Relativistic tunneling and accelerated transmission
Bernardini A E 2008 J. Phys. A: Math. Theor. 41 215302

It has come to the attention of IOP Publishing that this article should not have been submitted for publication owing to its substantial replication of an earlier-published paper (Bernardini A E 2008 Delay time computation for relativistic tunneling particles Eur. Phys. J. C 55 125-32) and consequent technical breach of the Editorial Guidelines. Consequently, this paper has been retracted by IOP Publishing.
Relativistic tunneling and accelerated transmission

Abstract

We obtain the solutions for the tunneling zone of a one-dimensional electrostatic potential in the relativistic (Dirac to Klein–Gordon wave equation) regime when the incoming wave packet exhibits the possibility of being almost totally transmitted through the potential barrier. The conditions for the occurrence of accelerated and, eventually, superluminal tunneling transmission probabilities are all quantified and the problematic superluminal interpretation originated from the study based on non-relativistic dynamics of tunneling is reevaluated. The treatment of the problem suggests revealing insights into condensed-matter experiments using electrostatic barriers in single- and bi-layer graphenes, for which the accelerated tunneling effect deserves a more careful investigation.

PACS numbers: 03.65.Xp, 03.65.Pm, 73.40.Gk

Finding a definitive interpretation of the nature of superluminal barrier tunneling has brought up a fruitful discussion in the literature [1–5] since pulses of light and microwaves appear to tunnel through a barrier at speeds faster than a reference pulse moves through a vacuum [6–9]. Tunneling occurs when a wave impinges on a thin barrier of opaque material and some small amount of the wave leaks through to the other side. The superluminal experiments that promoted the controversial discussions were performed with a lattice of layers of transparent and opaque materials arranged so that waves of some frequencies are reflected (through destructive interference) but other frequencies pass through the lattices in a kind of filter effect correlated to the Hartman effect [10].

In experiments described by the non-relativistic (Schrödinger) dynamics [5], the pulse (wave packet) that emerges from the tunneling process is greatly attenuated and front-loaded due to the filter effect (only the leading edge of the incident wave packet survives the tunneling process without being severally attenuated to the point that it cannot be detected). If one measures the speed by the peak of the pulse, it looks faster than the incident wave packet. Since the transmission probability depends analytically on the momentum component \( k \) \((T \equiv T(k))\), the initial (incident wave) momentum distribution can be completely distorted by the presence of the barrier of potential. As there is no sharp beginning to a pulse, we cannot declare the instant of its arrival at a certain point. Thus the computation of the tunneling time becomes
fundamentally meaningless. We could only watch the rising edge of the pulse and try to recognize what is arriving [2].

By employing a tunneling dynamics described by a relativistic wave equation we can reevaluate the most part of these difficulties. In this scenario, the existence of formal analogies between the barrier tunneling of the pulses of light and the tunneling transmission of relativistic particles allows for a close correspondence between quantum relativistic motions described by the Klein–Gordon equation and electromagnetic wave propagations in the presence of dissipation [11]. Here, we demonstrate with complete mathematical accuracy that, in some limiting cases of the relativistic (Klein) tunneling phenomena where the relativistic kinetic energy is approximately equal to the potential energy of the barrier, and \( mcL/\hbar \ll 1 \), particles with mass \( m \) can pass through a potential barrier \( V_0 \) of width \( L \) with transmission probability \( T \) approximately equal to 1. Since \( T \sim 1 \), the analytical conditions for the stationary phase principle applicability which determines the tunneling (phase) time for the transmitted wave packets are totally recovered. Differently from the previous (non-relativistic) tunneling analysis, the original momentum distribution is kept undistorted and there is no filter effect.

The tunneling time is then computed for a completely undistorted transmitted wave packet, which legitimizes any eventual accelerated transmission.

Some authors consider difficult and perhaps confusing the treatment of all interactions of plane waves or wave packets with a barrier potential using a relativistic wave equation [12–15]. This is because the physical content depends upon the relation between the barrier height \( V_0 \) and the mass \( m \) of the incoming (particle) wave, besides its total energy \( E \).

In the first attempt to evaluate this problem, Klein [16] considered the reflection and transmission of electrons of incidence energy \( E \) on the potential step \( V(x) = \Theta_1(x)V_0 \) in the two-dimensional time-independent Dirac equation which can be represented in terms of the usual Pauli matrices [17] by

\[
[\sigma^3 \sigma^i \partial_i - (E - \Theta(x_1)V_0 - \alpha^3 m)]\phi(k, x_1) = 0 \quad \text{(from this point} \ c = \hbar = 1) \tag{1}
\]

which corresponds to the reduced representation of the usual Pauli–Dirac gamma matrix representation \((i = 1, 2)\). The physical essence of such a theoretical configuration lies in the prediction that fermions can pass through large repulsive potentials without exponential damping. It corresponds to the so-called Klein tunneling phenomenon [13] which follows accompanied by the production of a particle–antiparticle pair inside the potential barrier. It is different from the usual tunneling effect since it lies in the energy zone of the Klein paradox [16, 17].

Taking the quadratic form of the above equation reduced to one dimension for a generic scalar potential \( V(x) \), we obtain the analogous Klein–Gordon equation,

\[
(i\partial_x + V(x))^2 \phi(k, x) = (E - V(x))^2 \phi(k, x) = (-\partial_x^2 + m^2) \phi(k, x), \tag{2}
\]

which, from the mathematical point of view, due to the second-order spatial derivatives, has similar boundary conditions to those of the Schrödinger equation and leads to stationary wave solutions characterized by a relativistically modified dispersion relation.

By depicting three potential regions by means of a rectangular potential barrier \( V(x) = \Theta_1(x)V_0 \) if \( 0 \leq x \leq L \), and \( V(x) = 0 \) if \( x < 0 \) and \( x > L \), we observe that the incident energy can be divided into three zones. Differently from the energy configuration relative to the non-relativistic (Schrödinger) dynamics, the above barrier energy zone, \( E > V_0 + m \), involves diffusion phenomena of oscillatory waves (particles). In the so-called Klein zone [13, 16], \( E < V_0 - m \), we find oscillatory solutions (particles and antiparticles) in the barrier region. In this case, antiparticles see an opposite electrostatic potential to that seen by the particles and hence they will ‘see’ a potential well where the particles ‘see’ a barrier [18, 19].

1 \( \Theta(x) \) is the heavyside function.
The tunneling zone, \( V_0 - m < E < V_0 + m \), for which only evanescent waves exist [20, 21] in the barrier region, is that of interest in this work.

By evaluating the problem for this tunneling (evanescent) zone assuming that \( \phi(k, x) \) are stationary wave solutions of equation (2), when the peak of an incident (positive energy) wave packet reach the barrier \( x = 0 \) at \( t = 0 \), we can write

\[
\phi(k, x) = \begin{cases} 
\phi_1(k, x) = \exp[ikx] + R(k, L) \exp[-ikx] & x < 0, \\
\phi_2(k, x) = \alpha(k) \exp[-\rho(k)x] + \beta(k) \exp[\rho(k)x] & 0 < x < L, \\
\phi_3(k, x) = T(k, L) \exp[ik(x - L)] & x > L,
\end{cases}
\]

where the novel dispersion relations: \( k^2 = E^2 - m^2 \) and \( \rho(k)^2 = m^2 - (E - V_0)^2 \), are modified with respect to the usual non-relativistic ones.

In order to proceed with a phenomenological analysis which allows us to establish a correspondence with the non-relativistic (NR) solutions, it is convenient to define the kinematic variables in terms of the following parameters: \( w = \sqrt{2mV_0}, \nu = V_0/m = w^2/2m \), and \( n^2(k) = k^2/w^2 = E_{NR}/V_0 \). The parameter \( w \) corresponds to the kinetic normalization parameter of the usual NR analysis where \( k^2 = 2mE_{NR} \). The previous quoted relation between the potential energy \( V_0 \) and the mass \( m \) of the incident particle is given by \( L \), the parameter \( \nu \). Finally, \( n^2(k) \) represents the dependence on the energy for all the results that are being considered here. After simple mathematical manipulations, it is easy to demonstrate that the tunneling zone for the above Klein–Gordon equation (2) is comprised by the interval \( (n^2(k) - \nu/2)^2 \leq 1 \) which made \( n^2(k) \) assume larger values \( (n^2(k) \gg 1) \), in opposition to the NR case where the tunneling energy zone is constrained by \( 0 < n^2(k) < 1 \). We shall observe that such a peculiarity has a suitable relation with the possibility of superluminal transmission through the barrier. The limits for NR energies \( (k^2 \ll 2\nu \text{ and } V \ll m) \) given by \( \nu n^2(k) \ll 1 \) and \( \nu/n^2(k) \ll 1 \) reproduce the Schrödinger wave solution results for the transmission coefficient and for the corresponding traversal time.

With regard to the standard one-way direction wave packet tunneling, for the set of stationary wave solutions given in equation (3), it is well known [23] that the transmitted amplitude \( T(n, L) = |T(n, L)| \exp[i\varphi(n, L)] \) is written in terms of

\[
|T(n, L)| = \left\{ 1 + \frac{wL}{\rho(n)wL} \sinh^2[\rho(n)wL] \right\}^{-1/2},
\]

where we have suppressed, from the notation the dependence on \( k \), and

\[
\varphi(n, L) = \arctan \left\{ \frac{n^2 - \rho^2(n)}{2n\rho(n)} \tanh[\rho(n)wL] \right\},
\]

for which we have made explicit the dependence on the barrier length \( L \) (parameter \( w, L \)), and we haverewritten \( \rho(n) = w\varphi(n) \), with \( \rho(n)^2 = \sqrt{1 + 2n^2w - (n^2 - \nu/2)^2} \).

The additional phase \( \varphi(n, L) \) that goes with the transmitted wave is utilized for calculating the traversal time \( t_0 \) of a transmitted wave packet when its peak emerges at \( x = L \),

\[
t_0 = \frac{dk}{dE(k)} \frac{dE(k)}{dn} \frac{d\varphi(n, L)}{dn} = \frac{(L)}{v} \frac{d\varphi(n, L)}{dn},
\]

evaluated at \( k = k_0 \) (the maximum of a generic symmetrical momentum distribution \( g(k-k_0) \) that composes the incident wave packet). By introducing the classical traversal time defined as \( \tau(k) = L(dk/dE(k)) = L/v \), we can obtain the normalized phase time,

\[
\frac{t_0}{\tau(k)} = \frac{f(n, L)}{g(n, L)},
\]
Tunneling transmission probabilities and the corresponding tunneling phase times for the dynamics of the relativistic wave equation. We have classified the energy zones by the line thickness: the thick line corresponds to the tunneling energy zone, the intermediate line corresponds to the Klein zone and the thin line corresponds to the above barrier energy zone. In fact the tunneling region is comprised by the interval intersection \((n^2 - \nu^2/2)^2 < 1\) and \(n^2 > 0\). Here we have adopted the illustratively convenient value of \(wL = 2\pi\). We have set \(\nu = 0, 1, 2, 5, 10\) and we have constrained our analysis to \(n^2(k) > 0\) since we have assumed \(V_0 > 0\). It is convenient to observe that the NR regime can be parametrized by the limit where \(\nu \to 0\).

We compare the theoretical results for the tunneling phase times in correspondence with the respective transmission probabilities in figure 1 for different propagation regimes \((\nu = 0 \text{ (NR)}, 1, 2, 5, 10)\). It is important to emphasize that the tunneling region is comprised by the interval \((n^2 - \nu^2/2)^2 \langle 1, n^2 \rangle 0\).

We can note the possibility of accelerated \((t_{\phi} < \tau_{(k)})\), and eventually superluminal (negative tunneling delays, \(t_{\phi} < 0\)) transmissions without recurring to the usual analysis of the opaque limit \((\rho(n)wL \to \infty)\) which leads to the Hartman effect [10]. In the NR dynamics (Schrödinger equation solutions), the opaque limit and its consequent superluminal interpretation (Hartman effect) were extensively discussed in the literature. Superluminal group velocities in connection with quantum (and classical) tunneling were predicted even on the basis of tunneling time definitions more general than the simple Wigner’s phase time \([24]\) (Olkhovsky et al, for instance, discuss a simple way of understanding the problem [5]).
Discussions on relativistic causality in addition to several analytical limitations have ruined
the most part of possibilities of superluminal interpretation of the NR tunneling phenomena
[4, 22, 23]. In a causal manner, the arguments consist in explaining the superluminal
phenomena during tunneling as simply due to a reshaping of the pulse, with attenuation,
as already attempted (at the classical limit) [25], i.e. the later parts of an incoming pulse are
preferentially attenuated, in such a way that the outcoming peak appears shifted toward earlier
times even if it is nothing but a portion of the incident pulse forward tail [7, 22].

We do not intend to extrapolate to the delicate question of whether superluminal group
velocities can sometimes imply superluminal signalling, a controversial subject which has
been extensively explored in the literature ([5] and references therein). Otherwise, the phase
calculation based on the relativistic dynamics introduced here offers distinct theoretical
possibilities of superluminal transmission in a novel scenario, for the limit case where \( \rho(n)wL \)
tends to 0 (with \( L \neq 0 \), in opposition to the opaque limit where \( \rho(n)wL \) tends to \( \infty \)). Let us
then separately expand the numerator \( f(n, L) \) and the denominator \( g(n, L) \) of equation (7)
in a power series of \( \rho(n)wL \) (\( \rho(n) \rightarrow 0 \)) in order to observe that in the lower (upper) limit
of the tunneling energy zone, where \( n^2 \) tends to \( \nu/2 + (-)1 \), the numerical coefficient of the
zero-order term in \( \rho(n)wL \) amazingly vanish in the numerator as well as in the denominator!
Since the coefficient of the linear term also is null, just the coefficient of the second-order
terms plays a relevant role in both series expansions. After expanding equation (7), such a
step-by-step mathematical exercise leads to

\[
\frac{t_{\nu}}{\tau(k)} = \frac{4}{3} \left[ \left( 4 + 4n^2\nu + \nu^2 \right)^{\sqrt{1 + 2n^2\nu}} - \left( 3n^2\nu \right)^{\sqrt{1 + 2n^2\nu}} \right] + O(\rho(n)wL)^2
\]

for small values of \( \rho(n) \). At the same time, since \( \lim_{mL \rightarrow \nu/2\pi} \rho(n) = 0 \), the tunneling
transmission probability can be approximated by

\[
\lim_{n^2 \rightarrow \nu/2+1} |T(n, L)| = \left[ 1 + \frac{(mL)^2}{2\nu} \right]^{-\frac{1}{2}} \left( 1 + (mL)^2 \right)^{-\frac{1}{2}},
\]

from which we recover the high probability of complete tunneling transmission when \( mL \ll 1 \).
Finally, for the corresponding values of the phase times evaluated in (8), we obtain,

\[
\lim_{n^2 \rightarrow \nu/2} \frac{t_{\nu}}{\tau(k)} = -\frac{1}{3 \nu^2}, \quad n^2 \rightarrow \nu/2 \mp 1, \quad n^2, \nu > 0,
\]

that does not depend on \( mL \) and we note that its asymptotic (ultra-relativistic) limit always
converges to 0. In particular, in the lower limit of the tunneling energy zone, \( n^2 \rightarrow \nu/2 - 1 \), it is
always negative. Since the result of equation (10) is exact, and we have accurately introduced
the possibility of obtaining total transmission (transparent barrier), our result ratifies the
possibility of accelerated transmission (positive time values), and consequently superluminal
tunneling (negative time values), for relativistic particles when \( mL \) is sufficiently smaller than
\( 1 (\Rightarrow T \approx 1) \). Keeping in mind that the barrier height has to be chosen such that one remains
in the transition regime, it is notorious that the transmission probability depends only weakly
on the barrier height, approaching the perfect transparency for very high barriers, in stark
cost to the conventional, non-relativistic tunneling where \( T(n, L) \) exponentially decays
with the increasing \( V_0 \). Since these results can be analytically extended to the Klein paradox
energy zone, such a relativistic effect is usually attributed to a sufficient strong potential that,
being repulsive for electrons, is attractive for positrons and results in unstable positron states
inside the barrier, which align the energy with the electron continuum outside [26].

Obviously, the above results correspond to a theoretical prediction, in certain sense, not
so far from the experimental realization. By considering the magnitude of the parameter
mL (mc²/[ℏ(c/L)]) in standard units) for an electron with mass ∼0.5 MeV, and observing that in natural units we have 0.2 MeV pm ∼ 1, we conclude that it should be necessary a potential barrier of width L ≪ 1 pm to permit the observation of the quoted superluminal transmission. By principle, its observation makes the effect relevant only for some exotic situations as positron production around super-heavy nuclei (Z ∼ 170) [27] or evaporation of black holes through generation of particle–antiparticle pairs near the event horizon [28].

In the most common sense, the above condition should be naturally expected since we are simply assuming that the Compton wavelength (ℏ/(mc)) is much larger than the length L of the potential barrier that, in this limit situation, becomes invisible for the tunneling particle. The relativistic quantum mechanics establishes that if a wave packet is spread over a distance d ≫ 1/m, the contribution of momenta |p| ∼ m ≫ 1/d is heavily suppressed, the negative energy components of the wave packet solution are negligible; the one-particle theory is then consistent. However, if we want to localize the wave packet in a region of space (wave packet width d) smaller than or of the same size as the Compton wavelength, that is d < 1/m, the negative energy solutions (positron states) start to play an appreciable role. This qualitative arguments report us to the Klein paradox and the creation of particle–antiparticles pairs during the scattering process which might create the intrinsic (polarization) mechanisms for accelerated and/or non-causal fermion teletransportation. The condition d < L < 1/m (where d < L is not mandatory) imposed over a negative energy component of the incident wave packet in the relativistic tunneling configuration excite the negative energy modes (antiparticles) in the same way that the movement of electrons in a semi-conductor is concatenated with the movement of positively charged holes.

Turning back to the context of the nanoscopic scale structures, the most challenging possibility of observing similar effects occurs for massless (or effective mass) Dirac fermions in graphene structures. Even though the linear spectrum of fermions in graphene implies zero rest mass, their cyclotron mass approaches mc/2 [29], which increases the superluminal tunneling scale to 1 Å. In spite of the theoretical analyses, the results here obtained apply to some configurations which should deserve further attention by experimenter in the study of the graphene structures where the dynamics of the electron is described by a relativistic-like dynamics. For bi-layer structures due to the chiral nature of their quasiparticles, quantum tunneling in these materials becomes highly anisotropic, qualitatively different from the case of normal, non-relativistic electrons. In fact, it has been recently speculated that, from the experimental point of view, the graphene provides an effective medium for mimicking relativistic quantum effects where; for instance, massless Dirac fermions allow a close realization of Klein’s gedanken experiment whereas massive chiral fermions in bi-layer graphene offer an interesting complementary system that elucidates the basic physics involved. The point is that, in conventional two-dimensional systems, sufficiently strong disorder results in electronic states that are separated by barriers with exponentially small transmittance [26]. In contrast, in single- and bi-layer graphene materials all potential barriers are relatively transparent (T(n, L) ≈ 1): the quasiparticles in graphene exhibit a linear dispersion relation E = ℏkv_f that corresponds to the pseudo-ultrarelativistic limit of our analysis for pseudo-massless particles traveling with their Fermi velocity v_f. In this case there are pronounced transmission resonances where T approaches unity for some particular geometric configurations, which does not allow charge carriers to be confined by potential barriers that are smooth on atomic scale. Moreover, some authors have demonstrated experimentally and theoretically that the biased graphene bi-layer is a tunable semiconductor where the electronic gap can be controlled by the electric field effect reaching values as large as 0.3 eV [30].
To summarize, as previously pointed out, we have considered tunneling by a wave packet obeying the Klein–Gordon equation, in a regime where the Compton wavelength of the particle is much larger than the width of the barrier, assumed rectangular. Our standard analysis has suggested the possibility of total transmission together with an accelerated tunneling. Once it has been observed that the physical essence of the Klein paradox lies in the prediction that particles can pass through large repulsive potentials without exponential damping [13, 14], the scenario of the Klein paradox and accelerated tunneling transmission associated with relativistic-like phenomena at nanoscopic scale can be tested experimentally using graphene devices. In a subsequent study we intend to investigate the appearance of an equivalent smaller effective mass value $M_{\text{eff}} \ll m$ due to the minimal coupling of the charged particle magnetic momentum with an external magnetic field, in particular, for the massless electron propagation in a single-layer graphene which could introduce some novel ingredients for quantifying these peculiarities of the relativistic tunneling effect.
