INTRODUCTION

The nutritional support of acute ill patients is very important and early enteral nutrition (EN) is recommended to maintain gut integrity and attenuate disease severity. Feeding via the nasogastric route is widely used for its ease of access if the patient cannot maintain volitional food intake. Recently, tubes for nasogastric feeding have been developed and used; however, Levin tubes, which have been designed for drainage of gastric contents, have been widely used in particular. Levin tubes have multiple side holes within 20 cm of the tip of the tube, so even if the tip is located in the stomach, the feeding formula can be delivered to the esophagus through the side holes. Herein, we report two cases of esophageal obstruction caused by malpositioned feeding tubes.

CASE REPORT

1. Case 1

An 87-year-old female was transferred to the intensive care unit (ICU) from a local hospital with a diagnosis of...
acute cholecystitis. She developed pain in the right upper quadrant while undergoing treatment for pneumonia 4 days prior to her transfer to the ICU. She had no specific past medical history.

She was intubated and mechanically ventilated due to exacerbation of the pneumonia and developed a parapneumonic pleural effusion the next day, during the treatment of acute cholecystitis. After she was hemodynamically stabilized on the 3rd day following her ICU admission, a Levin tube (size 14, French gauge) was inserted and continuous enteral feeding of a formula called Harmonilan® (Nutrichem Diät + Pharma GmbH, Roth, Germany) was administered at an infusion rate of 480 mL per day. Additionally, oral medication via the tube (powdered losartan and furosemide) was administered. The assigned doctor confirmed the position of the Levin tube by auscultation.

Her clinical course gradually improved with intravenous (IV) antibiotic administration and percutaneous drainage of the pleural effusion. Initially, we administered ceftriaxone and metronidazole with a focus on treating the acute cholecystitis. Subsequently, the antibiotics were changed from ceftriaxone to meropenem for treatment of biliary sepsis on the second hospital day, and on the 20th hospital day, they were changed to piperacillin/tazobactam and gemifloxacin to focus more on treating the pneumonia. IV pantoprazole and metoclopramide had been administered since her initial hospitalization. She was weaned off the mechanical ventilator on the 8th hospital day and was transferred to the general ward on the 22nd hospital day with nasal continuous positive airway pressure therapy.

Continuous enteral feeding via the Levin tube proceeded and was gradually increased to 960 mL per day. She defecated on the 16th hospital day for the first time since being hospitalized. Subsequently, she had loose stool but no diarrhea.

After a month of treatment, her Levin tube got occluded and was removed for replacement, but insertion of a new Levin tube failed repeatedly. Insertion of the Levin tube under guidance of gastrofiberscopy was attempted, but it also failed. Obstruction of the esophagus due to solidification of residual enteral feeding formula material at the level of 20 cm from the upper incisors was noted (Fig. 1A).

A gastroenterology physician was consulted and the bezoar was pushed downward to the stomach with a gastrofiberscope. After the whole bezoar was completely removed from the esophageal lumen (requiring about 11 minutes), shallow ulcers of the esophageal mucosa were observed (Fig. 1B). The esophageal mucosal ulcers were treated with IV esomeprazole. A new Levin tube was reinserted under guidance of a gastrofiberscope and continuous enteral feeding via the Levin tube resumed the next day with another feeding formula called Encover® (EN Otsuka Pharmaceutical Co., Hanamaki, Japan), without intolerance.

During a retrospective review of serial chest radiographs, we found that the tip of the Levin tube had been malpositioned above the gastroesophageal junction (GEJ) instead of inside the stomach (Fig. 2). The position of the newly inserted Levin tube was confirmed by the assigned physician using chest radiograph, and enteral feeding continued without complication.

The patient was scheduled to undergo elective chol-

![Image](image-url)
Ecystectomy; however, her clinical course worsened due to relapsing pneumonia. She expired on the 71st day of her hospitalization.

2. Case 2

A 68-year-old male complaining of severe chest pain was transferred to the ICU from a local hospital with a diagnosis of ascending aortic pseudoaneurysm. He had a past medical history of diabetes mellitus, left temporal cerebral infarction, right upper lobectomy due to lung cancer at another hospital one year prior to this hospitalization, and received an endovascular stent of the right common carotid artery and left subclavian artery two months prior to hospitalization.

On the second hospital day, he underwent ascending aorta replacement surgery with an artificial graft. IV cefbuperazone and IV pantoprazole were administered, and continuous IV injections of nitroglycerin, labetalol (for control of blood pressure), regular insulin (for control of blood glucose level), and furosemide (for proper fluid balance) were also administered.

Because he did not respond to pain stimulation and his mental status did not improve after cessation of sedatives on the first postoperative day (POD), magnetic resonance imaging of the brain was performed, and a neurologist diagnosed him as having acute multiple cerebral infarctions. We added a continuous injection of IV heparin to prevent further aggravation of the cerebral infarctions.

On the fourth POD, he was still receiving mechanical ventilation therapy. On that day, a Levin tube was inserted, and its placement was confirmed with auscultation. Continuous enteral feeding with Harmonilan was initiated with an infusion rate of 480 mL per day, and it was gradually increased to 960 mL per day. Administration of oral medication (levosulpiride) via the tube ensued, until the Levin tube occluded on the 12th POD. He had not defecated since his hospitalization. The assigned doctor attempted reinsertion of the Levin tube but failed repeatedly.

On the next day, gastrofiberoscopy was performed for evaluation of the esophagus and insertion of the Levin tube, but esophageal obstruction due to solidification of residual enteral feeding formula was noted (Fig. 3).

A gastroenterology physician was consulted, and again the bezoar was pushed downward to the stomach using a gastrofiberscope (requiring about 18 minutes). A new Levin tube was reinserted under the guidance of a gastrofiberscope and continuous enteral feeding with another feeding formula called Greenbia DM solution (Dr. Chung’s Food, Cheongju, Republic of Korea) via the Levin tube was resumed on the next day. The position of the newly inserted Levin tube was confirmed by the assigned physician with chest radiograph, and enteral feeding continued, without any sign of intolerance. The infusion rate of the
feeding was increased up to 1,440 mL per day.

In this patient, the tip of the former Levin tube had been positioned in the stomach, as noted in a retrospective review of chest radiographs. However, the portion of the tube that reached inside the stomach was about 15 cm in length (Fig. 4). Therefore, it is reasonable to assume that some of the side holes of the tube were located above the GEJ.

The patient had no complication associated with the ascending aorta replacement surgery, but as the cerebral infarction condition became chronic, the patient had a tracheostomy placed on the 15th POD. He was bedridden for about six months in ICU, and finally was transferred to a local hospital without significant improvement.

**DISCUSSION**

In most cases reporting esophageal obstruction caused by solidification of residual enteral feeding formula, Levin tubes were used and the position of the tip was not confirmed radiographically (Table 1). For example, Tawfic et al. reported a patient who suffered esophageal obstruction by bezoar from an enteral feeding formula. In that case, the malpositioning of the nasogastric tube (NGT) in the esophagus was confirmed, leading to an accumulation of the formula in the distal esophagus, which subsequently solidified. Tawfic et al. suggested that a major mistake was the failure to use a radiograph or a second method to confirm the correct position of the NGT. By radiographically confirming the location of the tip, it is possible to prevent esophageal obstruction.

Some case reports assume that the cause of solidification is the interaction of the casein component of the feeding formula with the acidic pH of the gastric juice. In a case report by Turner et al., an enteral feeding formula containing a casein component was administered, which resulted in esophageal obstruction. Since the formula containing dried skim milk instead of casein, which does not induce solidification even at a pH below one, Turner et al. suggested using a formula that does not contain casein and adminis-

**Table 1. Overview of the esophageal obstruction cases**

| Age/sex | Medical condition                                         | Enteral access | Malposition of tube tip | Treatment                          | Result                        |
|---------|----------------------------------------------------------|----------------|-------------------------|-----------------------------------|-------------------------------|
| Case 1  | 87/F                                                     | Levin tube (14 Fr) | Yes                     | Endoscopy                         | Successful clearing of esophagus |
| Case 2  | 68/M                                                     | Levin tube (14 Fr) | Yes                     | Endoscopy                         | Successful clearing of esophagus |
| Tawfic et al. | 20/M                                                      | NGT (14 Fr) | Yes                     | Endoscopy with sodium bicarbonate solution | Successful clearing of esophagus |
| Marcus et al. | 80/F                                | NGT (size unavailable) | No                   | Endoscopy                         | Successful clearing of esophagus |
| Degheili et al. | 69/M                            | NGT (size unavailable) | No                   | Feeding jejunostomy                | Unavailable                   |

F = female; M = male; NGT = nasogastric tube.
tering acid-lowering medications. Gupta et al.\(^6\) recommended administering pancreatic enzyme extract because it can prevent and liquefy the solidification of casein-containing formula. However, because Harmonilan\(^\text{®}\) does not contain casein, it is unknown which component caused solidification in the two aforementioned cases.

Since gastroesophageal reflux (GER) can increase the risk of esophageal obstruction during EN, it is recommended that risk for GER should be identified and decreased by maintaining elevation of the head of bed, and administering prokinetics and/or proton pump inhibitors.\(^3\) Douzinas et al.\(^7\) reported that GER became worse with a longer duration of NGT feeding in mechanically ventilated patients because NGT feeding causes mechanical irritation of the esophagus and relaxation of the lower esophageal sphincter. In addition, percutaneous gastrostomy and semi-recumbent positioning should be considered to lower the risk of GER.\(^8\)

More attention should be given to ICU patients receiving enteral feeding via an NGT. Degheili et al.\(^4\) reported a case of esophageal obstruction due to a bezoar from a casein-based feeding formula and suggested risk factors that predispose patients to gastrointestinal (GI) bezoars may include delayed gastric emptying, supine positioning, reduction in gastric acidity, history of previous gastric surgeries, peptic ulcer disease, achalasia, GI malignancies, Crohn’s disease, hypothyroidism, presence of hiatal hernia, and neuropathic or myotonic dystrophy. They also suggested that a multidisciplinary team approach is required for the estimation of the risk of GI obstruction from bezoar when providing ICU patients with enteral feeding. In a retrospective study of esophageal bezoar by Caldeira et al.\(^9\), there were 9 patients who were diagnosed with esophageal bezoar across the span of three years in 1,003 patients (0.9%) who received enteral feeding. The mean duration of enteral feeding was 12 days, and all these cases involved patients who were mechanically ventilated. So the duration of enteral feeding of mechanically ventilated patients can be a clue to which patients should be given more attention.

The NGT used for feeding in these two cases was a Levin tube with multiple side holes within 20 cm of the tip, which allows for drainage of gastric contents. Compared with an NGT designed only for feeding and made of polyurethane, a Levin tube is made of silicone and usually has a smaller inner diameter compared to that of a polyurethane tube. In the first case, the tip of the NGT was located in the esophagus. In the second case, the tip of the NGT was located in the stomach, but the distance from the GEJ to the tip of the tube was inadequate and some of the side holes might have been located in the esophagus. It is reasonable to assume that total or part of the administered feeding formula was retained in the esophagus and thus solidification occurred; additionally, the reflux of gastric contents with an acidic pH may have triggered the solidification. In the first case, the patient did not have a significant past medical history, but she received mechanical ventilation due to pneumonia. In the second case, the patient had a past medical history of diabetes mellitus and was diagnosed with acute cerebral infarction, which may alter the motility of the esophageal sphincter and cause retention of the enteral formula.\(^10\) Listed risk factors related to the patients in these two cases might have resulted in the esophageal obstruction observed in these two cases.

In conclusion, feeding tubes that are designed solely for feeding rather than drainage should be used to prevent esophageal obstruction due to enteral formula. The tube should be carefully inserted and checked radiographically to be sure that all side holes are located within the stomach. Risk factors for esophageal obstruction due to bezoar formation should be identified and minimized. Lastly, if a patient is expected to receive enteral feeding for an extended duration, casein-based formulas should be avoided, if possible.
