We present a novel discrete variable quantum teleportation scheme using pulsed optomechanics. In our proposal, we demonstrate how an unknown optical input state can be transferred onto the joint state of a pair of mechanical oscillators, without physically interacting with one another. We further analyze how experimental imperfections will affect the fidelity of the teleportation and highlight how our scheme can be realized in current state-of-the-art optomechanical systems.

I. INTRODUCTION

The process of quantum teleportation describes the transfer of an unknown input state onto a remote quantum system. First outlined by Bennett et al. [1], it has since evolved into an active area of research and is now recognized as an important tool for many quantum protocols such as quantum repeaters [2], measurement-based quantum computing [3], and fault-tolerant quantum computation [4]. Experiments have been realized first with photons [5], later with various systems such as trapped ions [6, 7], atomic ensembles [8], as well as several others [9]. Over the past few years, optomechanical devices have emerged as an interesting tool to explore quantum phenomena, both from a fundamental perspective, showing the limits of quantum mechanical rules on massive objects [10], as well as from an applied view, promising to act as efficient transducers connecting radio-frequency regime qubits to low-loss optical channels [11, 12]. While continuous variable teleportation using an optomechanical system has been proposed [13], an experimental realization of such a scheme remains beyond reach.

Here we present a protocol that will enable the realization of quantum teleportation of an unknown optical input state onto a stationary mechanical quantum memory based on discrete variables in the pulsed regime. Current state-of-the-art optomechanics devices [14] should be able to realize the proposed protocol. The optomechanical interaction is used as a source of EPR-type entanglement between the memory and an optical field, after which a successful Bell-state measurement with the input field completes the teleportation. The memory state can be read out on-demand back onto the optical field directly at telecom wavelengths [15]. With the recent progress in quantum storage in ultra long-lived mechanical oscillators, without physically interacting with one another. We further analyze how experimental imperfections will affect the fidelity of the teleportation and highlight how our scheme can be realized in current state-of-the-art optomechanical systems.

II. OPTOMECHANICAL INTERACTION

We start the discussion with a description of the optomechanical interactions which allow the generation of EPR-type entanglement and retrieve the stored state from the stationary memory after a successful teleportation trial. Our approach is valid for general optomechanical devices, however, the teleportation protocol requires initialization of the modes in the mechanical ground state which to date is most reliably done by cryogenic cooling of nanobeam optomechanical resonators [16–18]. The Hamiltonian for such systems reads [10]

\[
H = \omega_\xi \hat{a}^\dagger \hat{a} + \omega_m \hat{b}^\dagger \hat{b} - g_0 (\hat{a}^\dagger \hat{b}^\dagger + \hat{b} \hat{a}^\dagger) + i(Ee^{i\omega_\text{rf}t} \hat{a}^\dagger - h.c.),
\]

where \(\hat{a}\) and \(\omega_\xi\) (\(\hat{b}\) and \(\omega_m\)) are the annihilation operator and resonant frequency of the cavity (mechanical) mode, respectively, \(g_0\) is the single-photon optomechanical coupling rate, and \(E = \sqrt{2\kappa P/(\hbar\omega_m)}\) the coupling between the driving field with frequency \(\omega_{\text{rf}}\) and power \(P\), and the cavity with decay rate \(\kappa\) (HWHM). Pulsed optical driving at a laser frequency \(\omega_\text{rf} = \omega_\xi \pm \omega_m\) allows for the realization of two different types of optomechanical interactions in the resolved sideband limit \(\kappa \ll \omega_m\), namely the parametric down-conversion and the beamsplitter interaction [10]. For a blue-detuned pulse, \(\omega_\text{rf} \approx \omega_\xi - \omega_m\), the interaction Hamiltonian \(H_b \approx \hbar g (\hat{a}^\dagger \hat{b}^\dagger + \hat{b} \hat{a}^\dagger)\) results in optomechanical parametric down-conversion, or two-mode squeezing, correlating excitations in the mechanical mode and the Stokes field at the cavity frequency \(\omega_\xi\). Here \(g = g_0 \sqrt{n_c}\) is the effective optomechanical coupling rate, with the intra-cavity photon number \(n_c\). This entangling operation is used in the teleportation scheme to generate optomechanical EPR-type states. The success probability is given by \(g \tau\), where \(\tau\) is the interaction time or experimentally the pulse length. Using a coherent laser drive to enable the interaction, double or even multiple scattering events can occur with a probability on the order of \((g \tau)^n\), which we include in the later discussion. For a red-detuned pulse, \(\omega_\text{rf} \approx \omega_\xi - \omega_m\), the interaction Hamiltonian \(H_r \approx \hbar g (\hat{b} \hat{a}^\dagger \hat{b}^\dagger + \hat{a} \hat{b}^\dagger)\) results in an optome-
We now describe the teleportation of a photonic qubit state $|\psi\rangle$ in polarization encoding onto a memory element consisting of two optomechanical devices as shown in Fig. 1. The two resonators are subject to a simultaneous excitation using a blue-detuned drive after which a Bell-state measurement of the input photon with the Stokes field from the optomechanical devices enables the teleportation. For simplicity, we begin our protocol assuming at most single excitations in all relevant modes and subsequently discuss the effects of various excepted experimental imperfections. In this ideal case, a blue-detuned single-photon pulse is sent onto a 50/50 beamsplitter (BS1) such that a path-entangled state is realized by mixing the fields on a 50:50 beamsplitter (BS2) and subsequent polarization analysis using two polarizing beamsplitters (PBS). The teleported state is then retrieved from the optomechanical system using red-detuned driving and can be analyzed in the same Bell-state detection setup.

where the subscript $m_j$ ($\theta_j$) denotes the mechanical (optical) mode $j$ ($j = A, B$). Here we have assumed the ideal case that the two devices are identical and that mechanical modes are initially in the quantum ground state $|00\rangle_{m_A m_B}$ and neglected any heating effect due to light absorption. To realize optomechanical teleportation, we distinguish the two optical fields in path $A$ and $B$ by encoding them with orthogonal polarizations, where $H$ ($V$) denotes horizontal (vertical) polarization. This can be realized by placing a half-wave plate in one of the two optical paths. The entangled state (2) can then be written as

$$|\phi\rangle = \frac{1}{\sqrt{2}}[(|0101\rangle_{ABHV} + |1010\rangle_{ABHV})],$$

where hereafter the subscript $A$ ($B$) denotes mechanical mode $m_A$ ($m_B$) for simplicity. The optical fields from both paths are then filtered, such that only the photons on resonance with the optomechanical cavities are transmitted to the Bell-state detection setup (cf. Fig. 1).

The initial optical state for the teleportation $|\psi\rangle$ is an arbitrary superposition of two polarization modes of the form

$$|\psi\rangle = \cos \theta |01\rangle_{HV} + e^{i\varphi} \sin \theta |10\rangle_{HV},$$

where $\varphi$ is an arbitrary phase factor, which we choose as $\varphi = 0$. Such a state can be prepared by sending a single photon with frequency $\omega_c$ into a polarizing beamsplitter (PBS) with transmission (reflection) coefficient $\cos \theta$ ($\sin \theta$), for example.

This input photon is sent to port 1 of the Bell-state detection setup whereas the output of the interferometer containing the optomechanical devices is sent to port 2. Combining the states of equations (3) and (4) results in

$$|\Phi\rangle = |\phi\rangle \otimes |\psi\rangle$$

$$= \frac{1}{\sqrt{2}} \left[ \cos \theta |010101\rangle + \sin \theta |010110\rangle ight]_{ABHV} + \left[ \cos \theta |101001\rangle + \sin \theta |101010\rangle \right]_{ABHV}$$

where

FIG. 1. Sketch of a proposed setup to implement the teleportation protocol. Two optomechanical devices forming a quantum memory are placed in an optical interferometer in which the outgoing fields are combined in cross-polarization. Simultaneous driving of the devices under blue detuning entangles the state of the mechanical modes with optical fields at cavity resonance $\omega_c$. A Bell-state measurement between this Stokes field and an optical state to be teleported $|\psi\rangle$ is performed by mixing the fields on a 50/50 beamsplitter (BS2) and subsequent polarization analysis using two polarizing beamsplitters (PBS). The teleported state is then retrieved from the optomechanical system using red-detuned driving and can be analyzed in the same Bell-state detection setup.

FIG. 2. Diagram of the Bell-state projection $\hat{P}_c$ for two polarization modes, which consists of a 50/50 beamsplitter (BS2) and four single-photon detectors placed after two polarizing beam splitters (PBS). The subscript 1 (2) denotes the $H$ ($V$) polarization mode.
where the subscript 1 and 2 are used to distinguish the different input ports (see Fig. 1). The Bell-state detection setup consists of a 50/50 beamsplitter BS2 on which the input fields are mixed. Each output is then routed to a polarizing beamsplitter with two single-photon detectors at their respective outputs. A successful teleportation trial is heralded by a coincidence in two of the detectors corresponding to different polarization states, realizing a projection of the input state of equation (5) using

\[ \hat{P}_+ = \left( |0110\rangle + |1001\rangle \right)^\dagger_{H_2V_2H_1V_1} . \]

A coincidence measurement in the same output of BS2 projects the optical modes onto the state \( |0110\rangle + |1001\rangle \) for example, corresponding to \( \hat{P}_+ \). This can be seen as follows:

\[
\begin{align*}
(0110) + |1001\rangle &_{H_2V_2H_1V_1} \\
&= (\hat{a}_1^\dagger \hat{b}_1^\dagger + \hat{a}_2^\dagger \hat{b}_2^\dagger) |\text{vac}\rangle \\
&= \frac{1}{2} (\hat{c}_1^\dagger - \hat{d}_1^\dagger)(\hat{c}_2^\dagger + \hat{d}_2^\dagger) + (\hat{c}_1^\dagger - \hat{d}_1^\dagger)(\hat{c}_2^\dagger + \hat{d}_2^\dagger) |\text{vac}\rangle \\
&= (\hat{c}_1^\dagger \hat{c}_2^\dagger - \hat{d}_1^\dagger \hat{d}_2^\dagger) |\text{vac}\rangle .
\end{align*}
\]

(7)

Here \( \hat{a}_i^\dagger, \hat{a}_i, \hat{b}_i^\dagger, \hat{b}_i \) are the creation operators for the optical modes \( H_2, V_2, H_1, V_1 \) at the input ports of BS2. Furthermore \( \hat{c}_i^\dagger, \hat{c}_i, \hat{d}_i^\dagger, \hat{d}_i \) are the creation operators for the respective polarization output modes of BS2 (see Fig. 2) and \( |\text{vac}\rangle \) denotes the vacuum state.

Similarly, the projection \( \hat{P}_- \) is realized by a coincidence in two detectors corresponding to orthogonal polarizations at different sides of BS2 according to

\[
(0110) - |1001\rangle_{H_2V_2H_1V_1} = (\hat{c}_1^\dagger \hat{d}_1^\dagger - \hat{c}_2^\dagger \hat{d}_2^\dagger) |\text{vac}\rangle .
\]

(8)

Additionally, the other two types of Bell measurements \( (0101) \pm |1010\rangle \) with coincidences in detectors corresponding to the same polarization require the detection of two-photon states \( |2\rangle_{H_2V_2} \). While this can be realized using photon-number-resolving detectors, we will disregard these cases here for simplicity and experimental feasibility.

A successful Bell-state measurement of the joint state \( |\Phi\rangle \) of Eq. (5) with \( \hat{P}_+ \) projects the two mechanical modes \( A \) and \( B \) into a state of the form

\[ |\psi\rangle = \sin \theta |01\rangle_{AB} + \cos \theta |10\rangle_{AB}. \]

(9)

Comparing this to the state in (4), we see that the only difference between the initial optical state \( |\psi\rangle \) and the teleported mechanical state \( |\psi\rangle \) is that the probability amplitudes of the two eigenstates are exchanged. For the measurement \( \hat{P}_- \), the two mechanical modes are projected onto the state

\[ |\psi''\rangle = \sin \theta |01\rangle_{AB} - \cos \theta |10\rangle_{AB}, \]

(10)

which has a \( \pi \)-phase difference with respect to the state \( |\psi\rangle \).

In order to verify the successful teleportation, the mechanical state can be read out by sending a red-detuned pulse (i.e., utilizing the optomechanical state-swap interaction described in Sec. II) and the teleported state can be analyzed in the Bell-state detection setup with a few additional optical components for fast polarization control. Alternatively, it could be routed elsewhere using an optical switch, enabling advanced quantum communication protocols. A phase difference in the final mechanical state from projection with \( \hat{P}_- \) can in principle be corrected in this readout step using a feed-forward operation by applying a phase shift in the optical interferometer.

### IV. EXPERIMENTAL IMPERFECTIONS

#### A. Effect of residual thermal occupation

In any real experiment, the mechanical modes are not perfectly initialized in their quantum ground state \( |00\rangle_{AB} \) and in addition are heated through optical absorption from the pulses interacting with the devices [17–19]. We model these effects by assuming the mechanical modes are initially in a thermal state with non-zero thermal occupation \( \bar{n}_0 \ll 1 \). Note that, to simplify the model, we thus include the heating from the readout pulse into the initial residual thermal occupation as well. We furthermore assume that the two oscillators have equal thermal occupation \( \bar{n}_0 \), i.e. they are in the same thermal state

\[ \rho_{hh} = (1-s) \sum_{n=0}^{\infty} s^n |n\rangle\langle n|, \]

(11)

where \( s = \frac{\bar{n}_0}{\bar{n}_0+1} < 1 \). For \( \bar{n}_0 < 0.2, s < 0.17, s^2 < 0.03, \) and \( s^3 < 0.005 \) high-excitation terms \( |n\rangle \) \((n > 2)\) can be safely neglected and we approximate \( \rho_{hh} \approx (1-s) |00\rangle\langle 00| \). The density matrix of the two mechanical modes can then be written as \( \rho_{hh}^{AB} \approx \rho_{hh}^A \otimes \rho_{hh}^B \), which is a probabilistic mixture of nine pure states \( |jk\rangle_{AB} \) \((j,k = 0, 1, 2)\). The eigenstate \( |00\rangle_{AB} \) in \( \rho_{hh}^{AB} \) corresponds to the initial ground state assumed in Sec III, which results in the mechanical state \( |\psi'\rangle \) in (9) \(|\psi''\rangle\) in (10) after the Bell-state measurement \( \hat{P}_+ \).

The remaining eight states eventually lead to unwanted additional terms in the final mechanical state and thus reduce the fidelity of the teleportation, which we will now analyze more closely.

For the mechanical modes initially in the thermal state \( \rho_{hh}^{AB} \), we obtain the following final (unnormalized) mechanical state after the Bell-state projection \( \hat{P}_+ \):

\[ \rho_{final}^{AB} \propto |00\rangle\langle 00| + s|01\rangle\langle 01| + s^2|10\rangle\langle 10| + s^3|11\rangle\langle 11| + s^2|02\rangle\langle 02| + s^3|02\rangle\langle 20| + s^4|12\rangle\langle 21| + s^3|21\rangle\langle 21| + s^4|22\rangle\langle 22|, \]

(12)

where \( |\psi_{jk}\rangle \) is the final mechanical state corresponding to the mechanical modes initially in the pure state \( |jk\rangle_{AB} \) \((j,k = 0, 1, 2)\), and \( |\psi_{00}\rangle \equiv |\psi\rangle \). The remaining eight states \( |\psi_{jk}\rangle \) are...
then given by

\begin{align}
|\psi_{01}\rangle &= \sin \theta |02\rangle + \cos \theta |11\rangle, \\
|\psi_{10}\rangle &= \sin \theta |11\rangle + \cos \theta |20\rangle, \\
|\psi_{11}\rangle &= \sin \theta |12\rangle + \cos \theta |21\rangle, \\
|\psi_{20}\rangle &= \sin \theta |21\rangle + \cos \theta |30\rangle, \\
|\psi_{12}\rangle &= \sin \theta |13\rangle + \cos \theta |22\rangle, \\
|\psi_{21}\rangle &= \sin \theta |22\rangle + \cos \theta |31\rangle, \\
|\psi_{22}\rangle &= \sin \theta |23\rangle + \cos \theta |32\rangle.
\end{align}

(13)

For the Bell-state measurement \(\hat{P}_n\), we obtain \(\rho^{AB\text{final}}\) as in (12) but with the “+” replaced with “-” in each component \(|\psi_{jk}\rangle\).

Clearly, the above eight states are all unwanted contributions, but with the “+” replaced with “-” in each component \(|\psi_{jk}\rangle\). We plot the probability of these terms for increasing \(\bar{n}_0\) in Fig. 3. The probability of obtaining the ideal state \(|\psi_{00}\rangle\), i.e., the fidelity of the state \(\mathcal{F} = \langle \psi_{00} | \rho^{AB\text{final}} | \psi_{00}\rangle = 1 - P_{\text{add}}\), thus decreases with increasing \(\bar{n}_0\). A successful quantum teleportation requires the fidelity to be above 2/3, which is given by the maximum achievable value without using entanglement as a resource \([20]\). For our optomechanical teleportation scheme, this corresponds to a threshold of \(\bar{n}_0 \approx 0.23\). For \(\bar{n}_0 < 0.23\), the total probability of the higher-excitation terms \(|n\rangle (n > 2)\) in the thermal state (11) is less than 0.7\%, highlighting that our earlier approximation is quite good. In order to show optomechanical quantum teleportation, \(\bar{n}_0 \approx 0.23\) is therefore an upper bound in our present scheme.

**B. Weak coherent states input**

So far we have studied the special, idealized case where both optical input fields for the Bell-state measurement are single photons. This assumption, however, is unrealistic for devices in the optomechanical weak coupling regime which require blue-detuned pulses far above the single photon level to achieve practical scattering rates. Additionally, using a weak coherent state (WCS) as optical input for the teleportation enables greatly reduced experimental overhead and can increase the rate of the experiment. While the single photon case can be a good approximation for the case of low excitation probabilities, we now include higher-excitation terms \(|2\rangle\) to the optomechanically entangled state, as well as the initial optical state \(|\phi\rangle\). These terms are consequently affecting the final mechanical state which results in corrections to the achievable teleportation fidelity. The WCS \(|\alpha\rangle (|\beta\rangle)\) of the blue-detuned (resonant) pulse can be approximately expressed as \(|\mathcal{R}\rangle \approx |0\rangle + |\mathcal{R}| |1\rangle + \frac{|\mathcal{R}|^2}{\sqrt{2}}\langle |\mathcal{R}| \approx 1\rangle\), where \(\mathcal{R} = \alpha, \beta\).

We perform the analysis of the higher order terms considering several cases individually. We begin with the one where the resonant pulse \(|\phi\rangle_m\) that is used to prepare the initial state \(|\psi\rangle\) is a WCS but no optomechanical scattering occurs, i.e. \(|\phi\rangle = |0000\rangle_{ABHV,V}\). The single photon component of \(|\psi\rangle_m\) will then not trigger any coincidences in the Bell-state detection, leading to unsuccessful trials for the teleportation. The two-photon component \(|2\rangle\), however, results in an extra term in the final mechanical state. The joint state for the Bell-state measurement in this case is of the form

\(\langle 0000|_{ABHV,V} \otimes \left( \sin^2 \theta |20\rangle + \cos^2 \theta |02\rangle + \frac{\sin 2\theta}{\sqrt{2}} |11\rangle \right)_{HV,V}\). (15)

Such a state will trigger several different types of “double-clicks”, in particular

\begin{align}
|0020\rangle_{HV,V}&= \frac{1}{2 \sqrt{2}} (c^1_2 c^2_1 + d^1_2 d^2_1) |\text{vac}\rangle, \\
|0002\rangle_{HV,V}&= \frac{1}{2 \sqrt{2}} (c^1_2 c^2_1 + d^1_2 d^2_1 + 2 c^1_1 d^2_1 |\text{vac}\rangle, \\
|0011\rangle_{HV,V}&= \frac{1}{2} (c^1_2 c^2_1 + d^1_2 d^2_1 + c^1_1 d^2_1 + c^1_1 d^2_1 |\text{vac}\rangle.
\end{align}

(16)

Since successful Bell-state measurements of our protocol require coincidence detection of photons with orthogonal polarization, the “double-clicks” in the same polarization modes induced by the states \(|20\rangle_{HV,V}\) and \(|02\rangle_{HV,V}\) can be identified and thus disregarded. The coincidences caused by the state \(|11\rangle_{HV,V}\) on the other hand cannot be distinguished from those of \(P_2\) for the ideal case and result in errors in the final mechanical state. Fortunately, the mechanical modes are projected onto \(|00\rangle_{AB}\), which cannot be read out by the red-detuned pulse and thus has no actual impact on the measurement result. Note that in this section we assume zero thermal occupation of
the mechanical modes, and focus on the effect of higher order terms in the WCS of the blue-detuned and resonant pulses.

For the case where $|\psi\rangle_\text{in}$ is in a vacuum state $|0\rangle$, similarly, the single photon component in the blue-detuned pulse will not trigger “double-clicks” and thus have no impact on the fidelity. The two-photon component $|2\rangle$ of this field, however, can again yield false coincidences in the Bell-state measurement and result in extra terms in the mechanical state. In this situation, the joint state at the input ports of BS2 is

$$\frac{1}{2} \left( |2000\rangle + |0200\rangle + \sqrt{2} |1111\rangle \right)_{\text{ABV}} \otimes \left( |0\rangle \right)_{\text{HIV}}. \quad (17)$$

Similarly as the state (15), this state also triggers several different types of “double-clicks”. The mechanical modes are then projected onto the state $|20\rangle_{\text{AB}}, |02\rangle_{\text{AB}},$ and $|11\rangle_{\text{AB}}$ for optical modes being in $|20\rangle_{\text{HIV}}, |02\rangle_{\text{HIV}},$ and $|11\rangle_{\text{HIV}}$, respectively. Since $|20\rangle_{\text{HIV}}$ and $|02\rangle_{\text{HIV}}$ correspond to “double-clicks” of the same polarization, such events can be identified and discarded, but $|11\rangle_{\text{HIV}}$ leads to “double-clicks” that mix with those of Bell-state measurements $P_\pm$ in the ideal case and result in an additional term $|11\rangle_{\text{AB}}$ in the final mechanical state. The probability of this event with respect to the ideal case of the state $|\psi\rangle (|\psi''\rangle)$ is roughly $|\alpha\beta|^2 : |\alpha\beta|^2 = 3^2 : \frac{1}{2} |\alpha\beta|^2$. This implies that the effect of this additional term on the teleportation fidelity can be significantly reduced by using very weak blue-detuned pulses and introducing a hierarchy according to $|\alpha| \ll |\beta| \ll 1$.

For the other situations, where either of the two initial pulses are in $|2\rangle$, or one is in $|1\rangle$ and the other in $|2\rangle$, additional unwanted terms in the final mechanical state appear. However, their probabilities are much smaller compared to that of the idle state $|\phi\rangle (< |\phi''\rangle$ since WCSs $|\alpha|, |\beta| \ll 1$ are used.

The ratio of the probabilities are $|\phi|^2 : |\phi|^2 : \frac{|\alpha|^2 |\beta|^2}{4}$ : $1$ for the two pulses in $|12\rangle_{br}, |21\rangle_{br}, |22\rangle_{br}, |11\rangle_{br}$, respectively, where the subscript $b$ ($r$) denotes the state of the blue-detuned (resonant) pulse.

C. Photon loss and non-unity detection efficiency

An experiment typically suffers from various optical losses including inefficient optical coupling to on-chip waveguides, passing through filter cavities and photon detection with non-unity detection efficiency. These losses can be modeled by a beamsplitter (with transmittance $T$ and reflectance $R$, $T + R = 1$), where the reflection is treated as optical losses [21]. Given the different roles of optical losses, we classify them into two categories: detection losses and non-detection losses.

We study the effect of non-detection or propagation losses on the final mechanical state in detail in Appendix A, considering the EPR state (3) and the initial optical state (4). We show that for the Bell-state measurement $P_\pm$, the unnormalized teleported state is of the form $\rho_{\text{loss}}^{\text{AB}} = T |\psi\rangle \langle \psi'|$, where $0 < T < 1$ and $|\psi'|$ is the final mechanical state (9) in the ideal case without any losses. This implies that the optical losses will not affect the teleportation fidelity but only increase the measurement time. This is also true for the other Bell-state measurement $P_-$. We have further studied the case where the initial blue-detuned pulse is in a WCS while the resonant pulse is a single photon. When the former is in a two-photon state $|2\rangle$, the final mechanical state $\rho_{\text{loss}}^{\text{AB}}$ is a mixed state with eigenstates that are all unwanted with respect to $|\psi'\rangle$ (Appendix A). The probability of this state is much smaller than that of $\rho_{\text{loss}}^{\text{AB}}$ as they result from the state $|2\rangle$ and $|1\rangle$ in the expansion of WCS $|\alpha\rangle$, respectively, and the amplitude $|\alpha| \ll 1$.

Similarly, the effect of detection losses in the Bell-state measurement setup can be analyzed. We know from (7) and (8) that without losses, $P_\pm$ projects the optical modes onto Bell states $|1010\rangle \pm |0100\rangle \rangle_{\text{HIV}}$, which correspond to different types of “double-clicks” events. Detection losses can reduce them to either “single-click” or “no-click” events (see Appendix B), which then project the mechanical states onto mixed states. Since only “double-clicks” are valid Bell-state measurements in our protocol, however, these can be disregarded such that there is no actual impact on the teleportation fidelity. Detection losses thus also only reduce the probability of obtaining the desired state, again implying longer measurement time.

D. Additional imperfections

Experiments using the above protocol are expected to suffer from additional imperfections. One of the hardest experimental challenges is to find identical optomechanical devices. Apart from a few exceptions [22, 23], most systems to date have no in-situ tuning mechanism, such that devices with matching optical and mechanical frequencies have to be found after the fabrication is completed. Residual frequency offsets for devices which are well in the sideband-resolved regime mainly reduce the success probability for the teleportation by reducing the optomechanical scattering probabilities. Small additional offsets in the mechanical frequencies can be compensated for through the optical driving [14, 18]. Since the scattered fields are furthermore filtered before the Bell-state detection setup, such offsets do not affect the fidelity but only the success probability. Dark counts on the detectors can also cause false detection events in the Bell-state measurement, reducing the fidelity of the teleported state. However, by using superconducting nanowire single photon detectors with tens of Hertz of dark count rates and accounting for pulse lengths of tens of nanoseconds, these typically play only a minor role.

V. CONCLUSION

We have presented a quantum teleportation protocol based on an optomechanical system, which teleports an unknown quantum state of an optical field onto a pair of massive mechanical oscillators. The protocol consists of two central steps: the generation of optomechanical EPR-type states, and Bell-state detection of the optical fields. We start from an idealized case to illustrate the essence of the protocol, where the optical pulses are single photons and the mechanical modes
are in their quantum ground states. We then study various imperfections encountered in actual experiments. Specifically, we have analyzed the effects of residual thermal occupation, optical input of weak coherent states, photon losses and non-unity detection efficiency. This allows us to find an optimal parameter regime in a realistic situation where quantum teleportation could be successfully demonstrated in a state-of-the-art optomechanics experiment. Realizing such a teleportation scheme may find applications in various quantum information subjects, such as quantum communication, quantum repeaters, and quantum computing, as well as for fundamental studies of the quantum-to-classical transition and macroscopic quantum phenomena.

It is known that the process of linear optical loss can be modeled using a beamsplitter (BS), where its reflection is treated as the loss. \( \rho_{\text{trans}} \) denotes the state of an arbitrary quantum state \( \rho_{\text{in}} \) after experiencing linear loss.

**APPENDIX: EFFECT OF PHOTON LOSSES IN OPTOMECHANICAL TELEPORTATION**

For an arbitrary quantum state, denoted by a density matrix \( \rho \), it is known that the process of linear optical loss can be treated as the optical loss channel \([21]\). This model allows us to conveniently obtain the state of an arbitrary quantum state after experiencing some loss. In this Appendix, we first study the effect of non-detection losses (such as loss in coupling optical pulses to mechanical modes, an optical mode passing through a filter, etc.) and derive the final mechanical state by including these losses. We then continue to study the effect of detection loss in a Bell-state measurement.

For an arbitrary quantum state, denoted by a density matrix \( \rho_{\text{in}} \), impinging on a BS and with vacuum entering through the other input port (cf. Fig. A1), the state of the two outputs can be expressed as \([25]\)

\[
\rho_{\text{out}} = \sum_{m=0}^{\infty} \frac{1}{m!} \left( \frac{R}{T} \right)^m \hat{a}^\dagger \hat{a}^{m+1} \rho_{\text{in}} T \hat{a}^\dagger \hat{a}^m |m\rangle\langle m|, \tag{A1}
\]

where \( \hat{a} \) and \( \hat{a}^\dagger \) are the annihilation and creation operators acting on the input state \( \rho_{\text{in}} \), and \( T \) and \( R \) are the transmittance and reflectance of the BS, respectively, and \( T + R = 1 \) for a lossless BS. As any quantum state \( \rho \) can be expanded in the Fock-state basis

\[
\rho = \sum_{n=0}^{\infty} C_{n,s} |n\rangle\langle s|, \tag{A2}
\]

where \( C_{n,s} \) are coefficients, we can replace \( \rho_{\text{in}} \) with \(|n\rangle\langle s|\) in (A1), and trace over the lossy part (cf. Fig. A1). We then obtain the density matrix of the transmitted component \([26]\)

\[
\rho_{\text{trans}} = \sum_{m=0}^{\text{min}(n,s)} \frac{n!s!}{(m!)^2(s-m)!} R^m T^{s-m} |n-m\rangle\langle s-m|, \tag{A3}
\]

and therefore we can express an arbitrary state \( \rho \) after experiencing linear optical loss as

\[
\rho_{\text{loss}} = \sum_{n=0}^{\infty} C_{n,s} \rho_{n,s}. \tag{A4}
\]

For a single-photon state \(|1\rangle\rangle\), we have

\[
\rho_{\text{loss}}^{[1]} = T|1\rangle\langle 1| + R|0\rangle\langle 0|, \tag{A5}
\]

and for \(|0\rangle\langle 1|\) and \(|1\rangle\langle 0|\), we obtain

\[
\rho_{\text{loss}}^{[0]} = \sqrt{T}|0\rangle\langle 1|, \quad \rho_{\text{loss}}^{[1]} = \sqrt{T}|1\rangle\langle 0|. \tag{A6}
\]

### A. Non-detection losses

By placing a BS (which we call BS0) before the input port of BS2 in the main text (Fig. 1), we now include non-detection losses into the ideal case considered in Sec. III. The optical components (i.e., two polarization modes \( H_2 \) and \( V_2 \)) of the EPR state \(|\phi\rangle\rangle\) in (3) independently pass through BS0, and after tracing over the reflection, we hence obtain the following transmitted state, i.e., the state \(|\phi\rangle\rangle\) after the inclusion of non-detection losses

\[
\rho_{\text{loss}}^{|\phi\rangle\rangle} = \frac{1}{2} \left[ |01\rangle\langle 01| \otimes |0\rangle H_2, |0\rangle V_2 \right] \left( T |1\rangle\langle 1| + R |0\rangle\langle 0| \right)_{V_2} + |10\rangle\langle 10| \otimes \left( T |1\rangle\langle 1| + R |0\rangle\langle 0| \right)_{V_2} + |10\rangle\langle 10| \otimes \left( T |1\rangle\langle 1| + R |0\rangle\langle 0| \right)_{H_2} + |01\rangle\langle 01| \otimes \left( T |1\rangle\langle 1| + R |0\rangle\langle 0| \right)_{H_2}.
\]

Combining this with the initial state \(|\psi\rangle\rangle\) in (4), we therefore have the joint state at the input ports of BS2

\[
\rho_{\text{loss}}^{|\phi\rangle\rangle} = \left[ \rho_{\text{loss}}^{|\phi\rangle\rangle} \right]_{ABH_2V_2} \otimes \left[ |\phi\rangle\langle \psi| \right]_{H_2V_2}. \tag{A8}
\]

After performing the Bell-state measurement \( \hat{P}_+ \) on the optical modes, consequently the mechanical modes are projected onto the unnormalized state

\[
\rho_{\text{loss}}^{AB} = \text{Tr} \left[ \hat{P}_+ \rho_{\text{loss}^{AB}} \right] = T \left[ \sin^2 \theta |01\rangle\langle 01| + \cos^2 \theta |10\rangle\langle 10| + \frac{\sin 2\theta}{2} |01\rangle\langle 10| + \frac{\sin 2\theta}{2} |10\rangle\langle 01| \right]_{AB} \tag{A9}
\]
where $\ket{\psi'}$ is the projected mechanical state (9) in the ideal case without any losses. By comparing $\rho_{\text{loss}}^{AB}$ with $\rho_{\psi}$, we see that there is only a difference of a factor “$T$”, $0 < T < 1$, which means that the optical losses will not degrade the final mechanical state but only reduce its probability, implying longer measurement time.

The above analysis is for the ideal case of the optical pulses being single photon states. We now assume that the blue-detuned pulse is a WCS and derive the final mechanical state if this pulse is in a two-photon state $|2\rangle$, while the resonant pulse is still in $|1\rangle$. Following the same procedures, after extensive calculations, we obtain

$$\rho_{\text{loss}}^{AB} = \frac{1}{4} \left\{ \cos^2 \theta \left[ (T^2 + 2RT)|20\rangle\langle 20| + 2RT|11\rangle\langle 11| \right] + \sin^2 \theta \left[ (T^2 + 2RT)|02\rangle\langle 02| + 2RT|11\rangle\langle 11| \right] 
+ \frac{\sin 2\theta}{2} \left[ T^2|20\rangle\langle 02| + 2RT(20|11\rangle + |11\rangle|20|) \right] \right\}_{AB}. \quad (A10)$$

This state contains eigenstates that are all unwanted with respect to the ideal state $\ket{\psi'}$. The probability of this state is much smaller than that of the state $\rho_{\text{loss}}^{AB}$ as they result from the state $|2\rangle$ and $|1\rangle$ in the coherent state expansion, respectively. Therefore, a WCS $|\Omega| \ll 1$ must be used in order to reduce the probability of those unwanted terms in the final mechanical state.

### B. Detection losses

The non-unity detection efficiency in Bell-state measurements can be modeled by putting a BS in each arm of the two outputs of BS2, as depicted in Fig. A2. The reflections of the two hypothetical BSs (hypo-BSs) are used to model the detection losses, and the transmitted fields represent the optical fields after such losses and are measured by detectors with unity detection efficiency. We assume identical hypo-BSs given the symmetry of the Bell-state detection. The two output fields of BS2 then become the input fields of the hypo-BSs with vacuum entering the other input ports, and the transmitted fields of each hypo-BS are then measured by two detectors placed after a PBS, which measure orthogonal polarizations. Note that the transmitted fields contain two polarization modes and we use operator $\hat{O}_{j_{1(2)}}$ to denote the $H$ ($V$) polarization mode, where $\hat{O} = a, b, c, d, e, f, g, h, j, k$, see Fig. A2.

In the ideal case without detection losses, we know from (7) and (8) that the Bell-state measurements $\hat{P}_\pm$ project the optical modes onto the state $\left( |0110\rangle \pm |0011\rangle \right)_{H_2V_3;H_1V_1}$, which correspond to different types of “double-clicks” in the four detectors shown in Fig. 2. We now study the effect of detection losses and see if the “double-clicks” can still characterize the Bell-state projections $\hat{P}_\pm$.

The Bell-state measurement $\hat{P}_+$ projects the optical modes onto the state

$$\left( |0110\rangle + |0011\rangle \right)_{H_2V_3;H_1V_1}
= (c_1^a c_2^b - \hat{d}_1^a \hat{d}_2^b) \langle \text{vac} \rangle
= \left[ (\sqrt{T} f_1^a - \sqrt{R} g_1^a)(\sqrt{T} f_2^b - \sqrt{R} g_2^b) - (\sqrt{T} \tilde{k}_1^a - \sqrt{R} \tilde{j}_1^a)(\sqrt{T} \tilde{k}_2^b - \sqrt{R} \tilde{j}_2^b) \right] \langle \text{vac} \rangle
= (T|1100\rangle + R|0011\rangle - \sqrt{T} R|0110\rangle - \sqrt{T} R|1001\rangle)_{f_1f_2R_1R_2}
= |\Psi_{\text{out}}\rangle. \quad (A11)$$

Considering the detection losses, we trace over the output modes $g_{1(2)}$, $f_{1(2)}$ (which denote losses, see Fig. A2), and obtain

$$\rho_{jk} = \text{Tr}_{E_2} \left[ |\Psi_{\text{out}}\rangle \langle \Psi_{\text{out}}| \right]$$

$$= \left( T^2|11\rangle\langle 11| + R^2|00\rangle\langle 00| + TR|01\rangle\langle 01| + TR|10\rangle\langle 10| \right)_{f_1f_2}
+ \left( T^2|11\rangle\langle 11| + R^2|00\rangle\langle 00| + TR|01\rangle\langle 01| + TR|10\rangle\langle 10| \right)_{k_1k_2} \quad (A12)$$
FIG. A2. Beamsplitter model of detection losses in the Bell-state measurement. The reflection of the hypo-BS in each arm of the outputs of BS2 models the detection loss. A single mode operator is used to represent the two polarization modes, i.e., $\hat{O} \equiv \hat{O}_{(1),2}$.

Clearly, the detection losses lead to the emergence of additional states, which correspond to either “single-click” or “no-click” events. Since we record only the event of “double-clicks”, we actually measure the following state

$$\rho_{fk}' = T_2^2 \left( |11\rangle_{f1,f2} \langle 11| + |11\rangle_{k1,k2} \langle 11| \right),$$  \hspace{1cm} (A13)

which corresponds to “double-clicks” in the two detectors at the same side of BS2. This is the same as in the case without losses (see (7)), but detection losses reduce the probability of successfully measuring the state as $T_2^2 < 1$.

Similarly, for the other measurement $\hat{P}_-$, we actually measure

$$\rho_{fk}'' = T_2^2 \left( |11\rangle_{k1,f2} \langle 11| + |11\rangle_{k1,f2} \langle 11| \right),$$  \hspace{1cm} (A14)

which corresponds to “double-clicks” in the two detectors at two sides of BS2 that measure orthogonal polarizations. Comparing with (8) for perfect detectors, the probability of the successful “double-clicks” event is reduced, again, resulting in longer measurement times.

As before, the above analysis is for the ideal case of the pulses being single photon states. For the practical situation of pulses being WCSs, the components of high-excitation states will also lead to “double-clicks” (errors) in the presence of detection losses. Nevertheless, when the coherent states are sufficiently weak $|\alpha|, |\beta| \ll 1$, these errors are negligible.
