Abstract

We use Gaia Data Release 2 to search for possible surviving binary companions to three of the best-studied historical Milky Way core-collapse supernovae: Vela, the Crab, and Cas A. Consistent with previous work, we find there to be no plausible binary companion to either the Crab or Cas A supernovae. For the first time, we present a systematic search for a former companion to the Vela supernova, and rule out essentially any surviving luminous (>Lsun) companion. Based on parallax and proper motion, we identify a faint source (Star A; Gaia Source ID 5521955992667891584) that is kinematically consistent with being a former binary companion to the Vela SN progenitor. However, the inferred absolute magnitude of this source is extremely faint, raising the possibility that it may in fact be a background interloper. In addition, we derive a new distance (3.37±0.67 kpc) to the Crab SN based on the Gaia parallax measurements, which is significantly further than the 2 kpc distance typically adopted. Finally, we demonstrate that Gaia can be used to measure the secular decline in the luminosity of the Crab pulsar, and provide a new test of pulsar models.

Key words: ISM: supernova remnants – pulsars: general – pulsars: individual (Crab, Vela) – supernovae: general

1. Introduction

Massive stars with a zero-age main-sequence mass of more than around 8 M☉ are thought to end their lives as a core-collapse supernova (SN). As around three quarters of massive stars are found in binary systems (Sana et al. 2012), it is expected that many core-collapse supernovae will have a binary companion at the point of explosion (Kochanek 2009). Detailed calculations by Renzo et al. (2018) suggest that between 69% and 90% of supernovae will have a main-sequence or post-main-sequence companion at the point of explosion, and that 86±10% of these systems will be disrupted following the SN. We hence expect around half of all core-collapse supernovae to have an ejected stellar companion.

So far, putative binary companions have been identified for a handful of extragalactic core-collapse supernovae (e.g., SN 1993J, Maund et al. 2004; Fox et al. 2014; SN 2011dh, Folatelli et al. 2014; SN 2011ig, Ryder et al. 2018; SN 2006jc, Maund et al. 2016). In each instance a putative companion has been detected in broadband imaging or (in the case of SN 1993J) in low S/N spectroscopy.

In this paper, we search for surviving binary companions of massive stars that exploded as supernovae within the Milky Way. To date, such searches have focused on finding runaway stars associated with nearby SN remnants (Guseinov et al. 2005; Dincel et al. 2015; Boubert et al. 2017; Kerzendorf et al. 2017; Kochanek 2018; although see Tetzlaff et al. 2014 for a possible companion to the pulsar PSR J0826+2637). Since Gaia Data Release 2 (DR2; Gaia Collaboration et al. 2016, 2018a) provides exquisite 5D astrometry for the majority of point sources down to a limiting magnitude of G ~ 20, it is now possible to trace the motion of all sources in the vicinity of a pulsar, and search for a spatial coincidence at the point the SN would have exploded.

2. Sample Selection

In order to unambiguously identify the former binary companions to Galactic SNe, we require a precise parallax distance, along with measured proper motions for the associated pulsar. Furthermore, we require that the SN is sufficiently close (say, ≤10 kpc) that any companion will be bright enough for Gaia to measure its parallax, and sufficiently young (certainly less than 100 kyr) that it will still be relatively close to its birthplace on the sky.

We queried the Australia Telescope National Facility Pulsar Catalogue (Manchester et al. 2005) for all pulsars with a measured proper motion, an age less than 100 kyr, and a distance of less than 10 kpc. This query returned 15 pulsars, of which only one (Vela) had a measured parallax.

To expand our sample, in addition to Vela we also included the Crab pulsar, along with the neutron star detected at X-ray wavelengths in Cassiopeia A (Cas A). While neither of these sources has a measured parallax from VLBI, they are sufficiently young that the area to be searched for a companion is small, rendering the constraint on distance less important. The adopted parameters for Vela, the Crab, and Cas A are listed in Table 1.

We note that there are in principle other young pulsars that could be included in our sample, such as PSR B1757-24 (Manchester et al. 1985). While PSR B1757-24 has a proper motion measurement (Thorsett et al. 2002), it has no measured parallax from VLBI, and only weak constraints on its distance from the dispersion measure and H1 absorption. A similar situation exists for PSR B1951+32 (Zeiger et al. 2008). Expanding the sample of young pulsars with measured parallaxes from VLBI is hence of considerable interest.

3. Results

In the following section, we discuss each of our three pulsars/neutron stars in turn.

---

3 We note that since submitting this paper to ApJ, a paper by Kochanek et al. (2018) was posted to the arXiv describing a search for surviving (i.e., non-disrupted) binaries in SN remnants.
3.1. Vela

Vela is one of the closest, and youngest, SN remnants. It has long been known that the remnant is associated with a pulsar (Large et al. 1968). The age most commonly adopted for the Vela pulsar is 11.4 kyr (Reichley et al. 1970), which is comparable to that inferred for the SN remnant (Clark & Caswell 1976). We note, however, that some authors have advocated a significantly older age of ~20–30 kyr (Lyne et al. 1996). Due to its proximity, we assume no foreground extinction toward Vela (Franco 2012). We first search for a companion using a prior on runaway velocities from Renzo et al. (2018). Following this, we consider a more general search where we do not impose a prior, but rather search for any source that intersects the past pulsar trajectory. Finally, we consider the possibility that we do not find the putative companion to the Vela pulsar as it has no parallax measurement in Gaia DR2.

3.1.1. Searching for a Companion Using a Prior

To search for possible binary companions to Vela, we first determined the likely region where a possible binary companion could be found. Using the VLBI position and proper motion of the Vela pulsar reported in Dodson et al. (2003), we calculate possible coordinates (α, δ) that the Vela SN exploded at, accounting for the uncertainty in μα and μδ. We also account for the unknown explosion epoch, which we assume to have occurred any time between 20 and 5 kyr before the present. We tested our code by using the ASTROPY. COORDINATES package to propagate the pulsar motion forward in time from the inferred explosion location, and confirm that we recover its current position. For each explosion position, we then sample from the distribution of runway binary companion velocities calculated by Renzo et al. (2018), to calculate a possible present-day position for the binary companion. After 10⁷ Monte Carlo trials, we find that any binary companion to the Vela SN would have to lie within the red contours shown in Figure 1. The contours enclose 68.3%, 95.5%, and 99.7% of the Monte Carlo trials, i.e., they show the region where we would expect to find a companion at 1σ, 2σ, or 3σ confidence.

Values of μα and μδ for the Vela pulsar were also reported by Caraveo et al. (2001) based on Hubble Space Telescope (HST) observations. Their measurements are in significant disagreement with those of Dodson et al. (2003); however, as pointed out by Dodson et al., the reference sources used to anchor the astrometry in the HST images are themselves moving (as they lie within the Milky Way at distances of 2–10 kpc). When Dodson et al. correct for this effect, the values from Caraveo et al. move closer to those found from VLBI observations. In any case, we adopt the VLBI-based positions and proper motions in our analysis, as the radio data have higher resolution than HST, and are already in a well-defined reference frame.

We queried the Gaia DR2 archive⁴ for all sources within a large region encompassing the probable location of any companion; and found approximately⁵ 5350 sources to lie within the red contour in Figure 1. To reduce this number, we used the Gaia parallaxes to discard sources that were at a distance inconsistent with the Vela pulsar.

We take the distance of the Vela pulsar to be 287±19 pc, from the parallax seen in VLBI observations (Dodson et al. 2003). The distance is consistent with that measured from optical parallax with HST (294±70 pc; Caraveo et al. 2001), along with that inferred from high velocity absorption lines superimposed on spectra of background sources (250±30 pc; Cha et al. 1999). We have no constraint on the radial velocity of the Vela pulsar, however, even if we assume that it is moving at 10⁴ km s⁻¹ for 20 kyr, then the distance of the pulsar would have changed by at most ~20 pc. We apply distance cuts in the following that comfortably encompass this radial motion.

For each of the 5350 sources within the red contours, and for which have a measured parallax, we calculate the distance using a Bayesian approach following the recommendations in Luri et al. (2018) and Bailier-Jones (2015). We adopt an exponentially decreasing space density prior, and use the PYRALLAXES library to calculate posteriors for the distances. We take the mode of the posterior as our distance, and adopt the 5th and 95th percentiles as our lower and upper uncertainties. From this, we find approximately 23 sources that lie within the region where a binary companion might be found, and have a posterior on their distance that overlaps with the distance of the pulsar ±3σ (i.e., a distance range from 213 to 341 pc).

Our final selection criterion is to use the proper motions from Gaia to see whether any of these 23 sources have intersected the trajectory of the pulsar in the past. As before, we use a Monte Carlo technique and draw 10⁶ samples from the distribution of possible proper motions for each candidate and the Vela pulsar, accounting for uncertainties and the known correlation between μα and μδ in Gaia data. Following the method in Boubert et al. (2017), we compute the probability that each source passes within 3.843 arcsec (equivalent to a projected separation of 1000 au at 287 pc) of the pulsar between 5000 and 20,000 yr ago. We find six sources where this probability is greater than 0.0001%, and these are listed in Table 2.

Of the six candidate companions, four have a <1% probability of having intersected the trajectory of the pulsar.

---

⁴ https://gea.esac.esa.int/archive/

⁵ Since we use Monte Carlo simulations to delimit where a companion may be found, the exact boundaries of this region will change slightly every time the code is run.
Examination of Figure 1 reveals that these sources have significant fractional uncertainties on their proper motion. Furthermore, two of these sources have a 95% upper bound to their distance of several kiloparsecs, making it quite likely that these are simply faint background sources. We hence regard these as unlikely to be associated with the Vela SN. One candidate, however, Gaia DR2 5521955992667891584 (henceforth Star A), appears more promising with 6.8% of the samples meeting our strict criteria. Based on its measured proper motion, Star A was approximately coincident with the Vela pulsar 9260 ± 150 yr ago, which is similar to when the SN was believed to have exploded. Furthermore, the distance toward Star A (380 ± 78 pc) is in fair agreement with that inferred for the pulsar (287 ± 17 pc). However, if we take 300 pc as the distance toward Star A (i.e., consistent with both the VLBI parallax to the pulsar, and the Gaia DR2 parallax to the star), then we derive a distance modulus $m - M = 7.39$. This in turn implies that the absolute magnitude of Star A is $M_V = 12.69$. There is one other possible candidate, Gaia DR2 5521953626147707776, where 4.8% of its samples meet our criteria and it would have coincided with the pulsar 14430 ± 230 yr ago. However, Star A is the much more likely companion of these two because the median separation at closest approach across all its samples is only 16″, compared to 28″ for Gaia DR2 5521953626147707776.

A Hertzsprung–Russell Diagram is shown for the sources that are potentially at the same distance as Vela in Figure 2. Most of these are relatively red (BP – RP > 1.5),\(^6\) and lie below the main sequence. However, as these have asymmetric error bars due to their uncertain distance, it is quite likely that these are considerably further than the mode of the posterior would suggest, and are hence intrinsically more luminous. In addition to these, there is one blue source (BP – RP < 1.0) that is consistent with being a white dwarf (a handful of known

\[^6\]Gaia takes low-resolution spectra for nearly all the sources it detects with its onboard Blue Photometer and Red Photometer spectrographs. The BP–RP color is derived by integrating over the bandpass of each of these spectra and is approximately equivalent to a $V - I$ color.
white dwarfs within Gaia DR2 can be seen as the gray points in the lower left corner of Figure 2). Star A is visible on this plot as the black point, and if we take it to lie at the upper end of its possible range of absolute magnitudes, then it is approximately consistent with being a faint and cool dwarf on the main sequence. However, in this case Star A would be too distant to be associated with the Vela pulsar. To determine the nature of Star A, and hopefully confirm or rule out the source as a potential companion to the Vela SN, requires spectroscopy. In the absence of this, we searched for archival imaging of the field that could be used to constrain the spectral energy distribution of the star. No data were found in the HST archive, and while ground-based imaging in rHCO filters was available from the VPHAS+ survey (Drew et al. 2014), this did not provide additional information beyond the Gaia BP − RP colors.

3.1.2. Searching for a Companion with No Prior

We also tested the effects of removing the prior on the runaway velocity (from Renzo et al. 2018), and simply performing a search for sources that were at the same distance as Vela, and intersected the past trajectory of the pulsar. For this test, we queried the Gaia archive for all sources within a 0.5° radius of (129.07, −45.33), which yielded ∼78,500 results. 0.5° is approximately the angular distance of a star traveling at 200 km s$^{-1}$ for 11.4 kyr. We then checked whether any of these sources had intersected the pulsar trajectory at any time between 5 and 35 kyr ago. This is a wider range of possible ages than what we had previously assumed for the pulsar (5–20 kyr), in order to allow for the possibility we have significantly underestimated the SN age (Lyne et al. 1996). From this search, we found 13 sources within a 0.5° radius that intersected the pulsar trajectory. As expected, among these 13 sources were all of the candidates listed in Table 2. Aside from Star A, all of these sources were faint, and have a very low (1%–2%) probability of having intersected the pulsar.

From Figure 2, it is evident that there are no clear overluminous sources present in the field, as might be expected for a putative companion that had been shock heated by the impact of ejecta from the Vela SN. As an additional test, we took all bright sources (G < 16) that had a consistent distance, and plotted their past trajectories in Figure 3. None of these bright sources intersect the past trajectory of the pulsar, ruling them out as potential surviving companions to the Vela SN.

3.1.3. Searching Sources with No Reported Parallax

Finally, we must consider whether any sources lie within the possible region where a companion could be found, but have no reported parallax in Gaia DR2. We find around 650 such sources in Gaia DR2, and most of these have magnitudes fainter than G = 20. It is most likely that these are simply faint, distant sources for which Gaia was unable to measure a parallax. Whether a brighter source could have been missed by Gaia is somewhat harder to estimate. Around 1% of sources brighter than mag G = 17 in the field are missing parallax measurements in Gaia DR2. It is unclear what the reason for this is, but there are several possibilities, including marginally resolved visual binaries (where the astrometric solution may have failed to converge). It is unlikely we are missing any sources due to high proper motions—a star traveling at 200 km s$^{-1}$ will have a proper motion of 0.16 yr$^{-1}$ at the distance of Vela. We hence regard it as unlikely that a companion was simply missed by Gaia. We again note that while we have not considered the extinction toward Vela, its proximity means that E(B − V) will be low (Franco 2012).

From the preceding analysis, we can rule out a luminous massive star as a binary companion to the Vela SN. Star A is a viable candidate due to its astrometry; however, it appears to be significantly fainter than most main-sequence stars. While we must await follow-up spectroscopy of Star A, in either case any companion to the Vela SN at the point of explosion must have either been a white dwarf, neutron star, or black hole, or a low-mass main-sequence star fainter than $L \sim 10^{-3} L_{\odot}$.
3.2. The Crab

The supernova that gave rise to the Crab was famously observed in both China and Japan in CE 1054, and recorded as a “guest star” in numerous historical texts (Duyvendak 1942; see also the comprehensive review by Clark & Stephenson 1977). The detection of a young pulsar in the center of the Crab nebula (Comella et al. 1969) indicates that this was a core-collapse SN, while the H-rich ejecta seen in the nebula points toward an SN II (see Hester 2008, for a recent review of the Crab).

To search for possible companions to the Crab SN progenitor, we use the same technique as for Vela. We adopt the position and proper motion for the Crab pulsar from the Gaia DR2 catalog, and list these in Table 1. The Crab SN exploded in CE 1054, and we hence adopt an age for the pulsar of 961.5 yr (until CE 2015.5, which is the reference epoch of Gaia DR2). The foreground extinction is likely around $A_V \sim 1$ (the line-of-sight extinction toward the Crab at 2 kpc implies $E(B-V) = 0.34_{-0.02}^{+0.02}$; Green et al. 2018).

3.2.1. The Distance to the Crab

Despite being one of the best observed objects in the sky, the distance to the Crab is surprisingly poorly constrained. Trimble (1973) reviewed the various lines of evidence and found an unweighted average distance of 1.93 kpc. Since then, and in the absence of a parallax measurement from either optical or radio (see the Appendix in Kaplan et al. 2008, for a discussion of the various observational challenges), most authors have adopted 2 kpc as the nominal distance to the Crab.

At $V = 16.7$ mag (Sandberg & Sollerman 2009), the Crab pulsar is sufficiently bright in optical for Gaia to measure a parallax. While there is a “knot” of marginally extended optical emission located $\sim 0^{\prime}7$ to the southeast of the Crab pulsar (Sandberg & Sollerman), this is distant enough for the Gaia parallax to be unaffected, and otherwise the Crab pulsar should appear as a point source to Gaia.

We queried the Gaia archive, and found only a single source (Gaia Source ID 3403818172572314624) within a 5$^{\prime}$ radius of the nominal IRCS coordinates of the Crab pulsar. The G-band magnitude of this source ($G = 16.4$) is consistent with that of the Crab pulsar (Sandberg & Sollerman 2009). The parallax of this source is $0.27 \pm 0.12$ mas, which leads to a naive $1/\pi$ distance estimate of $3.70 \pm 1.65$ kpc.

Using the same Bayesian technique to infer distance from parallax as described in Section 3.1, we derive the distance to the Crab to be $3365_{-970}^{+4038}$ pc. While the posterior for the distance shown in Figure 4 is quite broad, we can exclude with 95% confidence a distance to the Crab of less than 2.4 kpc. We note that the exponentially decreasing distance prior that we employ is tuned for the “normal” stellar population, not pulsars. However, as the absolute magnitude of the Crab pulsar is by chance comparable to that of a typical low-mass dwarf, the prior should be equally valid in this case. We discuss the implications of this longer distance to the Crab further in Section 4.

We also checked our distance against that reported by Bailer-Jones et al. (2018), who have published a catalog of distances to all sources with measured parallax in Gaia DR2. The distance to the Crab pulsar from Bailer-Jones et al. is $2962_{-63}^{+1201}$ pc, where the value quoted comes from the mode of the posterior probability density, and the uncertainties encompass the $\pm 1\sigma$ range about the most probable distance. We note that the only difference between these two distances is that Bailer-Jones et al. used a scale-length for their exponentially decreasing prior that varied with location on the sky, based on a model of the Galaxy.

3.2.2. Searching for a Companion to the Crab

To search for a companion to the Crab, we use a similar methodology as in Section 3.1. Our starting measurements are the position of the Crab pulsar, its proper motion, and parallax-derived distance from Gaia DR2. Kaplan et al. (2008) also measured proper motions for the Crab pulsar from HST images. While their value of $\mu_\alpha$ ($-12.0 \pm 0.4 \text{ mas yr}^{-1}$) is consistent with that from Gaia ($-11.8 \pm 0.2 \text{ mas yr}^{-1}$), they find $\mu_\delta$ to be $4.1 \pm 0.4$, which is significantly higher than the Gaia value of $2.6 \pm 0.2 \text{ mas yr}^{-1}$. We assume that the Gaia values are more reliable in this instance as they come from a dedicated astrometric survey, whereas the HST data are taken with a number of different instruments, each of which has a small field of view, and are consequently difficult to calibrate onto a fixed astrometric reference frame.

We propagate the proper motion of the pulsar back to infer its position in CE 1054. From this point, we track how far a companion could have traveled, assuming the Renzo et al. (2018) velocity distribution. The results of this are shown in Figure 5.

There is no source in Gaia DR2 that lies within the region where we would expect to find a companion. Indeed, there are no sources within a radius of $10^{\prime}$ of our inferred explosion center. If we adopt the traditional distance of 2 kpc to the Crab, then a star would require a velocity greater than $\sim 100 \text{ km s}^{-1}$ in the plane of the sky to move beyond this. If our distance is greater than this, as the parallax to the Crab suggests, then the velocity that a companion must have had to have moved more than $10^{\prime}$ from the explosion center would be even higher.

Since the posterior of the distance to the Crab is quite broad, it is not feasible to identify potential companions by searching for sources at a consistent distance. Of the 63 sources in Gaia DR2 that lie within 1/5 of the present-day position of the Crab, over 60% have a posterior for their distance that overlaps with that of the Crab pulsar.
To determine an upper limit to the magnitude of any surviving companion to the Crab, we take line-of-sight extinctions from Green et al. (2018). At the canonical 2 kpc distance of the Crab, we expect an extinction of $E(B - V) = 0.34^{+0.03}_{-0.02}$ mag, while at 3.37 kpc, we take $E(B - V) = 0.38^{+0.03}_{-0.02}$ mag. For the line of sight toward the Crab, a distance of 3.37 kpc lies slightly beyond the range of validity for the Green et al. dust map. We hence caution that the true reddening could be somewhat higher than our adopted value, if the Crab is indeed at this distance. The limiting magnitude of $Gaia$, $G = 20.5$, implies that for the close distance, any companion must be fainter than $M_G \sim 7.9$. At 3.37 kpc, we require that $M_G$ is fainter than 6.7 mag in order to be unobservable in our data. While we cannot exclude the possibility of patchy dust that leads us to underestimate the reddening, our limits are sufficiently deep that we regard this as relatively unlikely. As for Vela, we hence conclude that the SNR most likely did not have a luminous ($>L_\odot$) stellar companion at the point of explosion.

The region in Figure 5 where we expect to find the companion to the Crab is consistent with that searched by Kochanek (2018), who similarly found no companion.

3.3. Cas A

Cas A is one of the few Galactic SNe for which we are certain of the spectral classification (Type Ib), thanks to the detection of light echoes by Krause et al. (2008). The absence of an unambiguous historical record of Cas A has long been noted, although Soria et al. (2013) suggested that Cassini may have observed the SN on or shortly prior to 1671, while Ashworth (1980) proposed that Flamsteed saw the SN in 1680 (although see Stephenson & Green 2005 regarding the latter claim). The distance to Cas A, as determined from the geometric expansion of the SN remnant is $3.4^{+0.3}_{-0.1}$ kpc (Reed et al. 1995). The foreground extinction toward Cas A is quite uncertain, although likely high ($A_V = 5 - 15$).

The neutron star in Cas A was detected in X-rays by Chandra (Tananbaum 1999), and an accurate measured position is reported by Hwang et al. (2004). While there is a measurement of the Cas A neutron star proper motion in DeLaney & Satterfield (2013), it is only marginally significant, and so we do not use it in the following. As the neutron star has not been detected in radio, the prospects for measuring its proper motion in future appear remote.

We searched a 2.5 region centered on $23:23:27.8 + 58:48:52.27$ (which is the geometric center of the Cas A remnant from Reed et al. 1995; updated from B1950 to ICRS) in Gaia DR2, and found 202 sources. Of the subset of these that had measured parallaxes, 149 sources were at a distance consistent with Cas A. As these sources lie within a region approximately the same radius as the SN remnant, if they were associated with the SN then they would have had a tangential velocity that is potentially as fast as the SN ejecta. A more reasonable search radius for a companion is $\sim 10^\circ$, which is the maximum distance a companion could travel in 340 yr at $500 \text{ km s}^{-1}$. Kerzendorf et al. (2017) recently presented a comprehensive search for a companion to Cas A within this small region, using deep HST images, and found no candidates. A similar result was obtained by Kochanek (2018) using PanSTARRS data. The sources considered by Kerzendorf et al. and Kochanek are below the limiting magnitude of Gaia, and so we cannot improve upon these results.

There is significant extinction toward Cas A, with estimates ranging from $A_V \sim 5$ (see discussion in Kochanek 2018), or potentially as much as $A_V \sim 15$ (De Looze et al. 2017). For a Gaia G limiting magnitude of $G = 20.5$, this corresponds to an absolute magnitude limit of between $+2.8$ and $-7.2$ for $A_V = 5$ and 15 respectively. One final test we can attempt is to use Gaia DR2 to search for any bright ($G < 20$) sources at the distance of Cas A that are outside the search radius of Kochanek (2018) and Kerzendorf et al. (2017), and which have proper motions that would imply they were at the center of the remnant. In Figure 6 we show the proper motions of all Gaia DR2 sources in the field. From this, it is clear that there are no high proper motion stars that have trajectories implying an origin in the center of the Cas A remnant.

4. Implications of Gaia for the Crab Supernova

While a detailed discussion of the impact of a greater distance toward the Crab is beyond the scope of this work, we note that the absolute magnitude of the SN from the historical lightcurve will of course increase. Smith (2013) suggested that at peak brightness, the Crab had an absolute magnitude at peak of $M_V \sim -18$, assuming a distance of 2 kpc and an extinction of $A_V = 1.6$ mag. Smith took the apparent magnitude of the Crab SN to be $V \sim -5$, as it was recorded as being visible during the daytime. However, it is possible that a source fainter than this could be seen in daylight. For example, on a clear day, Venus can be visible during the day, and as this is a point-like source (to the naked eye) with an apparent magnitude of $V = -4.4$, we take this as the faintest magnitude the Crab could have had that is still consistent with the historical records. For our Gaia parallax-derived distance, and taking $E(B - V) = 0.38$ from the Green et al. (2018) extinction map, we hence find an absolute magnitude at maximum for the Crab SN of $M_V = -18.2^{+0.7}_{-0.3}$, where the uncertainties reflect the uncertainties in distance and extinction toward the Crab. This absolute magnitude should strictly speaking be regarded as a lower limit, as it reflects the faintest apparent magnitude that could have been observed during the daytime, and the Crab SN
may have been considerably brighter than this. A longer distance to the Crab would also help explain its apparently low efficiency (\(\lesssim 1\%\)), as inferred from the ratio of the observed gamma-ray luminosity to spin-down power (Abdo et al. 2013). If the Crab were more distant, then its true gamma-ray luminosity would be higher, implying a higher efficiency.

Finally, we note that there is one more area where Gaia can contribute to our understanding of the Crab. There is expected to be a secular decrease in the optical luminosity of the Crab (Pacini 1971) over time, as energy is lost to synchrotron radiation. A number of attempts have been made to measure this decline; Nasuti et al. (1996) found a decline rate at optical wavelengths of \(8 \pm 4\) mmag yr\(^{-1}\), while Sandberg & Sollerman (2009) measured \(2.9 \pm 1.6\) mmag yr\(^{-1}\). By necessity, all such measurements to date have been made with heterogeneous archival imaging taken over a timescales of decades by a number of different instruments, or rely on reported magnitudes from the literature. Differences in filter bandpasses between telescopes, along with the precise details of flux calibration, result in large and hard-to-quantify systematic uncertainties associated with these measurements (Nasuti et al. 1996).

In contrast, Gaia offers the opportunity to make a precise measurement of the optical decline rate of the Crab pulsar in a uniform photometric system. The Gaia mission is currently planned to last for at least seven years. Given the ecliptic latitude of the Crab, and scaling the original prelaunch estimates from 5 to 7 yr, we expect that the Crab will be observed around 85 times. For each of these observations, we expect a photometric error of around 3 mmag in the broadband G-filter, given the color and magnitude \((V = 16.7; V-I = 1)\) of the Crab pulsar (Jordi et al. 2010). The expected decline in the Crab over this timespan \((20.3 \pm 11.2\) mmag\) should be clearly detected in the Gaia data, allowing for a new test of synchrotron emission mechanisms in pulsars. At present, the fluxes measured for individual transits necessary for this test are provisionally scheduled for release at the end of 2022 as part of the final Gaia catalog.

However, there is already evidence that Gaia may have detected the secular decline of the Crab in DR2. We queried the Gaia archive for all sources with the same number of observations as the Crab pulsar \((\text{MATCHED}\_\text{OBSERVATIONS} = 15\) and \(\text{PHOT}\_G\_\text{N}\_\text{OBS} = 129)\), and where the \(G\) magnitude is within 0.01 mag of that of the Crab. In Figure 7 we plot the percentage uncertainty in flux \((\text{calculated from} \frac{\text{PHOT}\_G\_\text{MEAN}\_\text{FLUX}\_\text{ERROR}}{\text{PHOT}\_G\_\text{MEAN}\_\text{FLUX}})\) for each of these sources. The majority of these sources have a percentage flux error of 0.1%, while the Crab pulsar is an outlier from the distribution. Over the 22 months of data included in Gaia DR2, we expect the Crab to have faded by 0.6%, and this is consistent with the Crab having a larger flux error than would be expected on the basis of its magnitude.

5. Conclusions

We have attempted to use Gaia DR2 to identify a former binary companion to three of the the best-studied core-collapse supernova remnants; namely Vela, Cas A, and the Crab. For the latter two, we cannot improve upon extant deep literature limits. In the case of Vela, we have identified a candidate companion (Star A); however, its faint absolute magnitude may be more consistent with an unrelated background source. It will be necessary to obtain spectroscopy of Star A both to confirm the spectral type of this star, and to search for possible contamination of the envelope by elements found in SN ejecta. If Star A is shown to be unrelated, then we can exclude the presence of effectively all nondegenerate binary companions to the Vela SN.

If Star A turns out to be an unrelated background source, then there are now three historical Milky Way SNe (Vela, Cas A and the Crab), along with SN 1987A in the LMC, which have no detected companion. From our initial expectation that between 69% and 90% of stars will have a main-sequence or post-main-sequence companion at the point they explode, the probability of not seeing a companion for all four SNe is between 1% and 0.01%. As noted by Kochanek (2018), increasing the rate of stellar mergers may help to alleviate this discrepancy.

One important consideration that we have not discussed so far is the role of newly formed dust in the SN remnant, which may serve to obscure any binary companion (Kochanek 2017). While to conclusively exclude a dust-enshrouded companion...
would require near and mid-IR observations, we note that for the Crab and Vela the optical depth $\tau_0$ from newly formed dust is probably relatively low (as this scales with $r^{-2}$). In the case of Cas A, the remnant is perhaps more likely to be obscured due to its relative youth. Indeed, as Cas A also suffers from a high and poorly known level of foreground extinction, a search for a companion in the near infrared may be worthwhile.

Finally, we have pointed out that Gaia can contribute to studies of the Crab pulsar itself, both through a new distance estimate (3.37$^{+0.04}_{-0.07}$ kpc), and through precisely measuring the secular decline of the pulsar over time.

We thank Rob Izzard, Wolfgang Kerzendorf, Fabio Acero, David Smith, and Antonio Martin-Carrillo for helpful discussions and advice. We thank the referee for their comments and suggestions. M.F. is supported by a Royal Society—Science Foundation Ireland University Research Fellowship. D.B. thanks the UK Science and Technologies Facilities Council for supporting his Ph.D.

This work has made use of data from the European Space Agency (ESA) mission Gaia (https://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular, the institutions participating in the Gaia Multilateral Agreement.

Based on observations made with the NASA/ESA Hubble Space Telescope, and obtained from the Hubble Legacy Archive, which is a collaboration between the Space Telescope Science Institute (STScI/NASA), the Space Telescope European Coordinating Facility (ST-ECF/ESA) and the Canadian Astronomy Data Centre (CADC/NRC/CSA).

The Digitized Sky Surveys were produced at the Space Telescope Science Institute under U.S. Government grant NAG W-2166. The images of these surveys are based on photographic data obtained using the Oschin Schmidt Telescope on Palomar Mountain and the UK Schmidt Telescope. The plates were processed into the present compressed digital form with the permission of these institutions.

We have made use of the ROSAT Data Archive of the Max-Planck-Institut für extraterrestrische Physik (MPE) at Garching, Germany. We acknowledge the use of NASA’s SkyView facility (http://skyview.gsfc.nasa.gov) located at NASA Goddard Space Flight Center.

Facility: Gaia.

Software: astropy (Astropy Collaboration et al. 2013).
