simeq 63^\circ30^\prime00^\prime$. Further to the east, there is a number of bright [O$\alpha$] filaments which are co-spatial with the H$\alpha$[N$\alpha$] structures, but still it is clear that the bright [O$\alpha$] filaments do not coincide with those in the H$\alpha$[N$\alpha$] and [S$\alpha$] emission. Interestingly, there are many thin [O$\alpha$] filamentary structures to the central region of HB3 (i.e. at $\alpha \simeq 02^h20^m16^s$, $\delta \simeq 62^\circ59^\prime00^\prime$, $\alpha \simeq 02^h19^m30^s$, $\delta \simeq 62^\circ53^\prime00^\prime$ and $\alpha \simeq 02^h14^m55^s$, $\delta \simeq 62^\circ49^\prime30^\prime$), which do not show any emission in H$\alpha$[N$\alpha$] and [S$\alpha$]. Taking into account all the emission line images presented in Fig. 1, and the RGB image presented in Fig. 3, it seems that HB3 traces an axi-symmetric bi-lobe structure with respect to its centre. This is an interesting approach and should be investigated further in the future when kinematical data will be available. In Fig. 5, we present an RGB image of slit positions 1 and 6 regions, where the H$\alpha$[N$\alpha$] (red), [S$\alpha$] (green) and [O$\alpha$] (blue)–higher–resolution images are combined. In the S1 image, the H$\alpha$[N$\alpha$] emission of the small thin filaments (i.e. at $\alpha \simeq 02^h11^m15^s$, $\delta \simeq 62^\circ43^\prime00^\prime$) in front of the large ones (i.e. at $\alpha \simeq 02^h11^m30^s$, $\delta \simeq 62^\circ44^\prime00^\prime$) coincide with that of the [O$\alpha$] and lie immediately ahead of the diffuse [O$\alpha$] emission (similar to SNR G 107.09.0; Fesen et al. 2020). Unfortunately, there is no [O$\alpha$] emission where the bright H$\alpha$[N$\alpha$] filaments are, so we cannot have a complete and clear view of the whole region.

3.2 The optical spectra

Deep low-resolution long-slit spectra were obtained for the brightest filaments of the remnant. The exact position of the silts is illustrated in Fig. 2 and the coordinates of their centres are listed in Table 1. The relative line fluxes as well as the signal-to-noise ratios for multiple apertures free of background stars are computed and listed in Table 3. The absolute H$\alpha$ fluxes are also determined for all the apertures and vary from 5 to 192 $\times$ 10$^{-17}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$. The lengths of these apertures and their offsets from the centre of the silts are also given in Table 1. For the extraction of the background emission, the areas were chosen north or south of the centre of the silts as being free of field stars and depending on the location of the filaments. Fig. 6 presents as representative examples the 1D spectra of six apertures. Our slit 1 covers the western filament, which has also been studied by D’Odorico & Sabbadin (1977) and Fesen et al. (1995), and it shows a good agreement despite the different position and orientation. In particular, we determine an [S$\alpha$]/H$\alpha$ ratio equals to 0.8 and 0.56 for the apertures 1a and 1b, respectively, very close to the values of 0.72 reported by Fesen et al. (1995) and 0.62 from D’Odorico & Sabbadin (1977). The [S$\alpha$] $\lambda$ 6716/6731 line ratio is calculated 1.32±0.06 and 1.39±0.05, close to the value of 1.5±0.2 found by Fesen et al. (1995), and even closer to the value of 1.44±0.01 from D’Odorico & Sabbadin (1977). A consistency between the studies is also found in the interstellar reddening (0.7±0.04; Fesen et al. 1995 and a median of 0.76 in this study). The [O$\lambda$] $\lambda$6300 line, a diagnostic for shock heated gas in SNRs (Kopsachelli et al. 2020), is also detected in our spectrum of slit 1. However, it has to be noted that the [Ni] $\lambda$5200 line which is reported by Fesen et al. (1995) is not detected in our spectrum, while the [O$\lambda$] $\lambda$5007/H$\beta$ ratio is three times higher in our data. Fig. 5 displays the RGB images of the western (area S1) and eastern (area S6) filaments. At the former (S1), there are interestingly two main filaments bright in H$\alpha$[N$\alpha$] and [O$\alpha$] $\lambda$5007 with an offset of a few arcsec. The second displays
Figure 6. Long-slit low resolution spectra from different positions of the observed area (see Table 1). The small shift in the wavelength axis is due to the different observing season (slightly different position of the grating).
some filaments in Hα[N ii] emission. This explains the difference in the [O iii] λ5007/Hβ ratio between our result and the one from Fesen et al. (1995) as their slit do not cover the [O iii] dominated filament resulting in lower [O iii] λ5007/Hβ ratio.

The common criterion for shock heated gas in SNRs, the [S ii]/Hα line ratio, is higher than 0.4 for all the filaments observed, while the [N ii]/Hα ratio varies from 0.5 to 1 (see Table 3). Both ratios verify the SNR nature of HB3 (see also Fesen & Gull 1983; Fesen et al. 1995). All the filaments are distributed in the locus of typical shock-heated SNRs well separated from the photo-ionized nebulae.

Note that all slits/apertures but two (2a and 2b) exhibit a weak or even not detectable [O iii] 5007Å line. The log([O iii]/Hβ) ratio is lower than 0.5 which indicates shocks with complete recombination lines (Cox & Raymond 1985; Hartigan et al. 1987) and velocities between 80-100 km s$^{-1}$ (Raymond et al. 1988; Osterbrock & Ferland 2006). The absence of the [O iii] 5007Å emission line in some filaments implies the presence of shock with even lower velocities ($<$80 km s$^{-1}$), and this result is consistent with the observed

---

Figure 7. The correlation between Hα[N ii] image and (a) the radio emission at 4850 MHz (blue line) and 330 MHz (red line). The blue contours scale linearly from $5 \times 10^{-3}$ Jy/beam to 0.03 Jy/beam, with step 0.05 Jy/beam. The red contours scale linearly from $7 \times 10^{-3}$ Jy/beam to 4.5 \times 10^{-2} Jy/beam, with step 0.05 Jy/beam. (b) the X-ray emission of ROSAT PSPC (yellow line, Lazendic & Slane 2006). The yellow contours scale linearly from $1 \times 10^{-5}$ counts arcmin$^{-2}$ s$^{-1}$ to $3 \times 10^{-4}$ counts arcmin$^{-2}$ s$^{-1}$, with step $2.8 \times 10^{-5}$ counts arcmin$^{-2}$ s$^{-1}$. (c) the molecular emission of $^{12}$CO ($J = 1 \rightarrow 0$), $^{13}$CO ($J = 1 \rightarrow 0$) and C$^{18}$O ($J = 1 \rightarrow 0$) in the velocity range of $-60$ to $-30$ km s$^{-1}$ (cyan line, Zhou et al. 2016). The cyan contours scale linearly from 0 to 13.5 K with step 5 K. (d) the γ-ray emission of background-subtracted FERMI LAT in the $1 \rightarrow 10$ GeV (blue line, Katagiri et al. 2016). The blue contours scale linearly from 0 to 22 counts pixel$^{-1}$ with step 5 counts pixel$^{-1}$.

---

MNRAS 000, 1–20 (2022)
are expected to be found.

Regarding the properties and evolution of HB3 as extracted by Lazendic & Slane (2006), we are not able to compute the electron temperature of the filaments without strong [O\alpha] diagnostic lines and the temden STS-DAS/IRAF routine. Due to the absence of the typical [O\alpha] λ4363 and [N\alpha] λ5755 diagnostic lines (based on Osterbrock & Ferland 2006), we are not able to compute the electron temperature of the gas and a value of 10^4 K is considered for all the filaments.

Finally, for all filaments where the H\beta line is detected, the interstellar extinction coefficient c(H\beta) is computed and varies from 0.62 (± 0.22) up to 1.14 (± 0.36) with a mean value of 0.9 or an A_V from 1.31 (± 0.48) to 2.32 (± 0.76), as presented in Table 3.

### 3.3 Comparison with other wavelengths

G132.7+01.3 has been studied in \gamma-rays, X-rays, radio, infrared and mm wavelengths (e.g. Routledge et al. 1991; Fesen et al. 1995; Lazendic & Slane 2006; Zhou et al. 2016; Rho et al. 2021, see also Introduction). Here we present the main results and conclusions regarding the properties and evolution of HB3 as extracted by the comparison of its emission properties in different electromagnetic bands. In Fig. 7 the contours of the emission that the remnant reveals in the radio, X-rays, CO lines and \gamma-rays are superposed on the H\alpha image of HB3 from our observations.

The optical morphology of the remnant displays a strong correlation with its radio emission at both large and small spatial scales, signifying that they have the same origin (Fig. 7a). In particular, the outer bright H\alpha filaments at the western portion of the remnant follow both the geometry and brightness of the radio emission that declines gradually, moving from the west to the northwest region of HB3. This advocates that the remnant encounters a denser ambient medium in the west part than in the northwest. Intriguingly, both in radio and optical the remnant reveals two antisymmetric local protrusions in west and east giving the morphological impression of two lobes in the overall shape of the remnant. In the southern portion of HB3 even though the optical and radio display a similar morphology, the two bands are not in good correlation. In particular, the optical emission in the south of HB3 displays a relatively faint and diffuse emission, while the radio emission in this portion is equally bright as compared to the west region of HB3. This could be attributed either to dust absorption affecting the optical photons and/or to a high local blast wave velocity that enhances the non-thermal synchrotron emission at this region. Finally, the eastern region of HB3 the radio emission of the remnant roughly follows the bright filament in H\alpha marking the border between the SNR and the ambient HII/MC complex.

Regarding the inner, thermal X-ray emission of the remnant (Fig. 7b) - a property that classifies HB3 as a MMSNR (Rho & Petre 1998; Lazendic & Slane 2006) - it is lying close to the center of the optical image of HB3 being centralized at about (\alpha, \delta) = (2^h 18^m 30^s, 62\degr 40.7'). The remnant’s X-ray brightness declines moving from the center to the outer portions of HB3, following initially a roughly spherical distribution but at the same time it displays two large anti-asymmetric wings towards the northeast and south that cover the whole optical image of the remnant in these regions. The overall X-ray morphology of HB3 is shifted towards the eastern region of the remnant where it intersects with the HII/MC complex, something that advocates that the mixed morphology properties of HB3 are related to the interaction of the remnant with the surrounding cloud. Such a hypothesis is aligned to evaporo-clouds models (White & Long 1991) and the reflected shock model (Chen et al. 2008) for the formation of MMSNRs as both demand the interaction of the SNR with a surrounding dense cloud (see also Sect. 4.3).

The molecular gas in the vicinity of HB3 as detected by millimeter observations of CO lines (Zhou et al. 2016), coincides with the bright H\alpha and [S\alpha] region of the SNR, lying about (\alpha, \delta) = (2^h 18^m 30^s, 62\degr 20.7'). Given that the optical emissivity of the shocked gas goes as \rho^{\beta} where \rho is its mass density, it is inferred that in this region the SNR blast wave is propagating in a dense environment. This result offers an additional evidence towards the conclusion that HB3 is currently interacting with the W3 H\alpha region/MC complex (see also Zhou et al. 2016; Routledge et al. 1991, for an additional argumentation).

Finally, the \gamma-ray emission discovered in the vicinity of HB3 (Tsygankov et al. 2016; Katagiri et al. 2016, see also Fig. 7d) is spatially correlated with the bright \(^{12}\)CO (J = 1-0) emission and it is adjacent to the southeast region of the remnant. Such a result favors for a hadronic origin of the \gamma-rays photons resulted by interactions between particles accelerated in the SNR and the molecular cloud.

All above evidence advocate that HB3 is indeed expanding in the vicinity of the W3 H\alpha region/MC complex and currently is interacting with it at its eastern portion. This interaction seems to substantially affect the morphology of the remnant as well as its emission properties all over the electromagnetic spectrum. The

a Observed fluxes normalized to F(Hα)=100 and uncorrected for interstellar extinction.

b Observed fluxes normalized to F(Hα)=100 and corrected for interstellar extinction.

c Numbers represent the signal to noise ratio of the quoted fluxes.

d In units of 10^{-17} erg s^{-1} cm^{-2} arcsec^{-2}.

e The logarithmic extinction is derived by c = 1.0348 \times \log((Hα/Hβ)_{obs}/2.85).

f The interstellar reddening was measured from the relation E_{B-V} \approx 0.77c (Osterbrock & Ferland 2006)

4 DISCUSSION

4.1 Properties of the optical filaments

Having an angular diameter of \(\sim 90' \times 120'\), HB3 is among the largest Galactic SNRs known. Furthermore, assuming a distance of \(\sim 2\) kpc, this means a linear diameter of \(52 \times 72\) pc, indicative of an evolved SNR being in the later Sedov–Taylor or in the radiative phase. The composite Hα/[N ii] image provides the best description of the morphology of G132.7+01.3 in its full extent making possible the identification of all of its detailed structures. Emission from the [S ii] \(\lambda \lambda 6716,6731\) doublet lines and the [O iii] \(\lambda 5007\) line has also been detected matching in shape and position the Hα/[N ii] emission, though being more diffuse and less filamentary. Furthermore, the prominent [O iii] emission indicates the existence of fast shocks travelling through the ionized gas all around the remnant. (Cox & Raymond 1985).

The [S ii]/Hα emission line ratio measured from the optical

ders between the SNR and the surrounding cloud are well justified by the radio observations and the bright Hα/[N ii] filaments at the eastern region of the remnant.
images of the Area A (Table 2) does not exceed the threshold (0.4) of supernova remnants. We thus argue that this particular area does not belong to G132.7+01.3, but it is associated with the Hα region. Note that the area A is also the brightest in the Hα emission line (see Table 2). All other areas display [S\text{II}]/Hα > 0.4, except area S7 for which a ratio of 0.35 is determined. Note that the width of the Hα+[N\text{II}] filter used for the computation of Hα emission is large enough to transmit the [N\text{II}] 6584 Å line. This extra emission is likely responsible for the lower [S\text{II}]/Hα ratio measured for the area S7.

Regarding our spectroscopic observations of eight filaments distributed over the entire remnant, the [S\text{II}]/Hα ratios are clearly higher than 0.4. The distribution of our spectra in the Hα+[S\text{II}] – Hα+[N\text{II}] space is consistent with the locus of shock-heated gas in SNRs and well separated from the UV-dominated PNe and H\text{ii} regions (e.g. Sabbadini et al. 1977; Meaburn et al. 2010; Leonidaki et al. 2013; Sabin et al. 2013; Akars et al. 2020). The strong [O\text{I}] λ6300 Å emission in most of the filaments provides an extra confirmation of their shock-heated origin.

In Fig. ??, we present the newly developed diagnostic diagrams between shock-heated and UV photon-ionized regions for different combinations of emission line ratios (Kopcsacheli et al. 2020). Our observed [S\text{II}]/Hα, [N\text{II}]/Hα and [O\text{I}]/Hα ratios from all eight filaments and different apertures satisfy the criteria and lie within the regime of expected shock-heated regions.

However, a small discrepancy is observed when the [O\text{I}]/H\beta criterion is used for slits 1 and 5. The measured intensities of the emission line(s) of these slits are highly uncertain, with signal-to-

\text{d} In units of 10^{-17} \text{erg s}^{-1} \text{cm}^{-2} \text{arcsec}^{-2}.
\text{e} The logarithmic extinction is derived by \text{e} = 1.0348 \times \log((\text{H}\alpha/\beta)_{\text{obs}}/2.85).
\text{f} The interstellar reddening was measured from the relation E_{B–V} \approx 0.77c (Osterbrock & Ferland 2006)
noise values of 2-4 (see Table 3). This is a possible interpretation why regions corresponding to Slit 1 and 5 fall outside the expected locus of shock-heated regions in the [O\textsc{iii}]/H\textbeta diagnostic diagrams. This can also be seen from the [O\textsc{iii}]/5007Å emission which is very weak or even absent at the position of the slits 1 and 5 (see RGB Figure 3 of HB3). A possible contribution in the H\textbeta weak or even absent at the position of the slits 1 and 5 (see RGB Figure 3 of HB3). A possible contribution in the H\textbeta emission from the nearby H\textalpha region W3 in slit 5, that would result in lower [O\textsc{iii}]/H\textbeta ratio, cannot be ruled out. We point out however that the new diagnostics do not account for shocks with velocities lower than 100 km s\(^{-1}\) (only models with shock velocities between 100 and 1000 km s\(^{-1}\) are considered, Kopsacheili et al. 2020). Furthermore, we note that all the diagnostics are characterized by incompleteness, which is higher in the case of [N\textsc{ii}]/H\alpha–[O\textsc{iii}]/H\textbeta (for more details see, Kopsacheili et al. 2020).

4.2 Origin and evolution of HB3

Adopted from the optical image extent of HB3 (~ 90\arcmin \times 120\arcmin) and a distance of \( d = 2 \) kpc, the average radius of the remnant is \( R_s = 31 \) pc. Assuming further that the remnant is still in the Sedov phase and the magnetic field pressure is negligible, the values of the preshocked ambient density (\( n_o \)) and the current shock’s velocity \( (V_s) \) can be constrained by using the relation (Dopita 1979):

\[
n_{\text{SHI}} \approx 45 \left( \frac{n_o}{\text{cm}^{-3}} \right) \left( \frac{V_s}{100 \text{ km s}^{-1}} \right)^2 \text{ cm}^{-3}, \tag{1}
\]

where \( n_{\text{SHI}} = 160 \pm 80 \text{ cm}^{-3} \), extracted from the [S\textsc{ii}] diagnostic lines. From Eq. (1), we get: \[
\left( \frac{n_o}{\text{cm}^{-3}} \right) \left( \frac{V_s}{100 \text{ km s}^{-1}} \right)^2 = 3.6 \pm 1.8. \]

Such a result is in agreement with the independent estimations of HB3 shock velocity and pre-shock density by Lazendic & Slane (2006) who found \( \left( \frac{n_o}{\text{cm}^{-3}} \right) \left( \frac{V_s}{100 \text{ km s}^{-1}} \right)^2 = 0.32 \pm 0.45 \). Additional constraints on the ambient medium density -and thus on the current shock velocity- we get by estimating the HB3 column density. Using the relation of Ryter et al. (1975), we obtain an \( N_H \) of \( 3.3 \pm 1.5 \times 10^{21} \text{ cm}^{-2} \) and \( 6.0 \pm 1.7 \times 10^{21} \text{ cm}^{-2} \) for the minimum and maximum (H\textbeta) values as calculated from our spectra, respectively. The extracted column density range is consistent to the estimated values of \( N_H \sim 6.2 \times 10^{21} \text{ cm}^{-2} \) (Dickey & Lockman 1990) and \( N_H \sim 7.7 \times 10^{21} \text{ cm}^{-2} \) (Kalberla et al. 2005) in the direction of HB3, and the one extracted by Fesen et al. (1995) using their optical spectra in HB3 western rim, who found \( N_H \sim 5.7 \times 10^{21} \text{ cm}^{-2} \). The corresponding pre-shocked ambient medium number density range is \( 0.5 - 1.0 \times 10^{-21} \text{ cm}^{-3} \) having a mean value of \( n_o = (0.82 \pm 0.15) \times 10^{-21} \text{ cm}^{-3} \), where \( d_2 \) the

Figure 8. 2D diagnostic curves of Kopsacheili et al. (2020) together with the results extracted by our spectroscopic data (blue points). The blue region is the locus that indicates shock excited gas emission.
distance of HB3 in units of 2 kpc. Using Eq. (1) we extract a mean shock wave velocity of \( V_s = (208 \pm 54) \times 10^3 \text{km s}^{-1}. \) Employing the aforementioned results extracted by our optical observations on the Sedov solution, we find an explosion energy for HB3 equal to \( E \sim 2.1 \times 10^{46} \left( \frac{n_o}{10^3 \text{ cm}^{-3}} \right)^3 \left( \frac{V_o}{100 \text{ km s}^{-1}} \right)^2 \left( \frac{d_2}{10 \text{ kpc}} \right)^2 = (2.3 \pm 1.1) \times 10^{51} \text{erg} \) (Ostriker & McKee 1988) while the SNR age is estimated to be \( t \sim (5.8 \pm 1.5) \times 10^4 \text{ d}_2^{1.5} \) yrs.

The large size of the remnant and its bright optical line emission indicate that HB3 has evolved beyond the SN adiabatic phases and currently is in the Pressure Driven Snowplow (PDS) phase. In order to assess the correctness of this assumption, we estimate the transition radii from the Sedov to the PDS phase extracted by Cioffi et al. (1988):

\[
R_{\text{PDS}} = 14.0 \left( \frac{E}{10^{51} \text{ erg}} \right) \left( \frac{n_o}{10^3 \text{ cm}^{-3}} \right)^{-\frac{2}{7}} \left( \frac{V_o}{100 \text{ km s}^{-1}} \right)^{\frac{2}{7}} \text{ pc},
\]

where \( E \) is the SN energy and \( \zeta_m \) a constant equal to unity for solar metallicity. In the PDS phase the SN energy is found to be \( E = 6.8 \times 10^{43} \left( \frac{n_o}{10^3 \text{ cm}^{-3}} \right)^{1.16} \left( \frac{V_o}{100 \text{ km s}^{-1}} \right)^{1.35} \left( \frac{R_o}{10 \text{ pc}} \right)^{3.16} \zeta_m = (3.7 \pm 1.5) \times 10^{51} \text{d}_2^{1.7} \text{ erg} \) (Cioffi et al. 1988) for which the corresponding transition radius is \( R_{\text{PDS}} = (22.2 \pm 3.1) \text{ d}_2^{1.2} \) pc. The transition radius is slightly smaller that the current radius of HB3 (\( R_s \sim 31 \text{ d}_2 \)) something that indicates that the remnant has evolved into the PDS phase or is currently in the transition phase between the Sedov and PDS stages. Intriguingly, this finding is commonly met in the class of MMSNRs (Shelton et al. 1999). The corresponding time in which HB3 started to enter into the PDS phase is \( t_{\text{PDS}} = 1.33 \times 10^4 \left( \frac{E}{10^{51} \text{ erg}} \right)^{\frac{1}{7}} \left( \frac{n_o}{10^3 \text{ cm}^{-3}} \right)^{-\frac{4}{7}} \left( \frac{V_o}{100 \text{ km s}^{-1}} \right)^{\frac{4}{7}} \left( \frac{R_o}{10 \text{ pc}} \right)^{\frac{10}{7}} \left( \frac{10}{3} \right) = (2.0 \pm 0.3) \times 10^4 \text{ d}_2^{1.5} \) yrs, while the current age of the remnant was found to be \( t = 3 \times t_{\text{PDS}} = (5.1 \pm 2.1) \times 10^4 \) yrs. These timescales indicate that HB3 has spent at least the 30% of its lifetime in the PDS phase.

4.3 On the mixed morphology of HB3

The previous approach provides a first order approximation on the current evolutionary properties of the remnant as well as on its parent SN explosion. Nevertheless, it neglects the following two major facts: a) the ambient medium properties around HB3 deviate substantially from the homogeneity revealing large spatial gradients. In particular, our optical study confirmed that HB3 interacts in its eastern region with a dense H\( \alpha \)/MC complex something that affects its morphology, kinematics and emission properties. Thus, the evolution of the remnant cannot be accurately approached by one-dimensional, spherically symmetric models; b) HB3 has been classified as a mixed morphology SNR being characterized by the coexistence of an optical/radio bright shell with a centrally peaked thermal X-ray emission. These SNR properties cannot be explained by the canonical SNR evolution models and therefore, additional ‘ingredients’ on its evolutionary history are required.

Lazendic & Slane (2006) provided an explanation on the mixed morphology properties of HB3 by invoking the so-called ‘evaporating clouds model’ (e.g. White & Long 1991; Slavin et al. 2017; Zhang et al. 2019) and adopting a \( q \) ratio of 3-5, where \( C \) is the mass ratio between the clouds and the intercloud medium and \( \tau \) is the ratio of the cloud evaporation timescale to the current SNR age.

Here we discuss an alternative evolutionary scenario of HB3 that potentially could led on its mixed morphology properties based on the ‘reflected shock model’. According to this model MMSNRs are formed by the action of a reflected shock, triggered by the collision of the SNR with the density walls of a pre-existing circumstellar cavity scultped by the mass outflows of the progenitor star (Dwarkadas 2005; Chen et al. 2008; Zhang et al. 2015).

If this was the case of HB3, the size of the formed wind-blown cavity should be comparable to the current size of the remnant. This fact provides us an estimation of the progenitor mass by employing the linear relation of Chen et al. (2013):

\[
R_b \sim (1.22 \pm 0.05) \times \left( \frac{M_{\text{ms}}}{M_\odot} \right) - (9.16 \pm 1.77) \text{ pc},
\]

where \( R_b \) the radius of the wind blown cavity and \( M_{\text{ms}} \) the stellar main sequence mass. Considering that the current radius of HB3 is \( R_s \sim 31 \text{ d}_2 \) pc we estimate that the remnant resulted by a progenitor star with a main sequence mass of about \( M_{\text{ms}} = 33.9 \pm 2.0 M_\odot \). According to the stellar evolution theory this star most likely passed through the Wolf-Rayet phase before its final explosion. If true, then HB3 resulted by a Type Ib/c SN (Smith 2014, and references therein).

According to this scenario, the remnant initially evolved into the wind blown cavity of a size \( R_b \sim 31 \text{ pc} \), shaped by the progenitor star. Describing the SN ejecta density profile with a power law of \( \rho_e \propto r^{-n} \), with \( n = 7 \) (appropriate for Type I SNe; Chevalier 1981), and assuming energy conservation, the evolution of the SNR within the wind cavity till its collision with the density walls of the circumstellar structure can be approached by employing the self-similar solution of Chevalier (1982). The radius \( (R_s) \) and velocity \( (V_s) \) of a SNR expanding in an wind blown cavity with a density profile \( \rho_{AM} = q r^{-n} \), where \( s=2 \) and \( q = \frac{M_{\text{ms}}}{2 \pi n s \rho_{AM}} \) are given by:

\[
R_s = 1.3 \times \left( \frac{A q^n}{q} \right)^{\frac{1}{n-1}} t^{\frac{n-3}{n-1}},
\]

\[
V_s = 1.3 \times \left( \frac{n-3}{n-8} \right) \left( \frac{A q^n}{q} \right)^{\frac{1}{n-1}} t^{\frac{n-3}{n-1}},
\]

where for \( n=7 \) we have \( A = 0.27 \) and \( q = \left[ \frac{25}{24} \left( \frac{r_e}{2 \pi C} \right) \right]^{-\frac{1}{1}} \) and \( t \) is the age of the remnant. By assuming the canonical energy for the SN explosion of \( E_{ej} = 10^{51} \text{ erg} \), an ejecta mass of \( M_{ej} = 9 M_\odot \) (as expected to be the final mass of a 34 \( M_\odot \) progenitor e.g. Meyer et al. 2021) and adopting typical WR wind properties \( \frac{M}{10^{-5} M_\odot \text{ yr}^{-1}} \times \left( \frac{n_s}{10^2 \text{ km s}^{-1}} \right)^{-1} = 1 \) we find that the remnant reached with the density walls of the wind blown cavity after \( t \approx 4500 \text{ yrs} \) of evolution having an incident shock velocity of \( V_s \approx 5400 \text{ km s}^{-1} \).

At the moment of the collision between the SNR and the density wall a pair of shocks is formed: the transmitted shock that starts to penetrate the density wall and the reflected shock that moves inwards and shocks the SN ejecta. Due to the high wall-to-cavity density contrast the transmitted shock is expected to decelerate substantially (Dwarkadas 2005, 2007; Chiotellis et al. 2012, 2013). In particular, the transmitted shock velocity \( (\delta \tau) \) right after the collision of the SNR with the cavity walls as a function of the incident shock velocity \( (V_s) \) is given by (Sgro 1975):

\[
V_{\delta \tau} = \left( \frac{\beta}{\Lambda} \right)^{\frac{1}{2}} V_s.
\]
where \( A \) is the wall to cavity density contrast and \( \beta \) the pressure ratio of the post-transmitted-shock gas to the post-incident-shock gas. The ratio \( \beta \) is related to the density contrast between the post-reflected-shock gas and post-incident shock gas \( (A_r) \) as:

\[
\beta = \frac{4A_r - 1}{4 - A_r},
\]  

and \( A_r \) in turn is related to \( A \) as:

\[
A = \frac{3A_r (4A_r - 1)}{\left(3A_r (4 - A_r)\right)^{\frac{1}{2}} - \sqrt{7} (A_r - 1)^{\frac{1}{2}}}. 
\]

For the adopted wind parameters the number density at the outer region of the wind cavity will be in the order of \( n_{\text{cav.}} \sim 10^{-3} \text{ cm}^{-3} \). The cavity wall density cannot be described by a single value as it is strongly related to the ambient medium density, that as discussed above deviates substantially from homogeneity. Adopting an ambient medium of \( n_s = 0.5 - 1 \text{ cm}^{-3} \), as extracted by the column density estimations, for the western and eastern regions of the remnant, and a \( n_{\text{cloud}} \sim 10^{-1} - 10^2 \text{ cm}^{-3} \) for the eastern cloud and considering that the ambient medium has been compressed by at least a factor of 4, we get \( A \sim 10^3 - 10^4 \) and \( A_r \sim 10^4 - 10^5 \) for the western and eastern regions of the remnant, respectively. Importing these values to Eq. (5) - (8) we get a transmitted shock velocity at west of \( V_r \approx 130 - 400 \text{ km s}^{-1} \) (consistent with the estimations of Lazendic & Slane 2006) while to the eastern region a much slower one in the order of \( V_r \approx 40 - 130 \text{ km s}^{-1} \).

Regarding the reflected shock, its initial velocity is given:

\[
V_r = \frac{1}{4} \left[ 3 - \frac{15A_r}{4 - A_r} \right]^\frac{1}{2} V_s, 
\]

from which we get \( V_r \approx 2300 - 2500 \text{ km s}^{-1} \) at the east and \( V_r \approx 2500 - 2000 \text{ km s}^{-1} \) at the west of HB3. A shock wave with such a high velocity will compress and heat the gas to temperatures that becomes X-ray bright.

Such a scenario seems consistent with the observed properties of HB3, since in principle can explain the low expansion velocities of HB3 forward shock and at the same time its central X-ray emission. As the remnant evolved further the transmitted shock penetrated more the density wall and it got further decelerated up to its current expansion velocities. Simultaneously, the reflected shock reached the center of the remnant producing the overall centrally X-ray peak morphology of HB3. In order to verify whether such a scenario could indeed reproduce the current properties of HB3 detailed hydrodynamic modeling is required.

5 CONCLUSIONS

(i) HB3 (G 132.71.3), which is among the largest supernova remnants, was studied in optical wavelengths in its full extent for the first time. Filamentary and diffuse structures are both present in its optical images. The [S ii] emission of HB3, though fainter, displays a similar morphology to that of the Hα[N ii] emission-line image, tracing all the filamentary structures. On the other hand, the [O iii] emission line, displays a different filamentary morphology compared to the former line images, indicating different shock velocities and physical conditions.

(ii) Spectroscopic data from eight filaments distributed across the whole remnant exhibit strong Hα, [N ii] \( \lambda \lambda 6548,6584, \lambda 6716,6731 \) and [O i] \( \lambda 6300,6363 \) emission lines and low-to-moderate emission from the [O iii] \( \lambda \lambda 4959,5007 \) lines. These findings indicate shock waves with velocities \(< 100 \text{ km s}^{-1}\) for most of the filaments with an exception of slit 2, which has higher [O iii]/Hβ ratio and shock velocity up to 120 km s\(^{-1}\). The [S ii] lines ratio implies an electron density \(< 240 \text{ cm}^{-3}\).

(iii) The observed emission line ratios are also found to be in agreement with the diagnostic diagrams that distinguish shock-heated gas (SNRs) and UV-photionized gas (Hr regions) verifying the origin of the optical emission from shock-heated gas.

(iv) We compared the Hα+[N ii] image extracted by our observations with the emission that HB3 displays in the radio, X-rays, millimeter and γ-rays bands. Overall, the radio emission of HB3 is co-spatial with the bright optical filaments of the remnant something that indicates the same physical origin of the two radiations and marks the border of the SNR in respect to the adjacent cloud. The X-ray emission peaks roughly close to the optical center of the remnant but its overall distribution tends to be shifted towards the east, advocating that there is a link between the interaction of the remnant with the Hr/MC complex and the mixed morphology properties of HB3. Finally, regarding the CO emission line and γ-ray emission there are co-spatial with the bright southeast optical filament of the remnant something that offers an additional evidence on the interaction of HB3 with the W3 complex.

(v) Based on the [S ii] diagnostic lines and column densities obtained by our observations, we estimated the current shock velocity and preshock ambient medium density of HB3 and we found to be \( V_s = 208 \pm 54 \text{ km s}^{-1} \) and \( n_s = 0.82 \pm 0.15 \text{ cm}^{-3} \), respectively. Regarding the evolutionary stage of HB3, we show that the remnant has most likely passed into the PDS phase or it is in transition between the Sedov and PDS stages. Under this assumption, the SN energy of HB3 was found to be \( (3.7 \pm 1.5) \times 10^{51} \text{ erg} \) and its current age \((5.2 \pm 2.1) \times 10^4 \text{ yrs} \).

(vi) We discussed the mixed morphology properties of HB3, under the reflected shock model. We show that the overall properties of the remnant, namely its optical/radio bright shocks and its central X-ray emission, can in principle be explained considering that the remnant is currently interacting with the density walls of a wind blown cavity shaped by a progenitor star with initial mass of \( \sim 32 - 36 \text{ M}_\odot \).
