**ABSTRACT**

We report simultaneous UBVRI photo-polarimetric observations of the long period (7.98 h) AM Her binary V1309 Ori. The length and shape of the eclipse ingress and egress varies from night to night. We suggest this is due to the variation in the brightness of the accretion stream. By comparing the phases of circular polarization zero-crossovers with previous observations, we confirm that V1309 Ori is well synchronized, and find an upper limit of 0.002 percent for the difference between the spin and orbital periods. We model the polarimetry data using a model consisting of two cyclotron emission regions at almost diametrically opposite locations, and centered at colatitude $\beta = 35^\circ$ and $\beta = 145^\circ$ on the surface of the white dwarf. We also present archive X-ray observations which show that the negatively polarised accretion region is X-ray bright.

**Key words:** stars:individual: V1309 Ori – stars: magnetic fields – novae, cataclysmic variables – white dwarfs: stars

**1 INTRODUCTION**

The X-ray source RX J0515.6+0105 (V1309 Ori) was preliminarily identified in the ROSAT All Sky Survey as a Cataclysmic Variable (CV) with an orbital period of $\sim 8$ hrs (Beuermann & Thomas 1993). Garnavich et al. (1994) showed that V1309 Ori has properties which are typical of magnetic CVs (mCVs). They also found a deep total eclipse in the light curves. Pointed X-ray observations made using ROSAT (Walter, Wolk & Adams 1995) showed extremely variable X-ray emission in short bursts (up to few seconds), suggesting inhomogeneous accretion of dense blobs. Detection of variable circular polarization in white light by Buckley & Shafter (1995) confirmed the classification of V1309 Ori as an AM Her star (synchronised mCVs).

The orbital period of V1309 Ori 7.98 h is $\sim 3$ hours longer than in any other known AM Her system. Three AM Hers are known to have periods over 4 hours (RX J1313–32: 4.25 h; AI Tri: 4.59 h; V895 Cen: 4.77 h; Ritter & Kolb 1998). The exceptionally long orbital period indicates that the separation between the primary and the secondary is large for mCV. According to Patterson’s (1994) scaling law, magnetic field strengths up to 150 – 730 MG should be required to synchronize the spin of the white dwarf with the rotation of the binary system, assuming a mass for the white dwarf $M_{WD}=0.6-1.0 M_\odot$ (Shafter et al 1995). However, spectroscopic studies have given significantly lower magnetic field values: 33 – 55 MG Garnavich et al. (1994); 61 MG Shafter et al. (1995); $< 70$ MG de Martino et al. (1998). Frank, Lasota & Chanmugam (1995) have proposed that these low magnetic field values can be understood in terms of the standard evolutionary model, if the system is in a low accretion state for a long enough time or if the magnetic field of the secondary is strong enough ($> 1$G) to maintain synchronism. For these reasons, V1309 Ori is one of the most important objects for studying synchronization and accretion processes in mCVs and their evolution. In this paper we present the results and analysis of our polarimetric, photometric and spectroscopic observations of this system.

2 OBSERVATIONS

Photo-polarimetric observations were made at the NOT (Nordic Optical Telescope, La Palma) using the Turpol-photo-polarimeter in October and November 1997 (see table 1 for the log of observations). Observations were also made on December 1997 and January 1998 with the 2.15 m CASLEO-telescope (Argentina) using the Turin-photo-polarimeter. This instrument at CASLEO is almost identical to the Turpol at the NOT.

The polarimeters have four dichroic filters, splitting the light into UBVRI bands. The time resolution for photometric data is 24 sec. One polarization measurement consists of eight integrations and takes ~3 minutes. Instrumental polarization was eliminated by using a calcite plate as a beam splitter. Sky background polarization was eliminated by using the double beam spectrograph using 600 lines/mm gratings. The effective wavelength coverage is 3800–5000 Å and 6200–7500 Å in the blue and red arms of the spectrograph, respectively. The conditions were photometric throughout the observations, and the effective resolution as measured from the FWHM of the arc lines was 2.1 Å. The exposure time was 300 sec for both blue and red spectra. Wavelength calibration of the flat-fielded and bias-subtracted two dimensional images was performed using He-Ar arc spectra taken at various points during the night.

The photometric ephemeris of Staude, Schwope & Schwarz (2001) (their equation (1)) is used to phase the data throughout the paper.

3 PHOTOMETRY

During our observations V1309 Ori was in a high accretion state (V=16), as found also in earlier photometric studies (Garnavich et al. 1994; Shafter et al. 1995). In Figure 1 we present simultaneous UBVRI light curves covering nearly the full orbital cycle, obtained on November 24/25, 1997, at the NOT. We show the circular polarisation data in Figure 2 and the linear polarisation data in Figure 3.

The most distinctive feature of the intensity curves (Figure 1) is the well known deep eclipse which has a duration of ~0.1 orbital phase and also a strong colour dependence (up to ~4 mag in U, and less than 1 mag in I). Flux variations outside the eclipse are about 1.5 mag in the U-band and about one magnitude in the BVR bands. Light curves show two local brightness maxima, at orbital phases Φ = 0.2 and Φ = 0.7.

There is a clear asymmetry between these two maxima: in the U-band the first peak near Φ = 0.2 is about 0.5 mag brighter than observed at Φ = 0.7, whereas in the B- and
3.1 The eclipse

The eclipse profiles of V1309 Ori are unusual compared to other eclipsing AM Her stars such as HU Aqr or UZ For: the ingress and egress of the eclipse are very shallow and have large night to night variations (Figure 5). This suggests that there is an unusually prominent stream component. We have analyzed the colours of the ‘extra’ emission defined as the flux difference between the shallowest (most disturbed) eclipse and the widest (cleanest) flat bottom light curve (Figure 5). The resulting colour indices for the additional flux \((U - B)_{e} = -1.0\), \((B - V)_{e} = 0.1\), and \((V - R)_{e} = 0.5\), match the (stream dominated) colours of V1309 Ori outside the eclipse. This supports the view that that eclipse

shape variations are caused by variations in the brightness or trajectory of the accretion stream.

Since the eclipse is composed of an eclipse of the white dwarf and stream, the mid-point of the eclipse may not be a good marker of the inferior conjunction of the secondary. This is clearly showed by Staude et al. (2001), who found that mid-eclipse of the white dwarf occurs 172±20 s earlier than the observed mid-eclipse seen in the light curves.

A more detailed examination of the eclipse profiles (Figure 6) reveals a rapid eclipse ingress of the white dwarf & accretion region between $\Phi = 0.951 - 0.952$, seen for the first time in the optical. This drop is most prominent in data obtained in 7/8 October 1997, while on the other observing nights in October this phenomenon was not as prominent. With a time-resolution of 24 sec, we cannot determine if this rapid drop is due to the eclipse of the hot spot, or the whole white dwarf. The corresponding egress of the white dwarf should take place at $\Phi=1.036$ according Staude et al. (2001). Our data (eg Figure 5), hints at a rise at orbital phase 1.04, although it is far from clear.

Interestingly, time resolved HST UV-spectroscopy by Schmidt & Stockman (2001) revealed a sharp drop in brightness, with duration of 6±2 sec at orbital phase $\Phi = 0.952$, which they identified as the eclipse ingress of hot accretion spot on the surface of the white dwarf. Staude et al. (2001) did not detect the ingress and egress of the white dwarf in their broad band optical photometry, but they re-analyzed the same HST-data on V1309 Ori and concluded that the ingress (duration of 45±30 sec) which occurs at orbital phase

Figure 5. V1309 Ori eclipse profiles ($UBVRI$), between $\Phi = 0.92 - 1.08$. Observations are plotted for two nights showing the largest difference in eclipse width: the 1997 Oct 6/7 (black circles) with the narrowest (most disturbed) eclipse is compared with the widest (flat bottom) light curve obtained on Nov 24/25 (crosses). Variations in the ingress and egress shape indicate different contributions from the extended accretion stream. Dashed lines show the start and end of the white dwarf eclipse according to Staude et al. (2001)
Figure 6. The ingress in $UBV_R$, observed at October 7/8, 1997, with the time resolution of 24 s. The two dashed lines show the place of the ingress between phases $\Phi = 0.951$ and $\Phi = 0.952$. This is the same phase as observed by Schmidt & Stockman (2001) and Staude et al. (2001) in HST far UV-data.

$\Phi = 0.952$ is actually due to the eclipse of the whole white dwarf.

The observed brightness of V1309 Ori during the mid-eclipse in the $V$-band is 17.3 magnitudes and colours: $U - B = 1.3$, $B - V = 0.9$, $V - R = 1.1$, and $R - I = 0.7$. The observed $B - V$ value corresponds to that of a K2 dwarf, whereas other colours ($U - B$, $V - R$, $R - I$) fit better K5, K7 or M0 dwarf (Cox 2000). The orbital period - secondary star relation given by Smith & Dhillon (1998) gives a much earlier spectral type for the secondary (K2-K3). The observed $B - V=0.9$ shows that there is $\sim 50$ per cent more flux in the B-band compared to that expected from a K7 spectral type dwarf. This extra flux might be emitted by an accretion stream which was not completely eclipsed even during the mid-eclipse. However, HST-spectroscopy analyzed by Staude et al. (2001), showed that the eclipse of the stream and the white dwarf was total in UV during their observations, implying that this was unlikely.

### 3.2 Quasi Period Oscillations

We have studied this phenomenon by performing wavelet time-series analysis of our photometric data. The main difference of using this method instead of standard Fourier analysis is that the shape of the (mother) wavelet can easily be adjusted to better correspond to the shape of the flares in flickering (for example, more triangular).

The moderate time-resolution of 24 sec of photometry does not allow us to search for variations on timescales much less than 1 min. CASLEO observations (January 1998) are not included in this analysis due to their higher noise level. In our analysis we used Morelet wavelets (for more details, see Lehto et al. 1999). Flickering up to 0.2 magnitudes occurs in the V1309 Ori light curves from night to night. This is most prominent between the orbital phases $\Phi = 0.20 - 0.25$.

Our results show evidence for variability on timescales of $\sim 10$ minutes (NOT observations on 6/7 October 1997; Figure 7), mostly in $UBV$. Other nights also similar variability. The QPOs and flickering in the light curves have largest amplitudes near orbital phases ($\Phi = 0.20-0.25$) when the accreting pole emitting positive circular polarization is seen face-on.

### 4 POLARIMETRY

#### 4.1 Circular polarization

Our $UBVRI$ circular polarimetry, obtained on 24/25 November 1997, over one complete orbital cycle (Fig. 2) shows both negative and positive polarization. Positive circular polarization is observed between phases $\Phi = 0.0$ and $\Phi = 0.4$, while negative circular polarization is observed between phases $\Phi = 0.5$ and $\Phi = 0.9$. The circular polarization show strong colour dependence: polarization is strongest in $B$ and $V$, and is fairly modest in $U$ and $I$. This can be explained by the combined effects from cyclotron emission and dilution by the stream.

The circular polarization variations indicate that accretion occurs onto two separate regions. A single accreting pole can only give brief sign reversal when the accreting region is near the limb of the white dwarf, if the geometry is such
that the angle between the line of the sight and the magnetic field can go through $90^\circ$.

The circular polarization sign is reversed at the same orbital phases ($\Phi = 0.0$ and $\Phi = 0.4$) both in our October and November 1997 data, setting tight constrains on the degree of synchronism of the spin of the white dwarf and the binary orbital period. This high degree of synchronism is strengthened when we compare our observations to the white light circular polarization data taken in December 1994 and January 1995 by Buckley & Shafter (1995): the sign of the circular polarization changes at the same orbital phases ($\Phi = 0.0$ and $\Phi = 0.4$) in their observations. An uncertainty of about 0.05 of the phase difference of the zero crossovers over more than 3000 orbital cycles corresponds to the white dwarf spin and orbital periods being equal to better than $\sim 10^{-5}$.

4.2 Linear polarization

Figure 3 (upper panel) combines our linear polarization data obtained in October, November, 1997 (NOT) and in January 1998 (CASLEO). These data have been vectorially averaged from individual observations in the $UBVRI$ bands into 40 phase bins, in order to increase the signal to noise ratio. Our linear polarization data cover a complete orbital cycle, in contrast to previous studies which were incomplete (Shafter et al. 1995; Buckley & Shafter 1995). However, the observed linear polarization in V1309 Ori is very low, less than 0.3-1.0 per cent during the orbital cycle, with no evidence for peaks near the orbital phases where the circular polarization changes its sign. Consequently, the position angle behaviour (Figure 3, lower panel) is noisy over the whole orbital cycle.

5 SPECTROSCOPY

5.1 Doppler tomography

Doppler tomography has become a standard tool in the analysis of interacting binary star research. Given a high enough spectral and binary orbital resolution, a map can be made of the emission from a line in velocity space. The first such map of a polar was made of VV Pup (Diaz & Steiner 1994). Since then the technique has been applied to several other polars (eg Schwope et al. 1999). Here we obtain emission velocity maps of V1309 Ori using the code of Spruit (1998).

Since our spectra of V1309 Ori cover 0.7 of an orbital cycle rather than a full cycle, we first determined if we could obtain useful tomograms using spectra sampling an incomplete binary orbital cycle. We extracted spectra of the polar HU Aqr from the data archive of the Isaac Newton Group, La Palma. When we use only 0.7 of the orbital cycle we find that the resulting Doppler tomograms are remarkably similar to that when we use the full orbital cycle. There are, however, some circular artifacts present in the maps and the leading face of the secondary appears to be more strongly irradiated rather than the trailing compared to the maps made using the full dataset. This test indicates that we can expect to obtain meaningful tomograms using spectra which do not fully sample the orbital cycle of V1309 Ori. Indeed, Marsh & Horne (1988) showed using simulations that useful Doppler maps can be made even when the orbital cycle has been under-sampled. However, care should be taken in not over interpreting the details of those tomograms.

V1309 Ori was found to be in a high accretion state in December 1998 with the spectra showing prominent emission lines of H and He. We generated Doppler tomograms of V1309 Ori in three emission lines ($H\alpha$, $H\beta$ and He II $\lambda 4686$) where we assume $i = 78^\circ$ and $q=0.7$ Staude et al. (2001).

We show in Figure 8 the resulting tomograms. Emission is seen from the heated face of the secondary star and from the ballistic component of the accretion stream. In the case of $H\alpha$, the bulk of the line emission originates from the secondary star with the stream emission being weaker. In He II the relative strength of these two components is more equal.

Doppler maps of V1309 Ori have been presented by Shafter et al. (1995) (although the spectral resolution was rather low), Hoard (1999) who presents maps in $H\beta$ and $H\gamma$ $\lambda 4686$ (they cover 0.8 of the orbital cycle) and also Staude et al. (2001) who show maps in $H\gamma$, $He \ II \lambda 4686$, 8236 and $H\beta$ and $He \ I \ 4471$ (they cover the complete orbit). In the case of the $He \ II$ map of Staude et al. (2001) the secondary and the stream are approximately equal, while in our map the secondary is stronger and in the map of Hoard, emission from the heated face of the secondary is much weaker than the stream. Since our maps do not sample the phase range between $\phi=0.71-0.92$, this could be the reason why the secondary appears brighter.

6 ARCHIVE X-RAY DATA

ROSAT was an imaging X-ray satellite launched in 1990 with an energy range $\sim 0.1-2.0\text{keV}$. It had two X-ray instruments, the PSPC and the HRI. The ROSAT data of Walter, Wolk & Adams (1995) showed evidence for a ‘two pole’ nature: during half of the orbital cycle stronger X-ray emission is seen, and during the rest of the cycle weaker emission is observed. We have extracted further ROSAT archive data of V1309 Ori and phased the data of Staude et al. (2001). We show in Table 2 the data which we have used. (There are three datasets in the archive where V1309 Ori was not significantly detected). We have scaled the data so that PSPC had an effective area of 8 times that of the HRI.

We corrected the time of each event to the barycenter of the solar system. We then phased each event on the ephemeris of Staude et al (2001) and binned the light curve. (The ephemeris is accurate enough that the phasing error is very small). We show this light curve in Figure 9. There is some uncertainty in comparing these various light curves since we do not know if they were in the same accretion state. However, as found by Walter et al. (1995), V1309 Ori is X-ray bright for approximately half the orbital cycle. It is faint from $\phi \sim 0.0-0.5$, and bright around $\phi \sim 0.5-0.6$ and 0.8-0.95. The X-ray bright phases correspond to the phases which are negatively circularly polarised.

7 CYCLOTRON MODEL CALCULATIONS

We have modelled the observed $UBVRI$ circular polarization variations (Figure 2) using simulation codes for cyclotron emission described in Pirola et al. (1987a, b; 1990, 1993). The cyclotron fluxes and polarization dependence on

© 0000 RAS, MNRAS 000, 000–000
7. Unpolarized background

Based on the earlier studies of V1309 Ori (Shafter et al. 1995; Schmidt & Stockman 2001; Staude et al. 2001) and our observations (§3) it is clear that variations in the light curves are mostly caused by prominent stream emission with a smaller fraction due to cyclotron emission. It is therefore necessary to include a large unpolarized background when modelling the polarised light curves. We have done this in two different ways: (1) with constant background as first approximation, and (2) adopting the observed total flux as a function of the orbital phase as the variable unpolarized background. The latter case is more realistic for V1309 Ori due to the large amount of the unpolarized flux from the stream emission which varies during orbital cycle. The diluting flux from stream emission in V1309 Ori is 5–10 times larger than the peak cyclotron flux, estimated from the fast drop of intensity at the eclipse of the compact source observed at phase $\Phi = 0.952$ (§3.1). The X-ray temperature is chosen $kT_{\text{brems}} = 10$ keV according to observations of de Martino et al. (1994).

7.2 Parameters for accretion geometry

Two-pole accretors, for example VV Pup (Wickramasinghe, Ferrario & Bailey 1989), UZ For (Schwope, Beuermann & Thomas 1990), DP Leo (Cropper & Wickramasinghe 1993) and QS Tel (Schwope et al. 1995), have been found to show different magnetic field strengths in the accretion regions located in opposite hemispheres: up to factor of 2 difference in the field strengths has been measured. The more strongly accreting pole has normally the weaker magnetic field. In the case of V1309 Ori there are no major differences seen in the wavelength dependence of the positive and negative
excursions of the observed circular polarization curves (Figure 2), suggesting that both accreting regions are accreting nearly equally. Therefore, we have chosen the electron temperature and the plasma parameter ($\Lambda=10^5$) to be the same in both regions. We assume an inclination of $i=78^\circ$ Staude et al. (2001). Parameters such as the longitude of the emission region(s) on the surface of the white dwarf, and extension of the accretion regions were varied to match the gross features seen in the circular polarization behaviour. Due to very low level of the linear polarization (less than 0.5 per cent), and noisy position angle variations, we have not tried to use linear polarization to fix any model parameters. Another reason for not doing so is that scattering from free electrons of the stream can introduce significant linear polarization effects, dominating over the low linearly polarized flux of cyclotron origin.

Estimates of the colatitude of the accretion region $\beta$ can be made if we assume that the observed circular polarization from different poles is not significantly affected by possible overlap of the polarized emission from another accretion region. We can estimate $\beta$ for this region using the duration of the self-eclipse of the accretion region and equation (1) of Visvanathan & Wickramasinghe (1981). Using the circular polarisation data shown in Figure 2, we find $\beta = 145^\circ$ for the positive pole, and $\beta = 35^\circ$ for the negative pole, assuming an inclination $i = 78^\circ$ by Staude et al. (2001).

### 7.3 Results from the modelling

Observed circular polarization variations can be reproduced reasonably well with a model consisting of two separate emission regions, one centered at colatitude $\beta = 145^\circ$ (the positive pole), seen closest to the observer at $\Phi = 0.20$, and another region centered in at $\beta = 35^\circ$ (the negative pole), seen closest to observer $\Phi = 0.70$. For both regions we have adopted in Figure 10 longitudinal extension of 30$^\circ$ (in white dwarf rotational coordinates), but these values are not strongly constrained. Extensions in the range 10$^\circ$ – 60$^\circ$ give almost similar results. Point-like emission region gives too sharp polarization variations and very extended emission regions (larger than 60$^\circ$) too smooth and low-amplitude curves.

The model shown in Figure 10 assumes that cyclotron harmonics 6, 5, 4, 3, and 2, dominate in the $UBVRI$ passbands, respectively. This corresponds to a magnetic field of about 50 MG, which is similar to the estimated values for magnetic field (33–55 MG Garnavich et al. 1994; 61 MG Shafter et al. 1995). For a 50 MG field the wavelengths of the harmonics 6 to 3 are at 3580 Å, 4300 Å, 5370 Å and 7160 Å, i.e. one cyclotron harmonic clearly dominates in each of the $UBVR$ bands. Our $I$ band (8300 Å) falls about half-way between the 3rd and 2nd harmonics at $B \sim 50$ MG. The best correspondence to the observed circular polarization variations is achieved using the model where unpolarized background varies in a similar way to the total observed flux over the orbital cycle (Figure 10, continuous line).

Our model parameters for the location of accretion regions (in white dwarf rotation coordinates), positive pole at $\beta = 145^\circ$, $\Psi = -70^\circ$ and negative pole at $\beta = 35^\circ$, $\Psi = 110^\circ$, are similar to the values reported by Harrop-Allin et al. (1999), who modelled white light data of Buckley & Shafter (1995): $\beta = 40^\circ$ and $\beta = 140^\circ$. In contrast Staude et al. (2001) derived values of $\beta = 17^\circ$ and $\Psi = -16^\circ$ from their Doppler maps. In that study it was assumed that only one accretion region was visible. Although it is possible for an accretion region to show both positive and negative circular polarisation, it is only for a short phase duration if we observe the ‘underside’ of the shock.

### 8 DISCUSSION

#### 8.1 A well synchronised system

By comparing our circular polarization curves with those found in the literature we confirm that the spin of the white dwarf in V1309 Ori is synchronised with the orbital period to a high degree. The zero-crossings of circular polarization take place at the same phase of the orbital period as found by Buckley & Shafter (1995), which puts an upper limit of
interesting that for masses between 0.6–0.7
though there is some considerable degree of uncertainty in
0.7
Harrop-Allin et al. 1997). We find that for
and˙\(O\)ri),
is
the white dwarf), we find that the end of the ballistic flow
assume
B
tance from the white dwarf that material gets coupled by the
M
⃝
found to show a small (\(\sim 0.1\) percent) degree of asynchronism.

8.2 Accretion geometry

Our circular polarimetry curves (Figure 2) shows clear posi-
tive and negative excursions which indicate that V1309 Ori
has two accreting poles. This is consistent with previous po-
larisation observations. The X-ray data from the ROSAT
archive suggests that the negative circularly polarised pole
is
\(\sim 0\) percent asynchronous (Geckeler & Staubert 1997); over two orders
of magnitude greater than V1309 Ori.

8.3 The mass of the white dwarf

Along the ballistic flow, emission extends to \(V_x \sim -800 \text{ km s}^{-1}\),
\(V_y \sim -200 \text{ km s}^{-1}\) in our maps and also the maps of
Hoard (1999). The maps of Staud et al.(2001) show the
flow extending to \(V_y \sim -100 \text{ km s}^{-1}\). Taking \(V_x, V_y\) from
our maps (giving a velocity of 820 km s\(^{-1}\)) and using
\(v = (2GM_{\text{wd}}/r)^{1/2}\) (where \(v\) is velocity and \(r\) is distance from
the white dwarf), we find that the end of the ballistic flow
is \(r = 2.4\) and \(2.8 \times 10^{10}\) cm distant from the white dwarf for
\(M_{\text{bol}} = 0.6\) and \(0.7M_\odot\) respectively.

We can compare these estimates to the expected dis-
tance from the white dwarf that material gets coupled by the
magnetic field (\(R_a\)) using equation (1b) of Mukai (1988). We assume
\(B = 50\) MG (typical of the estimates made for V1309 Ori),
\(\sigma B = 3\) (the radius of the stream in units of 10\(^8\) cm:
the value estimated for HU Aqr, Harrop-Allin et al. 1999)
and \(M_{\text{bol}} = 10\) (the mass transfer rate in units of \(10^{16} \text{ g s}^{-1}\),
Harrop-Allin et al. 1997). We find that for \(M_{\text{bol}} = 0.6\) and
\(0.7M_\odot\), we get \(R_a = 3.4\) and \(2.1 \times 10^{10}\) cm respectively.
Although there is some considerable degree of uncertainty in
how applicable the above formulation for \(R_a\) actually is, it is
interesting that for masses between 0.6–0.7\(M_\odot\) the predicted
value of \(R_a\) is consistent with our Doppler maps. This range
of mass is consistent with that estimated by Staud et al.
(2001).

8.4 QPOs and their timescales

Our photometric observations show evidence for QPOs on
time scales of 10 min with amplitudes up to 0.2 magnitudes.
This compares with 6.7 and 15.5 min: Shafer et al. (1995).
There are some examples of other AM Her systems where
flickering on time scales of few minutes have been observed:
4.5 min in BL Hya (Singh, Agrawal & Riegl 1984), 4 –
11 min in QQ Vul (Osborne, Cropper & Christiani 1987),
and in AI Tri 6.5– 7 min and 13.5 – 14 min (Schwarz et al.
1998). We speculate that the QPOs in V1309 Ori are due to
‘blobby accretion’, already observed in X-ray data (Walter,
Wolk & Adams 1995; de Martino et al. 1998).

We compare these timescales with those derived by
King (1989), and King (1995) (see also Chanmugam 1995).
The irradiation of the accretion flow may ionise the sub-
sonic accretion flow below the inner \(L_1\) point and modulate
gas flow through this point on the timescale of the dynamical
time scale in the Roche potential near \(L_1\). The equation
presented by King (1989)
\[
T_{\text{osc}} \sim \frac{H_c}{c_s} = 5.5 \times 10^{-2} \frac{P}{R}
\]

where \(H_c\) is the scale height and \(c_s\) is local sound speed
near \(L_1\), predicts the timescales for these oscillations. The
orbital period of 479 minutes gives us a prediction of 26
minutes for V1309 Ori. The observed timescales of QPOs
in V1309 Ori, 10 and 15 minutes, are approximately half
of the predicted. The QPOs are seen strongest in \(UBV\),
and are negligible in the longer wavelengths, which may due
to reason that only a fraction of flow will undergo these
oscillations near \(L_1\), as pointed out by King (1995).

8.5 Eclipse profiles

Several eclipsing polars have been observed with high sig-
nal to noise and high time resolution. These include HU
Aqr (Harrop-Allin et al. 1999) and UZ For (Perryman et al.
2001). Both of these systems show a sharp eclipse ingress
lasting several seconds. This sharp drop in intensity is asso-
ciated with the eclipse of the bright accretion region on the
white dwarf. In the case of UZ For there are two sharp in-
tensity drops, indicating that there are two accretion regions
visible during the eclipse.

One of the most striking features about the eclipse pro-
files of V1309 Ori is the obvious lack of a sharp ingress or
egress which indicate the (dis)appearance of the white dwarf
and/or hot spots in the surface of the white dwarf behind
the secondary. The relative faintness of the accretion region(s),
compared to the bright accretion stream in V1309 Ori, may
be the reason for this.

After the eclipse of the white dwarf, the accretion
stream is still visible for a length of time. Observations of
other polars such as HU Aqr (Glenn et al. 1994, Bridge et
al. 2002) show that this length of time can vary from one
cycle to the next. The fact that we observe a variable eclipse
ingress of the accretion stream in V1309 Ori is therefore not
un-typical of polars. However, what does make V1309 Ori

© 0000 RAS, MNRAS 000, 000-000
unique amongst polars is the fact that the eclipse egress is highly variable: all other polars show a rapid rise at the same phase coming out from eclipse. The fact that V1309 Ori does not imply either that we can observe the stream above the orbital plane before the white dwarf is visible, or that the accretion stream travels far enough around the white dwarf so that it is visible before the white dwarf itself.

To investigate if this further, we shown in Figure 11 the view of the system at two different phases ($\Phi=0.96$ and 1.04). We use the following system parameters in determining these: $i=78^\circ$, $q=0.67$, $M_{\text{seq}}=0.7 M_\odot$ (Staude, Schwroe & Schwarz 2001) and a white dwarf - secondary star separation of $1.47\times10^{11}$ cm (determined using the above parameters and standard Roche lobe geometry). We also show a single magnetic field line originating from the negative circularly polarised accretion region ($\beta=35^\circ$ and face onto the observer at $\Phi=0.2$, §7.3). In Figure 11, the accretion streams leading to both poles are visible at $\Phi=0.96$. At $\Phi=0.04$ only the stream leading to the negative pole is visible. The white dwarf appears before the stream leading to the positive pole is visible. Even if the negative pole is not visible at 0.04, the emission from the stream leading to that pole is. We take $R_*/a=0.2$: this implies $R_*=2.9\times10^{10}$ cm. This is consistent with our findings in §8.3. This shows that for this accretion stream geometry the accretion stream is visible after the white dwarf has been eclipsed and also before the white dwarf comes out of eclipse. If the stream emission was highly variable then this could explain the variable egress profile.

8.6 Evolution

Garnavich et al. (1994) and Shafter et al. (1995) noted that the secondary star in V1309 Ori is oversized for its spectral type (M0 - M1) and mass (0.4–0.6 $M_\odot$). Indeed, recent binary evolution models (eg Smith & Dhillon 1998 and Baraffe & Kolb 2000) which assume an unevolved donor star and typical mass transfer rates, all predict either a much earlier or later spectral type for V1309 Ori than observed (cf Figure 1 of Baraffe & Kolb 2000).

However, by assuming an evolved donor it is possible to match the observed spectral type to the predicted value. For instance, from Figure 3 of Baraffe & Kolb (2000), for an initial secondary star mass of $M_2=1.2 M_\odot$, a central Hydrogen abundance at the start of mass transfer of $X_*=0.05$, and a mass transfer rate of $\dot{M}=1.5\times10^{-9} M_\odot$ ($\sim 1\times10^{-7}$ g s$^{-1}$) we find we that a spectral type of M1 is predicted for an orbital period of 8 hrs. This is within the estimated range of values required to satisfy conditions for observed oversized secondary to fill its Roche lobe (the main uncertainties are the distance and the mass of the white dwarf, eg Harrop-Allin et al. 1997, de Martino et al. 1998).

As already noted by King, Osborne & Shenker (2002), V1309 Ori is indeed a good possible candidate for a binary system which has gone through a supersoft source phase and contains a nuclear evolved donor star. Szkody & Silber (1996) and Schmidt & Stockman (2001) have noticed that V1309 Ori has extraordinary strong excitation lines of N V $\lambda 1240$ and O V $\lambda 1370$ which may support such an interpretation.

9 ACKNOWLEDGMENTS

Nordic Optical Telescope is operated on the island of La Palma jointly by Denmark, Finland, Iceland, Norway, and Sweden, in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofisica de Canarias. This work has been supported by the European Commission through the Activity “Access to Large Scale Facilities” within the Programme “Training and Mobility of Researchers” awarded to the Instituto de Astrofisica de Canarias to fund European Astronomers access to its Roque de Los Muchachos and Teide Observatories (European Northern Observatory), in the Canary Islands. SK is grateful for the Finnish Academy of Sciences and Letters for support. We would like to thank also the Australian National University for the allocation of telescope time and Dr Henk Spruit for the helpful advice and generous use of his Doppler Tomography software. The ROSAT data were extracted from the Leicester Database and Archive Service.
