Acceleration of an iterative method for the evaluation of high-frequency multiple scattering effects

Yassine Boubendir∗, Fatih Ecevit†, and Fernando Reitich‡

Abstract

High frequency integral equation methodologies display the capability of reproducing single-scattering returns in frequency-independent computational times and employ a Neumann series formulation to handle multiple-scattering effects. This requires the solution of an enormously large number of single-scattering problems to attain a reasonable numerical accuracy in geometrically challenging configurations. Here we propose a novel and effective Krylov subspace method suitable for the use of high frequency integral equation techniques and significantly accelerates the convergence of Neumann series. We additionally complement this strategy utilizing a preconditioner based upon Kirchhoff approximations that provides a further reduction in the overall computational cost.

1 Introduction

In the last two decades significant advances have taken place in the realm of computational scattering with notable theoretical as well as practical contributions in the domains of finite elements [28, 17, 9] and integral equations [12, 3, 8, 37, 11]. However, simulation strategies based upon the former are usually restricted to low and mid frequency applications. Indeed, use of finite element methods in exterior scattering simulations requires not only utilization of an artificial interface to truncate the infinite computational domain but also introduction of appropriate absorbing boundary conditions on this interface to effectively replicate the behaviour of solution at infinity [6, 21, 25, 26, 27]. This, in return, renders finite-element methods impractical in high-frequency applications and may result in a loss of accuracy and increased computational cost. Moreover, this difficulty is further amplified on models involving multiple scatterers, such as the one treated in the present paper, because the distance that separates the obstacles naturally increases the size of the truncated domain. Integral equation methods, in contrast, are more accurate for these situations since, on the one hand, they explicitly enforce the radiation condition by simply choosing an appropriate outgoing fundamental solution and, on the other hand, they are solely based on the knowledge of solution confined only to the scatterers which, in surface scattering applications, provides a dimensional reduction in computational domain [16]. Nevertheless, they deliver dense linear systems whose sizes increase in proportion to $k^p$ with increasing wavenumber $k$ where $p$ is the dimension of the computational manifold.

Broadly speaking, the success of integral equation approaches in high-frequency simulations is directly linked with the incorporation of asymptotic characteristics of the unknown into the solution strategy. This is essentially the path we follow in this manuscript, since it transforms the problem into the determination of a new unknown whose oscillations are virtually independent of frequency. While pioneering work in this direction is due to Nedélec et al. [11, 2] who, in two-dimensional simulations, have provided...
a reduction from $O(k)$ to $O(k^{1/3})$ in the number of degrees of freedom needed to obtain a prescribed accuracy, the single-scattering algorithm of Bruno et al. [13] (based on a combination of Nyström method, extensions of the method of stationary phase, and a change of variables around the shadow boundaries) has had a significant impact as it has demonstrated the possibility of $O(1)$ solution of surface scattering problems (see [10] for a three-dimensional variant). Alternative implementations of this approach built on a collocation and geometrical theory of diffraction combo [21], a collocation and steepest descent amalgamation [31], and a p-version Galerkin interpretation [18] have later appeared. In this latter setting, Ecevit et al. [19] have recently developed a rigorous method which demands, for any convex scatterer, an increase of $O(k^\epsilon)$ (for any $\epsilon > 0$) in the number of degrees of freedom to maintain a prescribed accuracy independent of frequency.

The single-scattering algorithm [13] has been successfully extended by Bruno et al. [14] to encompass the high-frequency multiple-scattering problems considered in this paper, relating specifically to a finite collection of convex obstacles. Roughly speaking, the approach in [14] was based on: 1) Representation of the overall solution as an infinite superposition of single scattering effects through use of a Neumann series, 2) Determination of the phase associated with each one of these effects using a spectral geometrical optics solver, and 3) Utilization of the high-frequency single scattering algorithm [13] for the frequency independent evaluation of these effects. While every numerical implementation in [14] has displayed the spectral convergence of Neumann series for two convex obstacles, unfortunately, a rigorous proof of this fact was not available. Indeed, we have later shown for several convex obstacles in both two- [20] and three-dimensional [5] settings that the Neumann series can be rearranged into contributions associated with primitive periodic orbits and an explicit rate of convergence formula can be rigorously derived on each periodic orbit in the high-frequency regime. While, on the one hand, these analyses depict the convergence of Neumann series for all sufficiently large wavenumbers $k$, on the other hand, the rate of convergence formulas display that convergence can be rather slow particularly when (at least) one pair of nearby obstacles exists. This analysis of the rate convergence [20, 5] was performed by using double layer potentials. In this work, we show that use of combined field integral equations lead to the same rate of convergence. Accordingly, novel mechanisms are much needed for the accelerated solution of multiple scattering problems that retain the frequency independent operation count underlying the algorithm in [14]. However, this is a rather challenging task since the algorithm in [14] undeviatingly rests on reducing the problem, at each iteration, to the computation of an unknown with a single-valued phase, and thus any strategy aimed at accelerating the convergence of Neumann series must also preserve the phase information related with the iterates.

In this paper, we develop a Krylov subspace method that significantly accelerates the convergence of Neumann series, in particular in the case where the distance between obstacles decreases hence deteriorating the rate of convergence. This method is well adapted to the high frequency aspect of the present problem as it retains the phase information associated with the iterates and delivers highly accurate solutions in a small number of iterations. Note specifically that a direct implementation of Krylov subspace methods inhibits the use of the algorithm in [14] as this makes it impossible to track the phase information of the corresponding iterates. As we shall see, a natural attempt to overcome this issue would be to simply use the binomial formula, however, this disrupts the convergence of the method as displayed in the numerical results. We defeat this additional difficulty by introducing an alternative numerically stable decomposition of the iterates. In summary, our approach is based on three main elements: 1) Utilization of an appropriate formulation of the multiple scattering problem in the form of an operator equation of the second kind, 2) Alternative representation of the associated Krylov subspaces so as to guarantee that basis elements are single-phased and thus retain the frequency independent operation count underlying the algorithm in [14], and 3) A novel decomposition of the iterates entering in a (standard) Krylov recursion to prevent instabilities that would otherwise arise in a typical implementation based on binomial identity. Indeed, as depicted in our numerical implementations, the resulting methodology is immune to numerical instabilities as it removes the additive cancellations arising from a direct use of binomial
theorem. Moreover, it provides additional savings in the number of needed iterations when compared with the classical Padé approximants used in [14].

We additionally complement our Krylov subspace approach utilizing a preconditioner based upon Kirchhoff approximations to further reduce the number of iterations needed to obtain a given accuracy. Indeed, since the knowledge of the illuminated regions at each iteration are readily available through the geometrical optics solver we have used to precompute the phase of multiple scattering iterations, essentially the only additional computation needed for the application of this preconditioner is the use of stationary phase method to deal with non-singular integrals wherein the only stationary points are the target ones. This kind of dynamical preconditioning is unusual and its originality resides in the fact that the location of illuminated regions varies at each reflection. This clearly distinguishes our preconditioning strategy from classical approaches where the preconditioners are usually steady by design.

While the success of this Kirchhoff preconditioner is clearly displayed in our numerical tests, the utilization of Kirchhoff approximations for the multiple scattering iterations naturally arises the question of convergence of the associated Neumann series. We address this problem by showing that this series converges for each member of a general general class of functions, and explain the exact sense in which the spectral radius of the Kirchhoff operator is strictly less than 1. The importance of this result is twofold. First, it verifies that the multiple scattering problem can be solved by using solely the Kirchhoff technique, and further it rigorously answers the validity of our preconditioning strategy.

The rest of the paper is organized as follows. In §2 we introduce the scattering problem and provide a comparison of the equivalent differential and integral equation formulations of multiple scattering problems. §3 is reserved for a comparison of convergence characteristics of these approaches. In §4 we provide a short review of the algorithm in [14] as the ideas therein lie at the core of frequency independent evaluation of multiple scattering iterations as well as the iterates associated with our newly proposed Krylov subspace method detailed in §5. In §6 we explain how this Krylov subspace approach can be preconditioned while utilizing Kirchhoff approximations. Finally, in §7 we present numerical implementations validating our newly proposed methodologies.

2 Scattering problem and multiple scattering formulations

Given an incident field \( u^{\text{inc}} \) satisfying the Helmholtz equation in \( \mathbb{R}^n \) \((n = 2, 3)\), we consider the solution of sound-soft scattering problem

\[
\begin{aligned}
\left\{ \begin{array}{ll}
(\Delta + k^2) u = 0 & \text{in } \mathbb{R}^n \setminus \Omega \\
u = -u^{\text{inc}} & \text{on } \partial\Omega \\
\lim_{|x| \to \infty} |x|^{(n-1)/2} (\partial_x - ik) u(x) = 0
\end{array} \right.
\end{aligned}
\]

(1)

in the exterior of a smooth compact obstacle \( \Omega \subset \mathbb{R}^n \). Potential theoretical considerations entail that [16] the scattered field \( u \) satisfying (1) admits the single-layer representation

\[ u(x) = -\int_{\partial K} \Phi(x, y) \eta(y) \, ds(y) \]

where

\[ \eta = \partial_{\nu} (u + u^{\text{inc}}) \quad \text{on } \partial\Omega \]

is the unknown normal derivative of the total field (called the surface current in electromagnetics), \( \nu \) is the exterior unit normal to \( \partial\Omega \),

\[ \Phi(x, y) = \begin{cases} 
\frac{i}{4} H_0^{(1)}(k|x-y|), & n = 2, \\
\frac{1}{4\pi} \frac{e^{ik|x-y|}}{|x-y|}, & n = 3,
\end{cases} \]
is the fundamental solution of the Helmholtz equation, and $H_0^{(1)}$ is the Hankel function of the first kind and order zero. Although $\eta$ can be recovered through a variety of integral equations [16], we use the uniquely solvable combined field integral equation (CFIE)

$$\eta(x) - \int_{\partial\Omega} \left( \partial_{\nu(x)} + ik \right) G(x,y) \eta(y) \, ds(y) = f(x), \quad x \in \partial\Omega \quad (2)$$

where $G = -2\Phi$ and $f(x) = 2 \left( \partial_{\nu(x)} + ik \right) u^{inc}(x)$.

In case the obstacle $\Omega$ consists of finitely many disjoint sub-scatterers $\Omega_1, \ldots, \Omega_J$, denoting the restrictions of $\eta$ and $f$ to $\partial\Omega_j$ by $\eta_j$ and $f_j$ so that

$$\eta = (\eta_1, \ldots, \eta_J)^t \quad \text{and} \quad f = (f_1, \ldots, f_J)^t, \quad (3)$$
equation (2) gives rise to the coupled system of integral equations

$$(\mathcal{I} - \mathcal{S}) \eta = f \quad (4)$$

where

$$(\mathcal{S}_{jj'} \eta_{j'}) (x) = \int_{\partial\Omega_j} \left( \partial_{\nu(x)} + ik \right) G(x,y) \eta_{j'}(y) \, ds(y), \quad x \in \partial\Omega_j.$$ 

In connection with the operator $\mathcal{I} - \mathcal{S}$, the following result will be useful in extending our two-dimensional results in [20] concerning the convergence of multiple scattering iterations to the case of CFIE.

**Theorem 1** For each $k > 0$, the diagonal operator $\mathcal{D} = \text{diag} (\mathcal{I} - \mathcal{S}) : L^2 (\partial\Omega) \to L^2 (\partial\Omega)$ is continuous with a continuous inverse. Moreover, if each $\Omega_j$ is star-like with respect to a point in its interior, then given $k_0 > 0$ there exists a constant $C_{k_0} > 0$ such that

$$\|\mathcal{D}^{-1}\|_2 \leq C_{k_0} \quad (5)$$

for all $k \geq k_0$.

**Proof.** This is immediate since $\mathcal{D}$ is a diagonal operator and, as shown in [15, Theorem 4.3], each operator $\mathcal{I} - \mathcal{S}_{jj} (j = 1, \ldots, J)$ on its diagonal satisfies inequality (6). ■

Multiplying equation (4) with the inverse of $\mathcal{D}$ yields the equivalent operator equation of the second kind

$$(\mathcal{I} - \mathcal{T}) \eta = g \quad (6)$$

where

$$T_{jj'} = \begin{cases} 0, & j = j', \\
(\mathcal{I} - \mathcal{S}_{jj})^{-1} \mathcal{S}_{jj'}, & j \neq j',
\end{cases} \quad (7)$$

and

$$g = (g_1, \ldots, g_J)^t$$

with $g_j = (\mathcal{I} - \mathcal{S}_{jj})^{-1} f_j$. Under suitable restrictions on the geometry of scatterers, the solution of the operator equation (6) is given by the Neumann series [20, 5]

$$\eta = \sum_{m=0}^{\infty} \eta^m \quad (8)$$

where the multiple scattering iterations

$$\eta^m = (\eta_1^m, \ldots, \eta_J^m)^t \quad (9)$$
are defined by
\[ \eta^m = \begin{cases} g, & m = 0, \\ T \eta^{m-1}, & m \geq 1. \end{cases} \quad (10) \]

As was presented in [7], the multiple scattering problem described above possesses an equivalent differential equation formulation. Naturally, the convergence analysis carried out in [7] is directly linked with that of the Neumann series (8) and here we present the exact connection. Indeed, the fields \( u_j \) given by the single-layer potentials
\[ u_j(x) = -\int_{\partial \Omega_j} \Phi(x, y) \eta_j(y) \, ds(y) \]
in connection with the components of \( \eta \) in (3) correspond precisely to the unique solutions of the exterior sound-soft scattering problems
\[
\begin{cases}
(\Delta + k^2) u_j = 0 \quad \text{in} \ \mathbb{R}^n \setminus \Omega_j, \\
u_j = -u^{\text{inc}} - \sum_{j' \neq j} u_{j'} \quad \text{on} \ \partial \Omega_j, \\
\lim_{|x| \to \infty} |x|^{(n-1)/2} (\partial_{|x|} - i k) u_j(x) = 0,
\end{cases}
\]
and they provide the decomposition of the scattered field \( u \) as
\[ u = \sum_{j=1}^{\infty} u_j. \quad (11) \]

On the other hand, the iterated fields \( u_j^m \) given by the single-layer potentials
\[ u_j^m(x) = -\int_{\partial \Omega_j} \Phi(x, y) \eta_j^m(y) \, ds(y) \quad (12) \]
in relation with the components of \( \eta^m \) in (9) are precisely the unique solutions of the exterior sound-soft scattering problems
\[
\begin{cases}
(\Delta + k^2) u_j^m = 0 \quad \text{in} \ \mathbb{R}^n \setminus \Omega_j, \\
u_j^m = -h_j^m \quad \text{on} \ \partial \Omega_j, \\
\lim_{|x| \to \infty} |x|^{(n-1)/2} (\partial_{|x|} - i k) u_j^m(x) = 0
\end{cases}
\]
with
\[ h_j^m = \begin{cases} u^{\text{inc}}, & m = 0, \\ \sum_{j' \neq j} u_{j'}^{m-1}, & m \geq 1, \end{cases} \]
and thus, in case the Neumann series (8) converges, each solution \( u_j \) can be expressed as the superposition
\[ u_j = \sum_{m=0}^{\infty} u_j^m. \quad (13) \]

3 Convergence of multiple scattering iterations

Preliminary work on the justification of identity (13) in a three-dimensional setting has appeared in [7]. Indeed, while [7, Theorem 1] establishes uniqueness of decomposition (11), [7, Theorem 3] justifies the convergence of the series in (13) under suitable restrictions on the geometry of the obstacles \( \Omega_j \) as stated in the next theorem.
Theorem 2 (cf. [7]) Assume that $u^{inc} \in H^1(\partial \Omega)$ and, for $j = 1, \ldots, J$, the obstacle $\Omega_j$ is non-trapping in the sense that
\[
\beta_j = \frac{1}{\text{diam} (\Omega_j)} \sup_{y \in \Omega_j} \inf_{x \in \partial \Omega_j} \nu(x) \cdot (x - y) > 0.
\]
Let
\[
\delta = \max_{1 \leq j \leq J} \text{diam} (\Omega_j), \quad d = \min_{1 \leq j \leq J} \text{dist} (\Omega_j, \Omega_j'), \quad |\partial \Omega| = \text{surface area of } \partial \Omega.
\]
Then there exists a constant $\beta > 0$ that depends on $\beta_1, \ldots, \beta_J$ such that if
\[
\frac{\delta d^2}{|\partial \Omega|} \beta > k^3 (1 + (\delta k)^2) \sqrt{1 + 2 (\delta k)^2},
\]
then, for $j = 1, \ldots, J$, identity (13) holds in the sense of convergence in $H^1_{\text{loc}} (\mathbb{R}^n \setminus \Omega_j)$.

As is clear, Theorem 2 establishes convergence of the series (13) for non-trapping obstacles only if the wavenumber $k$ is sufficiently small. Work on rigorous justification of the convergence of Neumann series (8) (and thus of identity (13)) in high-frequency applications, on the other hand, reduces to our work [20] and [5] that relates to a finite collection of smooth strictly convex (and thus non-trapping in the sense of Theorem 2) obstacles in two- and three-dimensions, respectively. Indeed, as we have shown in [20, 5], the Neumann series (8) can be rearranged into a sum over primitive periodic orbits and a precise (asymptotically geometric) rate of convergence $\mathcal{R}_p$ (where $p$ is the period of the orbit), that depends only on the relative geometry of the obstacles $\Omega_j$, can be derived on each periodic orbit in the asymptotic limit as $k \to \infty$.

To review these results, for the sake of simplicity of exposition, we assume that the scatterer $\Omega$ consists only of two smooth strictly convex obstacles $\Omega_1$ and $\Omega_2$ in which case there are only two (primitive) periodic orbits (initiating from each $\Omega_j$ and traversing the obstacles in a 2-periodic manner) and relation (10) is equivalent to
\[
D \eta^m = f^m, \quad (m \geq 0),
\]
where
\[
f^0 = f = 2 (\partial_n + ik) u^{inc}, \quad \text{on } \partial \Omega,
\]
and, for $m \geq 1$,
\[
f^m = \begin{bmatrix} 0 & S_{12} \\ S_{21} & 0 \end{bmatrix} \eta^{m-1}.
\]
In connection with identity (14), Theorem 1 implies in two-dimensional configurations that, given any $k_0 > 0$, there exists $C_{k_0} > 0$ such that for any $k \geq k_0$
\[
\| \eta^{m+2} - \mathcal{R} \eta^m \|_{L^2(\partial \Omega)} \leq C_{k_0} \| f^{m+2} - \mathcal{R} f^m \|_{L^2(\partial \Omega)}
\]
holds for any constant $\mathcal{R} \in \mathbb{C}$, and thus the aforementioned geometric rate of convergence of the Neumann series (8) is directly linked with that of the right-hand sides $f^m$. Indeed, assuming that the incidence is a plane-wave $u^{inc}(x) = e^{ik \alpha \cdot x}$ with direction $\alpha$ ($|\alpha| = 1$) with respect to which the obstacles $\Omega_1$ and $\Omega_2$ satisfy the no-acclusion condition (which amounts to requiring that there is at least one ray with direction $\alpha$ that passes between $\Omega_1$ and $\Omega_2$ without touching them), denoting by $a_j \in \partial \Omega_j$ the uniquely determined points minimizing the distance between $\Omega_1$ and $\Omega_2$, and setting $d = |a_1 - a_2|$, we have the following relation among the leading terms $f^m_A$ in the asymptotic expansions of $f^m$ which extends our analyses in [20, 5] to the case of CFIE.

Theorem 3 There exist constants $C = C (\Omega, \alpha) > 0$, $0, \delta = \delta (\Omega, \alpha) \in (0, 1)$, and $\mathcal{R}_2 = \mathcal{R}_2 (\Omega, k) \in \mathbb{C}$ with the property that, for all $m \geq 1$,
\[
\| f^{m+2}_A - \mathcal{R}_2 f^m_A \|_{L^2(\partial \Omega)} \leq C k \delta^m.
\]
The constant $R_2$ is given in two-dimensional configurations by

$$R_2 = e^{2ikd} \left( \sqrt{(1 + d\kappa_1)(1 + d\kappa_2)} \times \left[ 1 + \sqrt{1 - \left( (1 + d\kappa_1)(1 + d\kappa_2) \right)^{-1}} \right]^{-1} \right)$$

where $\kappa_j$ is the curvature at the point $a_j$; and in three-dimensional configurations

$$R_2 = e^{2ikd} \left( \sqrt{\det \left[ (I + d\kappa_1) (I + d\kappa_2) \right]} \times \det \left[ I + \sqrt{I - [T (I + d\kappa_1) T^{-1} (I + d\kappa_2)]^{-1}} \right]^{-1} \right)$$

where $I$ is the identity matrix,

$$\kappa_j = \begin{bmatrix} \kappa_1(a_j) & 0 \\ 0 & \kappa_2(a_j) \end{bmatrix}$$

is the matrix of principal curvatures at the point $a_j$, and $T$ is the rotation matrix determined by the relative orientation of the surfaces $\partial\Omega_j$ at the points $a_j$.

**Proof.** Assume first that the dimension is $n = 2$. Writing $f^m = [f_1^m \ f_2^m]^t$ and $f^m_A = [f_{A,1}^m \ f_{A,2}^m]^t$, it suffices to show that, for $\ell = 1, 2$,

$$\|f_{A,\ell}^{m+2} - \mathcal{R}_2 f_{A,\ell}^m\|_{L^2(\partial\Omega_\ell)} \leq C_\ell k \delta^m$$

for some constant $C_\ell = C_\ell (\Omega, \alpha)$. On the other hand, [20, Theorems 3.4 and 4.1] display that (a more general version of) this estimate holds on any compact subset of the illuminated regions (see the next section for a precise definition of these regions) when $f_{A,\ell}^{m+2}$ and $f_{A,\ell}^m$ are replaced by the leading terms $\eta_{A,\ell}^{m+1}$ and $\eta_{A,\ell}^{m-1}$ in the asymptotic expansions of $\eta_{A,\ell}^{m+1}$ and $\eta_{A,\ell}^{m-1}$. Finally applying the stationary phase lemma [22] to each component of identity (15), the same techniques used to prove [20, Theorem 4.1] delivers estimate (18). In case $n = 3$, the argument is the same and is based upon [5, Theorems 3.3 and 4.3].

Although Theorem 3 is valid under the no occlusion condition, extensive numerical tests in [20, 5] display that the conclusion of Theorem 3 is valid not only when this condition is violated but also when the convexity assumption is conveniently relaxed.

**Remark 4** In light of estimates (16)-(17), for $M \gg \log k$, we have

$$\eta = \sum_{m=0}^{\infty} \eta^m \sim \sum_{m=0}^{M} \eta^m + (\eta^{M+1} + \eta^{M+2}) \sum_{m=0}^{\infty} \mathcal{R}_2^m$$

which signifies that the Neumann series converges with the geometric rate $\mathcal{R}_2$. Note however that, as the distance between the obstacles $\Omega_1$ and $\Omega_2$ decreases to zero, $|\mathcal{R}_2|$ increases to 1, and thus convergence of the Neumann series significantly deteriorates.

The same remark is valid when the configuration consists of more than two subscaterers and involves at least one pair of nearby obstacles. Indeed, as we have shown in [20, 5], this is also completely transparent from a theoretical point of view since, in this case, the Neumann series can be completely dismantled into single-scattering effects and rearranged into a sum over primitive periodic orbits including, in particular, 2-periodic orbits.

The next section is devoted to the description of how we adopt the high-frequency integral equation method in [14] to the evaluation of iterates arising in our Krylov subspace approach and also in its preconditioning through Kirchhoff approximations. As explained in the introduction, the strength of the work in [14] is due to retaining information on the phases of multiple scattering iterations, and therefore our Krylov subspace and Kirchhoff preconditioning strategies are also designed to posses the same property.
4 High-frequency integral equations for multiple scattering configurations

For simplicity of exposition we continue to assume that the obstacle \( \Omega \) consists only of two disjoint subscatterers \( \Omega_1 \) and \( \Omega_2 \). In what follows, for \( j, j' \in \{1, 2\} \), we will always assume that \( j \neq j' \). In this case, relation (14) can be written, for \( j = 1, 2 \), in components as

\[
(I - S_{jj}) \eta^0_j = f^0_j \quad \text{on} \quad \partial \Omega_j,
\]

and

\[
(I - S_{jj}) \eta^m_j = S_{jj'} \eta^{m-1}_{j'} \quad \text{on} \quad \partial \Omega_j,
\]

for \( m \geq 1 \). As identity (19) displays, \( \eta^0_j \) is exactly the surface current generated by the incidence \( u_{\text{inc}} \) on \( \partial \Omega_j \) ignoring interactions between \( \Omega_1 \) and \( \Omega_2 \). Similarly, for \( m \geq 1 \), equation (20) depicts that \( \eta^m_j \) is precisely the surface current generated by the field \( u^{m-1}_{j'} \) (note that \( S_{jj'} \eta^{m-1}_{j'} = 2(\partial \nu + ik) u^{m-1}_{j'} \)) acting as an incidence on \( \partial \Omega_j \) ignoring, again, interactions between \( \Omega_1 \) and \( \Omega_2 \). Therefore identities (19) and (20) entail that the Neumann series (8) completely dismantles the single scattering contributions and allows for a representation of the surface current \( \eta \) as a superposition of these effects. More importantly, in geometrically relevant configurations, these observations allow us to predetermine the phase \( \phi^m_j \) of \( \eta^m_j \) and express it as the product of a highly oscillating complex exponential modulated by a slowly varying amplitude in the form

\[
\eta^m_j = e^{ik \varphi^m_j} \eta^{m, \text{slow}}_j
\]

and this, in turn, grants the frequency-independent solution of equations (19)-(20) as described in (14). To review the algorithm in (14) and set the stage in the rest of the paper, we first describe the phase functions \( \varphi^m_j \) in combination with the various regions they determine on the boundary of the scatterers, and we present one of the main results in (20) (5) that displays the asymptotic characteristics of the amplitudes \( \eta^{m, \text{slow}}_j \).

Indeed, in case the obstacles \( \Omega_1 \) and \( \Omega_2 \) are convex and satisfy the no occlusion condition with respect to the direction of incidence \( \alpha \), the phase \( \varphi^m_j \) in (21) is given by

\[
\varphi^m_j = \begin{cases} 
\phi^m_j, & \text{if } m \text{ is even,} \\
\phi^m_{j'}, & \text{if } m \text{ is odd.}
\end{cases}
\]

Here, for any of the two obstacle paths \( \{\Gamma^m_{\ell}\}_{m \geq 0} \) and \( \{\Gamma^m_2\}_{m \geq 0} \) defined by

\[
\Gamma^{2m}_{\ell} = (\partial \Omega_1, \partial \Omega_2) \quad \text{and} \quad \Gamma^{2m+1}_{\ell} = (\partial \Omega_2, \partial \Omega_1)
\]

for all \( m \geq 0 \), the geometrical phase \( \phi^m_\ell \) at any point \( x \in \Gamma^m_\ell \) \( (\ell = 1, 2) \) is uniquely defined as (20) (5)

\[
\phi^m_\ell(x) = \begin{cases} 
\alpha \cdot x, & m = 0, \\
\alpha \cdot \lambda^m_0(x) + \sum_{r=0}^{m-1} |\lambda^m_r(x) - \lambda^m_{r+1}(x)|, & m \geq 1,
\end{cases}
\]

where the points \( \{\lambda^m_0(x), \ldots, \lambda^m_m(x)\} \in \Gamma^m_1 \times \cdots \times \Gamma^m_\ell \) are specified by

(a) \( \lambda^m_0(x) = x \),
(b) \( \alpha \cdot \nu(\lambda^m_0(x)) < 0 \),
(c) \( (\lambda^m_{r+1}(x) - \lambda^m_{r}(x)) \cdot \nu(\lambda^m_{r}(x)) > 0 \),
(d) \( \frac{\lambda^m_{r+1}(x) - \lambda^m_{r}(x)}{|\lambda^m_{r+1}(x) - \lambda^m_{r}(x)|} = \alpha - 2 \alpha \cdot \nu(\lambda^m_0(x)) \nu(\lambda^m_0(x)) \),
(e) \( \frac{\lambda^m_{r+1}(x) - \lambda^m_{r}(x)}{|\lambda^m_{r+1}(x) - \lambda^m_{r}(x)|} = \frac{\lambda^m_{r+1}(x) - \lambda^m_{r}(x)}{|\lambda^m_{r+1}(x) - \lambda^m_{r}(x)|} - 2 \frac{\lambda^m_{r+1}(x) - \lambda^m_{r}(x)}{|\lambda^m_{r+1}(x) - \lambda^m_{r}(x)|} \cdot \nu(\lambda^m_0(x)) \nu(\lambda^m_0(x)) \)
for $0 < r < m$. These conditions simply mean the phase $\phi^m_r(x)$ is determined by the ray with initial direction $\alpha$ sequentially hitting at and bouncing off the points $X^m_r(x)$ ($r = 0, \ldots, m - 1$) according to the law of reflection to finally arrive at $x \in \Gamma^m_\ell$. Moreover, these rays divide $\Gamma^m_\ell$ into two open connected subsets, namely the illuminated regions

$$\Gamma^m_\ell(IL) = \begin{cases} \{ x \in \Gamma^m_\ell : \alpha \cdot \nu(x) < 0 \}, & m = 0, \\ \{ x \in \Gamma^m_\ell : (X^m_\ell(x) - X^m_{\ell-1}(x)) \cdot \nu(x) < 0 \}, & m \geq 1, \end{cases}$$

and the shadow regions

$$\Gamma^m_\ell(SR) = \begin{cases} \{ x \in \Gamma^m_\ell : \alpha \cdot \nu(x) > 0 \}, & m = 0, \\ \{ x \in \Gamma^m_\ell : (X^m_\ell(x) - X^m_{\ell-1}(x)) \cdot \nu(x) > 0 \}, & m \geq 1, \end{cases}$$

and their closures intersect at the shadow boundaries

$$\Gamma^m_\ell(SB) = \begin{cases} \{ x \in \Gamma^m_\ell : \alpha \cdot \nu(x) = 0 \}, & m = 0, \\ \{ x \in \Gamma^m_\ell : (X^m_\ell(x) - X^m_{\ell-1}(x)) \cdot \nu(x) = 0 \}, & m \geq 1, \end{cases}$$

each of which consists of two points in two-dimensional configurations or a smooth closed curve in three-dimensions. In connection with the phase functions $\phi^m_\ell$, illuminated regions $\partial \Omega^m_\ell(IL)$, shadow regions $\partial \Omega^m_\ell(SR)$, and the shadow boundaries $\partial \Omega^m_\ell(SB)$ are then given by

$$\partial \Omega^m_\ell(\cdot) = \begin{cases} \Gamma^m_\ell(\cdot), & m \text{ is even}, \\ \Gamma^m_\ell(\cdot), & m \text{ is odd}. \end{cases}$$

Generally speaking this means that the rays emanating from $\partial \Omega^m_\ell$ return to $\partial \Omega^m_\ell$ after an even number of reflections, and those initiating from $\partial \Omega^m_\ell$ arrive $\partial \Omega^m_\ell$ after an odd number of reflections. Finally let us note that the phase functions $\phi^m_\ell$ are smooth and periodic as they are confined to the boundary of the associated scatterers. The computation of these phases are performed using a spectrally accurate geometrical optics solver. This also allows for a simple and accurate determination of the shadow boundary points and thus the illuminated and shadow regions.

With these definitions we can now state one of the main results in \cite{2005a} that completely clarifies the asymptotic behavior of amplitudes $\eta^m_{\ell, k}$ in \cite{2005a}.

**Theorem 5 (\cite{2005a})** (i) On the illuminated region $\partial \Omega^m_\ell(IL)$, $\eta^m_{\ell, k}$ belongs to the Hörmander class $S^1_{1,0}(\partial \Omega^m_\ell(IL) \times (0, \infty))$ (cf. \cite{2005a}, \cite{2005b}) and admits the asymptotic expansion

$$\eta^m_{\ell, k}(x) \sim \sum_{p \geq 0} k^{1-p} a^m_{\ell, p}(x) \quad (23)$$

where $a^m_{\ell, p}$ are complex-valued $C^\infty$ functions. Consequently, for any $P \in \mathbb{N} \cup \{0\}$, the difference

$$r^m_{\ell, p}(x) = \eta^m_{\ell, k}(x) - \sum_{p=0}^{P} k^{1-p} a^m_{\ell, p}(x) \quad (24)$$

belongs to $S^{-P}_{1,0}(\partial \Omega^m_\ell(IL) \times (0, \infty))$ and thus satisfies the estimates

$$|D^\beta D^\nu_k r^m_{\ell, n}(x, k)| \leq C_{m, \beta, n, S}(1 + k)^{-P-n} \quad (25)$$

on any compact subset $S$ of $\partial \Omega^m_\ell(IL)$ for any multi-index $\beta$ and $n \in \mathbb{N} \cup \{0\}$. 

9
(ii) Over the entire boundary \( \partial \Omega_j \), \( \eta_j^{m,\text{slow}}(x,k) \) belongs to the \( \text{Hörmander class} \ S^{1}_{2/3,1/3}(\partial \Omega_j \times (0, \infty)) \) and admits the asymptotic expansion

\[
\eta_j^{m,\text{slow}}(x,k) \sim \sum_{p,q \geq 0} k^{2/3 - 2p/3 - q} b_{j,p,q}^{m}(x) \Psi^{(p)}(k^{1/3}Z_j^{m}(x)) \tag{26}
\]

where \( b_{j,p,q}^{m}(x) \) are complex-valued \( C^\infty \) functions, \( Z_j^{m}(x) \) is a real-valued \( C^\infty \) function that is positive on \( \partial \Omega_j^{m}(IL) \), negative on \( \partial \Omega_j^{m}(SR) \), and vanishes precisely to first order on \( \partial \Omega_j^{m}(SB) \), and the function \( \Psi \) admits the asymptotic expansion

\[
\Psi(\tau) \sim \sum_{\ell \geq 0} c_\ell \tau^{1-3\ell} \quad \text{as} \quad \tau \to \infty, \tag{27}
\]

and it is rapidly decreasing in the sense of Schwartz as \( \tau \to -\infty \). Note specifically then, for any \( P,Q \in \mathbb{N} \cup \{0\} \), the difference

\[
R^{m}_{P,Q}(x,k) = \eta_j^{m,\text{slow}}(x,k) - \sum_{p,q} k^{2/3 - 2p/3 - q} b_{j,p,q}^{m}(x) \Psi^{(p)}(k^{1/3}Z_j^{m}(x))
\]

belongs to \( S^{1}_{2/3,1/3}(\partial \Omega_j \times (0, \infty)) \), \( \mu = \min\{2P/3, Q\} \), and thus satisfies the estimates

\[
|D^{\beta}_{x} D^{k}_{y} R^{m}_{P,Q}(x,k)| \leq C_{m,\beta,n}(1 + k)^{-\mu - 2n/3 + |\beta|/3} \tag{28}
\]

for any multi-index \( \beta \) and \( n \in \mathbb{N} \cup \{0\} \).

The first main ingredient underlying the algorithm in [14] was the observation that, while \( \eta_j^{m,\text{slow}} \) admits a classical asymptotic expansion in the illuminated region \( \partial \Omega_j^{m}(IL) \) as displayed by equation [23], it possesses boundary layers of order \( \mathcal{O}(k^{-1/3}) \) around the shadow boundaries \( \partial \Omega_j^{m}(SB) \) and rapidly decays in the shadow region \( \partial \Omega_j^{m}(SR) \) as implied by the expansion [26], and the mentioned change in the asymptotic expansions of the function \( \Psi \). Therefore, as depicted in [14], utilizing a cubic root change of variables in \( k \) around the shadow boundaries, the unknown \( \eta_j^{m,\text{slow}} \) can be expressed in a number of degrees of freedom independent of frequency, and this transforms the problem into the evaluation of highly oscillatory integrals.

Indeed, a second main element of the algorithm in [14] is based on the realization that the identity

\[
\frac{d}{dz} H_{0}^{(1)}(z) = -H_{1}^{(1)}(z) \tag{29}
\]

combined with the asymptotic expansions of Hankel functions [3] entails

\[
(\partial_{\nu}(x) + ik) G(x,y) \sim e^{ik|x-y|} \left( e^{-i\pi/4} \left( \frac{k}{2\pi|x-y|} \right)^{1/2} \left( 1 + \frac{x-y}{|x-y|}, \nu(x) \right) \right),
\]

and thus, in light of factorization [21], equations [19]–[20] take on the form

\[
e^{ik\phi_j^{m}(x)} \eta_j^{0,\text{slow}}(x) = \int_{\partial \Omega_j} e^{ik(\phi_j^{m}(y) + |x-y|)} F(x,y) \eta_j^{0,\text{slow}}(y) \, ds(y) = f_j^{0}(x), \quad x \in \partial \Omega_j^{0}, \tag{30}
\]

and, for \( m \geq 1 \),

\[
e^{ik\phi_j^{m}(x)} \eta_j^{m,\text{slow}}(x) - \int_{\partial \Omega_j} e^{ik(\phi_j^{m}(y) + |x-y|)} F(x,y) \eta_j^{m,\text{slow}}(y) \, ds(y)
\]

\[
= \int_{\partial \Omega_j} e^{ik(\phi_j^{m-1}(y) + |x-y|)} F(x,y) \eta_j^{m-1,\text{slow}}(y) \, ds(y), \quad x \in \partial \Omega_j^{m}, \tag{31}
\]
where
\[ F(x, y) = e^{-ik|x-y|} \left( \partial_\nu(x) + ik \right) G(x, y). \]

As depicted in [14], frequency independent evaluations of integrals in (30)-(31) can then be accomplished to any desired accuracy utilizing a localized integration (around stationary points of the combined phase \( \varphi_m(y) + |x-y| \) and/or the singularities of the integrand) procedure based upon suitable extensions of the method of stationary phase.

The third main element of the algorithm in [14] is the use of Nystöm and trapezoidal discretizations and Fourier interpolations to render the method high order, and the scheme is finally completed with a matrix-free Krylov subspace linear algebra solver to obtain accelerated solutions.

While the above discussion provides a brief summary of the algorithm in [14], it clearly signifies the importance of retaining the phase information in connection with the multiple scattering iterations since this allows for a simple utilization of the aforementioned localized integration scheme. Accordingly, any strategy aiming at accelerating the convergence of Neumann series must also preserve the phase information. As we explain, both the novel Krylov subspace method we develop in the next section and its preconditioning discussed in section 6 posses this property.

5 Novel Krylov subspace method for accelerating the convergence of Neumann series

As with the solution of matrix equations, Krylov subspace methods provide a convenient mechanism for the approximate solution of operator equations

\[ A\eta = g \]

in Hilbert spaces (see e.g. [36] and the references therein). These methods are orthogonal projection methods wherein, given an initial approximation \( \eta^0 \) to \( \eta \), one seeks an approximate solution \( \eta^m \) from the affine space \( \eta^0 + K_m \) related with the Krylov subspace

\[ K_m = \text{span} \{ r^0, Ar^0, A^2r^0, \ldots, A^{m-1}r^0 \} \]

of the operator \( A \) associated with the residual \( r^0 = g - A\eta^0 \) imposing the Petrov-Galerkin condition

\[ g - A\eta^m \perp K_m. \]

In connection with the operator equation (6), taking \( \eta^0 = 0 \), the approximate solution \( \eta^m \) belongs to the Krylov subspace

\[ K_m = \text{span} \{ g, (I-T)g, (I-T)^2g, \ldots, (I-T)^m g \} \]

for which, in light of identity (10), the functions \( (I-T)^n g \) can be expressed as linear combinations of the multiple scattering iterations \( \eta^\ell \) through use of the binomial theorem as

\[ (I-T)^n g = \sum_{\ell=0}^{n} \binom{n}{\ell} (-1)^\ell T^\ell g = \sum_{\ell=0}^{n} \binom{n}{\ell} (-1)^\ell \eta^\ell. \] (32)

This relation clearly entails

\[ K_m = \text{span} \{ \eta^0, \ldots, \eta^{m-1} \} \]

and thus, any information about the Krylov subspace \( K_m \) can be obtained in frequency independent computational times using the algorithm briefly described in §4.
A particular Krylov subspace method we favor for the solution of multiple scattering problem is the classical ORTHODIR iteration which, for the initial guess \( \mu^{(0)} = 0 \), takes on the form

1. Set \( r^{(0)} = p^{(0)} = g \).
2. For \( j = 0, 1 \ldots \) DO
   2.1 \( \alpha_j = \langle r^{(j)}, Ap^{(j)} \rangle / \langle Ap^{(j)}, Ap^{(j)} \rangle \),
   2.2 \( \mu^{(j+1)} = \mu^{(j)} + \alpha_j p^{(j)} \),
   2.3 \( r^{(j+1)} = r^{(j)} - \alpha_j Ap^{(j)} \),
   2.4 For \( i = 0, \ldots, j \), \( \beta_{ij} = -\langle A^2 p^{(j)}, Ap^{(i)} \rangle / \langle Ap^{(i)}, Ap^{(i)} \rangle \),
   2.5 \( p^{(j+1)} = Ap^{(j)} + \sum_{i=0}^{j} \beta_{ij} p^{(i)} \).

This iteration entails, through a straightforward induction argument, the following recurrence relation for \( A = I - T \) where \( T \) is the iteration operator specified by equation (7).

**Theorem 6** For \( A = I - T \), the iterates \( p^{(j)} \) generated by the ORTHODIR algorithm satisfy the recurrence relation

\[
p^{(j)} = (I - T)^j p^{(0)} + \sum_{\ell=0}^{j-1} \sum_{i=0}^{\ell} \beta_{\ell \ell} (I - T)^{j-1-\ell} p^{(i)}, \quad j = 0, 1, \ldots \tag{33}
\]

Although this relation can be used in combination with the binomial identity to recursively compute \( p^{(j)} \), this approach is bound to result in numerical instabilities when the distance \( d \) between the obstacles \( \Omega_1 \) and \( \Omega_2 \) is close to zero since, in this case, the asymptotic rate of convergence \( R_2 \) is close to 1.

Concentrating for instance on the term \( (I - T)^j p^{(0)} \), this instability is apparent from the subtractive cancellations in binomial identity (32) upon noting that \( p^{(0)} = g \) and \( \eta^{\ell+2} \sim R_2 \eta^\ell \sim \eta^\ell \) for \( \ell \gg \log k \) by inequality (16) and Theorem 3.

On the other hand, since \( p^{(0)} = g \), a combined use of (32) and (33) clearly shows that the iterates \( p^{(j)} \) generated by the ORTHODIR algorithms can alternatively be computed through the following identification procedure.

**Corollary 7** Each \( p^{(j)} \) is a linear combination of \( \eta^0, \ldots, \eta^j \), say

\[
p^{(j)} = \sum_{i=0}^{j} \gamma_{ij} \eta^i, \tag{34}
\]

this allows for the computation of the next iterate as

\[
p^{(j+1)} = (I - T) p^{(j)} + \sum_{i=0}^{j} \beta_{ij} p^{(i)} = \sum_{i=0}^{j} \gamma_{ij} \eta^i - \sum_{i=0}^{j} \gamma_{ij} \eta^{i+1} + \sum_{i=0}^{j} \beta_{ij} p^{(i)}
= \sum_{i=0}^{j+1} \gamma_{i,j+1} \eta^i \tag{35}
\]

where the new coefficients \( \gamma_{i,j+1} \) are easily computed by identification.

Note specifically that, since the phases of \( \eta^i \) are known, identity (34) allows for a utilization of the localized integration scheme briefly summarized in §4 in the evaluation of inner products in steps 2.1 and 2.4 in the ORTHODIR iteration. On the other hand, the identification procedure (35) provides a numerically stable way of recursively computing \( p^{(j)} \) as it clearly eliminates subtractive cancellations arising from the use of binomial identity (32).
6 Preconditioning using Kirchhoff approximations

Although the novel Krylov subspace approach discussed in the previous section provides an effective mechanism for the accelerated solution of multiple scattering problem (6), this can be further improved if the operator equation (6) is properly preconditioned. Indeed, for an appropriately defined operator \( K \) approximating the iteration operator \( T \), the preconditioned form of equation (6) reads

\[
(I - K)^{-1} (I - T) \eta = (I - K)^{-1} g, \tag{36}
\]

In this connection, we note the following useful alternative.

**Theorem 8**  If the spectral radius \( r(K) \) of \( K \) is strictly less than 1, then the preconditioned equation (36) can be written alternatively as

\[
\left( I - \sum_{\ell=0}^{\infty} K^\ell (T - K) \right) \eta = \sum_{\ell=0}^{\infty} K^\ell g. \tag{37}
\]

**Proof.**  Since \( r(K) < 1 \), we have the Neumann series representation

\[
(I - K)^{-1} = \sum_{\ell=0}^{\infty} K^\ell. \tag{38}
\]

Use of (38) in the identity

\[
(I - K)^{-1} (I - T) = I - (I - K)^{-1} (T - K)
\]

delivers the desired result. \( \blacksquare \)

It is therefore natural to approximate the solution of (6) with the solution of the truncated equation

\[
\left( I - \sum_{\ell=0}^{N} K^\ell (T - K) \right) \eta = \sum_{\ell=0}^{M} K^\ell g \tag{39}
\]

which we shall write as

\[
A_{K,N} \eta = g_{K,M}. \tag{40}
\]

While equation (40) displays the preconditioning strategy we shall utilize for the solution of multiple scattering problem (6), it is clearly amenable to a treatment by the Krylov subspace method developed in the preceding section to further accelerate the solution of problem (6).

As for the requirement that \( K \) has to approximate the iteration operator \( T \), we recall that each application of \( T \) corresponds exactly to the evaluation of the surface current on each of the obstacles \( \Omega_1 \) and \( \Omega_2 \) generated by the fields scattered from, respectively, \( \Omega_2 \) and \( \Omega_1 \) at the previous reflection as depicted by the identity

\[
\begin{bmatrix}
\eta_1^{m-1} \\
\eta_2^{m-1}
\end{bmatrix} = T \begin{bmatrix}
\eta_1^{m} \\
\eta_2^{m}
\end{bmatrix} = \begin{bmatrix}
0 & (I - S_{11})^{-1} S_{12} \\
(I - S_{22})^{-1} S_{21} & 0
\end{bmatrix} \begin{bmatrix}
\eta_1^{m-1} \\
\eta_2^{m-1}
\end{bmatrix}.
\]

It is therefore reasonable to define the operator \( K \) in the form

\[
K = \begin{bmatrix}
0 & K_{12} \\
K_{21} & 0
\end{bmatrix}
\]
and require that $\eta_j^m \approx K_{jj'} \eta_{j'}^{m-1}$. Accordingly, the operators $K_{jj'}$ must retain the phase information to preserve the frequency independent operation count while, concurrently, providing a reasonable approximation to the slow densities to guarantee an accurate preconditioning. This requirement can be satisfied only if the operators $K_{jj'}$ are defined in a dynamical manner so as to respect the information associated with the iterates, and this distinguishes our preconditioning strategy from classical approaches where the preconditioners are steady by design. The most natural approach is to design the operators $K_{jj'}$ so that they yield the classical Kirchhoff approximations as these preserve the phase information exactly and approximate $\eta_j^{m, \text{slow}}$ with the leading term in its asymptotic expansion. Concentrating on two-dimensional settings, in this connection, a basic relation we exploited in [20] was the observation that while, on the one hand, this term coincides with that of twice the normal derivative of $u_j^{m-1}$ in [12] on the illuminated region $\partial \Omega_j^m(\text{IL})$, and on the other hand, identity (29) combined with asymptotic expansions of Hankel functions [3] entails

$$\partial_\nu(x, y) G(x, y) \sim e^{ik|x-y|} \left( e^{-i\pi/4} \sqrt{\frac{k}{2\pi|x-y|}} \cdot \nu(x) \right) \quad (41)$$

so that use of (41) in (12) yields

$$2 \partial_\nu(x) \eta_j^{m-1}(x) \sim \int_{\partial \Omega_j} \frac{k}{2\pi} e^{ik(\psi_j^{m-1}(y)+|x-y|)-i\pi/4} \eta_{j'}^{m-1, \text{slow}}(y) F(x, y) \, ds(y), \quad x \in \partial \Omega_j, \quad (42)$$

where

$$F(x, y) = \frac{1}{\sqrt{|x-y|}} \cdot \nu(x). \quad (43)$$

As for the oscillatory integral in (42), as we have shown in [20], it is treatable through an appropriate use of stationary phase method [22] which states that the main contribution to an oscillatory integral comes from the stationary points of the phase.

**Lemma 9 (Stationary phase method)** Let $\psi \in C^\infty[a, b]$ be real valued, and let $h \in C^\infty_0[a, b]$. Suppose that $t_0$ is the only stationary point of $\psi$ in $(a, b)$, $\psi''(t_0) \neq 0$, and $\sigma = \text{sign} \psi''(t_0)$. Then there exists a constant $C$ such that, for all $k > 1$,

$$\left| \int_a^b e^{ik\psi(t)} h(t) \, dt - e^{ik\psi(t_0) + i\pi\sigma/4} h(t_0) \sqrt{\frac{2\pi}{k|\psi''(t_0)|}} \right| \leq C k^{-1} ||h||_{C^2[a, b]}.$$ 

Indeed, it turns out [20] that the combined phase function

$$\phi_j^{m-1}(x, y) = \phi_j^{m-1}(y) + |x-y|$$

has two stationary points, one in the shadow region $\partial \Omega_j^{m-1}(\text{SR})$ with a contribution of $O(k^{-n})$ (for all $n \in \mathbb{N}$) due to rapid decay of the amplitude $\eta_j^{m-1, \text{slow}}$, and another one in the illuminated region $\partial \Omega_j^{m-1}(\text{IL})$ given by $y(x) = \chi_j^{m-1}(x)$ (at which the combined phase has a positive “second derivative”) whose contribution agrees, to leading order, with that given by stationary phase evaluation of the integral in [12]. While this discussion clarifies how Kirchhoff operators $K_{jj'}$ must be designed so that they yield the leading terms in the asymptotic expansions of $\eta_j^m$ on the illuminated regions $\partial \Omega_j^m(\text{IL})$ at each iteration, the rapid decay of $\eta_j^m$ in the shadow region $\partial \Omega_j^m(\text{SR})$, in turn, provides the motivation that $K_{jj'}$ must simply approximate $\eta_j^m$ by zero in these regions. Being aware of these, we use $\gamma_j(t_j) = (\gamma_j^1(t_j), \gamma_j^2(t_j))$ to denote the arc length parametrazation of $\partial \Omega_j$ (in the counterclockwise orientation) with period $L_j$ ($j = 1, 2$) so that, for each $x_j \in \partial \Omega_j$, $t_j$ is the unique point in $[0, L_j)$ with $\gamma_j(t_j) = x_j$, and define the Kirchhoff operators $K_{jj'}$ as follows.
Definition 10 For a smooth phase \( \phi_{j'} : \partial \Omega_{j'} \to \mathbb{R} \) having the property that, for each \( x_j \in \partial \Omega_j \), the function \( \phi_{j,j'} : \partial \Omega_j \times \partial \Omega_{j'} \to \mathbb{R} \) given by

\[
\phi_{j,j'}(x_j, x_{j'}) = \phi_{j'}(x_{j'}) + |x_j - x_{j'}|
\]

has a unique stationary point \( y_{j'} = x_{j'}(x_j) \in \partial \Omega_{j'} \) such that \( [x_j, y_{j'}] \cap \partial \Omega_{j'} = y_{j'} \), define the transformed phase \( \phi_j : \partial \Omega_j \to \mathbb{R} \) by setting

\[
\phi_j(x_j) = \phi_{j,j'}(x_j, y_{j'}).
\]

Assume further \( \phi_{j,j'}(t_j, t_{j'}) = \phi_{j,j'}(x_j, x_{j'}) \) has \( \partial^2_{t_j, t_{j'}} \phi_{j,j'}(t_j, t_{j'}) > 0 \) at \( t_{j'} = \gamma^{-1}_{j'}(y_{j'}) \) and for a given amplitude \( A_{j'} : \partial \Omega_{j'} \to \mathbb{C} \), define the transformed amplitude \( A_j : \partial \Omega_j \to \mathbb{C} \) by setting

\[
A_j(x_j) = \begin{cases} 
B_j(x_j), & \text{if } [x_j, y_{j'}] \cap \partial \Omega_j = \{x_j\}, \\
0, & \text{otherwise},
\end{cases}
\]

where, with the function \( F \) as defined in (36),

\[
B_j(x_j) = A_{j'}(y_{j'}) F(x_j, y_{j'}) (\partial^2_{t_j, t_{j'}} \phi_{j,j'}(t_j, t_{j'}))^{-1/2}.
\]

Finally, define the Kirchhoff operator \( K_{j,j'} \) by setting

\[
K_{j,j'}(\phi_{j'}, A_{j'}) = (\phi_j, A_j).
\]

We abbreviate identity (44) as

\[
K_{j,j'}(e^{ik\phi_{j'}}, A_{j'}) = e^{ik\phi_j}, A_j,
\]

and extend \( K_{j,j'} \) by linearity so that

\[
K_{j,j'}(\sum_{\ell=0}^N e^{ik\phi_{j'}} A_{j'}^\ell) = \sum_{\ell=0}^N K_{j,j'}(e^{ik\phi_{j'}} A_{j'}^\ell).
\]

In connection with the requirement that the operators \( K_{j,j'} \) must retain the phase information exactly while providing a reasonable approximation to the slow densities, we note that

\[
K_{j,j'}(e^{ik\phi_{j}} e_{j'}^{m-1 \text{, slow}})(x) = e^{ik\phi_j} e_{j}^{m} (x) \lambda_j^{m, \text{slow}}(x), \quad x \in \partial \Omega_j,
\]

where, with \( F \) as given in (36),

\[
\lambda_j^{m, \text{slow}}(x) = \begin{cases} 
\eta_j^{m-1, \text{slow}}(x, y_{j'}) \cdot F(x, y_{j'}) (\partial^2_{t_j, t_{j'}} \phi_{j,j'}(t_j, t_{j'}))^{-1/2}, & x \in \partial \Omega_j^m(\text{IL}), \\
0, & \text{otherwise},
\end{cases}
\]

so that \( K_{j,j'} \) preserves the phase information, and the leading term in the asymptotic expansion of \( \lambda_j^{m, \text{slow}} \) agrees with that of \( \eta_j^{m, \text{slow}} \) in the illuminated region \( \partial \Omega_j^m(\text{IL}) \) as desired (cf. [20] Theorems 3.3 and 3.4]).

As for the alternative form \( \eta_j^{m, \text{IL}} \) of the preconditioned equation (36), we have the following result.

Theorem 11 Suppose that the obstacles \( \Omega_1 \) and \( \Omega_2 \) satisfy the no-occlusion condition with respect to the direction of incidence \( \alpha \). Considering any given function \( h \in C(\partial \Omega) \) as \( h(x) = e^{ik\alpha \cdot x} h_0(x) \), the series

\[
\sum_{\ell=0}^{\infty} \|K_\ell h\|_\infty
\]

converges for all \( k > 0 \).
Proof. The same technique used to prove [20] Theorem 4.1 entails the existence of constants $C = C(\Omega, \alpha) > 0$ and $\delta = \delta(\Omega, \alpha) \in (0, 1)$ such that, for all $\ell \in \mathbb{Z}_+$,

$$\|K^{\ell+2}h - R_2K^\ell h\|_\infty \leq \delta^\ell \left( \min \left\{ 2, \exp \left( Ck \delta^\ell \right) - 1 \right\} \delta^2 + C \delta^{\ell - 2} \right) \|h\|_\infty$$

which yields

$$\|K^{\ell+2}h - R_2K^\ell h\|_\infty \leq \delta^\ell \left( 2\delta^2 + C \delta^{\ell - 2} \right) \|h\|_\infty.$$ 

Using $C = C(\Omega, \alpha)$ to denote a positive constant whose value may be different at each appearance in what follows, this inequality clearly implies

$$\|K^{\ell+2}h - R_2K^\ell h\|_\infty \leq C \delta^\ell \|h\|_\infty.$$ 

Since $|R_2| < 1$, choosing $\delta$ larger, if necessary, we may assume that $\delta^2 \in (|R_2|, 1)$. In this case, the preceding inequality yields, for $\ell \in \mathbb{Z}_+$ and $m = 0, 1$,

$$\|K^{m+2\ell}h\|_\infty \leq \|R_2^mK^\ell h\|_\infty + \sum_{j=0}^{\ell-1} \|R_2^{\ell-(j+1)}K^{m+2(j+1)}h - R_2^{\ell-j}K^{m+2j}h\|_\infty$$

$$= |R_2|^{\ell} \|K^m h\|_\infty + \sum_{j=0}^{\ell-1} |R_2|^{\ell-(j+1)} \|K^{m+2(j+1)}h - R_2^{\ell-j}K^{m+2j}h\|_\infty$$

$$\leq |R_2|^{\ell} \|K^m h\|_\infty + C \sum_{j=0}^{\ell-1} |R_2|^{\ell-(j+1)} \delta^{m+2j} \|h\|_\infty$$

$$= |R_2|^{\ell} \|K^m h\|_\infty + \delta^m \frac{|R_2|^{\ell}}{|R_2|} - \delta^{2\ell} \|h\|_\infty$$

$$\leq \delta^m \delta^{2\ell} \|K^m h\|_\infty + C \delta^{m+2\ell} \|h\|_\infty.$$ 

Since, we clearly have $\|K^m h\|_\infty \leq C\|h\|_\infty$ for $m = 0, 1$, we conclude

$$\|K^{m+2\ell}h\|_\infty \leq C (\delta^m + \delta^{m+2\ell}) \|h\|_\infty \leq C \delta^{m+2\ell} \|h\|_\infty,$$

and this gives, for all $\ell \in \mathbb{Z}_+$,

$$\|K^\ell h\|_\infty \leq C \delta^\ell \|h\|_\infty.$$  \hspace{1cm} (47)

Thus the result.  \hspace{1cm} \blacksquare 

Remark 12 Considering $K$ as an operator $K : C(\partial \Omega) \to C(\partial \Omega)$, inequality (47) implies

$$r(K) = \lim_{\ell \to \infty} \|K^\ell\|_\infty^{1/\ell} \leq \delta < 1$$

for the spectral radius of $K$, and this explains the sense in which identity (37) in Theorem 8 holds.

In connection with the application of the ORTHODIR iteration to the preconditioned equation (49), setting $\varphi^m = [\varphi_1^m, \varphi_2^m]^\ell$ and using $\mu^\ell (\ell = 0, 1, \ldots)$ to denote generic functions defined on $\partial \Omega$ which may be different from line to line, we thus see through equations (45)-(46) that

$$p^{(0)} = g_{\kappa, M} = \sum_{\ell=0}^{N} K^\ell g = \sum_{\ell=0}^{M} K^\ell (e^{ik}\varphi^0, q_0, \text{slow})$$

is of the form

$$p^{(0)} = \sum_{\ell=0}^{M} e^{ik}\varphi^\ell \mu^\ell.$$  \hspace{1cm} (48)

More generally, we have the following result.
Theorem 13 For $j = 0, 1, 2, \ldots$, the ORTHODIR iterates $p^{(j)}$ are of the form

$$p^{(j)} = \sum_{\ell=0}^{M+j(N+1)} e^{ik\ell} \mu^\ell.$$  \hspace{1cm} (49)

Proof. This follows by a straightforward induction based on equations (45)-(46), (48) and the recursion

$$p^{(j+1)} = A_{\kappa,N} p^{(j)} + \sum_{i=0}^{j} \beta_{ij} p^{(i)} = \left( I - \sum_{\ell=0}^{N} \kappa^\ell \left( \mathcal{T} - \mathcal{K} \right) \right) p^{(j)} + \sum_{i=0}^{j} \beta_{ij} p^{(i)}.$$ \hspace{1cm} (50)

The main point behind this theorem is that use of (49) in (50) clearly allows for an application of the aforementioned localized integration scheme in connection with the execution of the operator $\mathcal{T}$ in (50). Moreover, it is clear that each realization of the Kirchhoff operator $\mathcal{K}$ is frequency independent. Consequently, the preconditioned equation (39) is amenable to a treatment by the Krylov subspace method described in §5 to obtain even more accelerated solutions of the multiple scattering problem (6) while still retaining the frequency independent operation count if desired.

7 Numerical implementations

Here we present numerical examples that display the benefits of our Krylov subspace approach as well as its preconditioning through use of Kirchhoff approximations. To this end, we have designed two different test configurations (see Fig. 1). First we have considered two circles illuminated by a plane-wave incidence coming in from the left with wavenumber $k = 200$. While the radii of the circles are 1 and 1.5, they are centered at the origin and $(0, 0.9625, -2.6444)$ respectively. Second we have treated a configuration consisting of two parallel elliptical obstacles with centers at $(0, 0)$ and $(0, -4.5)$, and major/minor axes 10/1 and 7/2. The illumination is provided by a plane wave with direction along the major axes and wavenumber $k = 40$.

Figure 2 provides a comparison of (a) the Neumann series, (b) the Padé approximants, (c) the Krylov subspace method based on a combined use of binomial formula (32) and identity (33), and (d) the alternative implementation of the latter based on decomposition (34) leading to equation (35).
precisely, Figure 2 depicts the number of reflections versus the logarithmic $L^2$ error

$$\log_{10}\|\eta - \hat{\eta}\|_2$$

between the exact solution $\eta$ and the approximations $\hat{\eta}$ obtained by the four aforementioned schemes. In both cases, the reference solution $\eta$ is computed using an integral solver with sufficiently many discretization points to guarantee 14 digits of accuracy. As we anticipated, combined use of binomial formula (32) and identity (33) suffers from subtractive cancellations and fails to approximate the solution as the number of reflections increases. The implementation of Krylov subspace method based on decomposition (34) and resulting equation (35) clearly resolves this issue. Furthermore, when compared with the Padé approximants considered in [14], approximations provided by this alternative implementation of the Krylov subspace method are more stable and give better accuracy at each iteration. Incidentally, note specifically that a direct use of Neumann series would require about $77/522$ iterations to obtain 12 digits of accuracy for circular/elliptical configurations in Figure 1 and thus our Krylov subspace approach provides savings of 78%/87% in the required number of reflections.

Finally, in Figure 3 we display a comparison of (a) the Neumann series, (b) the stable implementation of our Krylov subspace approach based on decomposition (34) and equation (35), and (c) Kirchhoff preconditioning of the latter. Note precisely that (c) is based on the Krylov subspace iterations (described in §5) applied to the truncated version (40) of preconditioned form (47) of the multiple scattering problem (6) utilizing the Kirchhoff operator $K$. In our implementations we have taken $N = M$ in equation (40) and used $N = 12/40$ for the circular/elliptical configurations in Figure 1. As depicted in Figure 3, in both cases only three ORTHODIR iterations are sufficient to obtain 3−digits of accuracy which would require 20/100 iterations if Neumann series is directly used. The fact that the error does not attain the machine precision is due to the truncation of the series used to compute the preconditioner ($N = 12/40$). Obviously inclusion of more terms yields better accuracy but at the expense of slightly more expansive numerics.

8 Conclusion

We have developed an acceleration strategy for the solution of multiple scattering problems based on a novel and effective use of Krylov subspace methods that retains the phase information and provides significant savings in computational times. Further, we have coupled this approach with an original preconditioning strategy based upon Kirchhoff approximations that greatly reduces the number of iterations needed to obtain a prescribed accuracy. In the forthcoming work, we will extend this numerical algorithm for configurations of more than two obstacles. Indeed, our new Krylov method can be easily applied to this kind of configurations without adding any additional computational cost. On the other
hand, although the Kirchhoff preconditioner greatly enhances the convergence of the Krylov subspace method for two obstacles, its utilization for several obstacles requires some numerical optimization.
