Abstract

*Hypnomys* is a genus of Gliridae (Rodentia) that occurred in the Balearic Islands until Late Holocene. Recent finding of a complete skeleton of the chronospecies *H. morpheus* (Late Pleistocene-Early Holocene) and two articulated skeletons of *H. cf. onicensis* (Late Pliocene) allowed the inference of body size and the calculation of several postcranial indexes. We also performed a Factorial Discriminant Analysis (FDA) in order to evaluate locomotory behaviour and body shape of the taxa. Using allometric models based on skull and tooth measurements, we calculated a body weight between 173 and 284 g for *H. morpheus*, and direct measurements of articulated skeletons yielded a Head and Body Length (HBL) of 179 mm and a Total Body Length of 295 mm for this species. In addition to the generally higher robustness of postcranial bones already recorded by previous authors, *H. morpheus*, similar to *Canariomys tamarani*, another extinct island species, displayed elongated zygopodium bones of the limbs and a wider distal humerus and femur than in an extant related taxon, *Eliomys quercinus*. Indexes indicated that *Hypnomys* was more terrestrial and had greater fossorial abilities than *E. quercinus*. This was also corroborated by a Discriminant Analysis, although no clear additional inference of locomotory abilities could be calculated.

Introduction

The autochthonous mammal fauna of the upper Pleistocene and Holocene of Mallorca and Menorca (Western Mediterranean, Figure 1) consists of three endemic species. Remains of *Myotragus balearicus* (Artiodactyla: Bovidae), *Hypnomys morpheus* (Rodentia: Gliridae) and *Nesiotites hidalgo* (Soricomorpha: Soricidae) are abundant in the fossil sites of these islands. They all derived from a single Messinian colonization event to Mallorca, and then colonized Menorca probably during the first upper Pliocene glaciations. They are the most recent representatives of three colonized Menorca probably during the first upper Pliocene

frequently limit the weight estimates to those derived from the teeth and other cranial parameters, while they constrain the approach to other body parameters.

Several proxies have been proposed to infer body weight in extinct rodents. All these methods are related to measurements of different parts of the skeleton: postcranial bones [15]–[17], skull [18], isolated incisors [19], [20] or isolated molars [21], [22].

No attempts to infer body weight of the fossil dormouse *Hypnomys* (Gliroidae) [23] have been published, although Mills (1976) [24] accurately described its skeleton. It was a large dormouse, adapted to eat harder food than *Eliomys quercinus* [25]. Until now, only one skeleton of *Hypnomys morpheus* has been reported (Cova des Penyal Blanc, Cabrera)[26]. Unfortunately, it was disarticulated and covered by a thick flowstone layer, precluding the possibility to measure the bones and to estimate its body size and proportions. Recently collected associated material of this species offers a unique opportunity to estimate its body size parameters, and allows a reliable approach to reconstruct its life aspect. In addition, some complete skeletons of *Hypnomys cf. onicensis*, an ancestor of *H. morpheus* dated c. 2.5–2 My, have been found, some of them embedded in flowstone and with bones in articulation. The goal of this paper is to present the body shape and weight of *Hypnomys* on the basis of this new material.

**Materials and Methods**

An almost complete skeleton of *Hypnomys morpheus* (Figures 2a and 3a) was recently discovered in a cave in the northern Mallorcan mountains (Cova des Coral-loides, Calvià, southwest of Serra de Tramuntana)[27]. Its accession number is CDC-2. Other five partial associated skeletons of *H. morpheus* obtained in this cave have been also studied (CDC-10, CDC-27, CDC-39 and CDC-40).

Pictures of different articulated *Hypnomys cf. onicensis* skeletons obtained at Cova des Pas de Vallgornera (Llucmajor, Mallorca) [20] were used to obtain direct body measurements (Figure 4). The material was not extracted, particularly because of the difficulties to reach the site and the extreme fragility of the specimens.

We compared *Hypnomys* in detail with its closest living relative, *Eliomys quercinus* [23], [29]. Specimens of three populations of *Eliomys quercinus* living in the Balearic Islands (E. *q. quercinus* from Mallorca, E. *q. gymnesticus* from Menorca and E. *q. opheusae* from Formentera) were included. The two first populations include specimens with a body size similar to the Iberian mainland populations [30], [31], while the Formentera population consists of large-sized animals [32]. These specimens were collected at the end of the 70’s and their skeletons are currently curated at IMEDEA. Specimens are listed in Appendix S1. Measurements are illustrated in Figure 5 and follow Samuels & Van Valkenburgh (2008)[33] for postcranial bones and Kahmann (1970)[32] for skull and mandible. All measurements were taken with a digital caliper of an accuracy of 0.02 mm. Additional skull biometrical data of *E. quercinus* from the Balearic Islands have been obtained from Alcover (1983)[34]. Data of condylobasal length and body weight of *E. quercinus* from various Mediterranean islands (Sicily, Sardinia, Lipari, Menorca and Formentera) to infer body weight in *H. morpheus* were taken from Kahmann & Lau (1972)[35].

The following measurements were used (Figure 5). *Skull and mandible*: BCL: Basicranial Length; BNH: Braincase Height; BNL: Braincase Length; BNW: Braincase Width; CBL: Condylobasal Length; DL: Diastema Length; FL: Foramina Incisivi Length; FW: Frontal Width; IMD: mesiodistal diameter of upper incisor at wear level; IOW: Interorbital Width; IW: Incisors Width; LTRL: Lower Toothrow Length; LTRW: Lower Toothrow Width; M2-M2: Breadth between labial margins of M2; ML: Mandibular Length; MW: Mastoid Width; NL: Nasal Length; RoL: Rostral Length; RTRA: Rectangular Lower Toothrow Area (calculated as LTRL ×LTRW); RW: Rostral Width; STL: Skull Total Length; TBL: Tympanic Bulla Length; TBW: Tympanic Bulla Maximum Width; TbW: Tympanic Bulla Minimum Width; Upper T: Upper Incisor Transverse Diameter; UTL: Upper Toothrow Length; ZL: Zygomatic Length; ZW: Zygomatic Width. *Postcranial skeleton*: DPCP: Length of Deltopectoral Crest of the Humerus; FAPD: Midshaft Anteroposterior Diameter of the Femur; FEB: Epicondylar Breadth of the Distal Femur; FGT: Height of the Greater Trochanter of the Femur; FL: Femur Length; FUL: Functional Length of the Ulna; HEB: Epicondylar Breadth of the Distal Humerus; HMLD: Midshaft Mediolateral Diameter of the Humerus; HL: Humerus Length; HMLD: Midshaft Mediolateral Diameter of the Humerus; PL: Pelvis Length; RL: Radius Length; SL: Scapula Length; TL: Tibia Length; TMLD: Midshaft Mediolateral Diameter of the Tibia; TSL: Length of Tibial Tuberosity; UMLD: Midshaft Mediolateral Diameter of the Ulna; UOL: Length of the Olecranon Process of the Ulna. Additionally, we used the Head and Body Length (HBL), Tail Length (TaL) and Weight (W) as external body size parameters.

To obtain body weight estimates, slope and intercept values of allometric models used here were obtained from literature in its log or ln transformation of the power function Y = aX^b (estimations based on skull measurements obtained from [30], dental measurements from [19], [22], [37] and postcranial elements from [38]). A ln-transformation of an allometric model for body weight estimation from Condylar length was applied to *Eliomys quercinus* data from [35]. Data for comparative analysis of the body proportions and the locomotion were taken from [33].
The choice of the variables to estimate the body weight is important, because the different proxies give a large variety of results. In order to evaluate the reliability of the equations used to approach the body weight of Hypnomys, estimates of body size of an Eliomys quercinus specimen from Mallorca (IMEDEA 7335) with known body weight (74 g) were calculated. The best approaches of body weight were obtained through the allometric model of [22] for RTRA (Rectangular lower Tooth Row Area), [19] for IMD, [36] for skull CBL and the linear correlation between body size and CBL obtained from [35].

Statistical procedures were performed with Statistica (version 6.0). The morphological variability of extant and extinct compared dormice (i.e., Hypnomys and three insular populations of Eliomys quercinus) was quantified using Samuels and Van Valkenburgh (2008)[33] procedure based on measurement of morphological (e.g., osteological and muscular) characteristics used to compute limb indexes. For each analysis, a set of 13 robustness, morphofunctional and proportion indexes was considered: SMI, BI, HRI, HEB, OLI, URI, CI, GI, FRI, FEB, TRI, TSI and IM (see Appendix S2 for definitions). MANOVA in association with a test of significance (Wilk’s Lambda test) was performed on these indexes in order to assess the effects of life-style. Then, a Factorial Discriminant Analysis (FDA) of shape coordinates was performed in order to maximize discrimination among rodents belonging to different locomotory groups. The analysed dormice (i.e., Eliomys and Hypnomys) were supplemented with additional data of other rodents [33].

Results

Body size

One of two well preserved articulated skeletons of Hypnomys cf. onicensis in the Cova des Pas de Vallgornera (Llucmajor, Mallorca; e.g., Figure 4)[28] could be measured although partially covered with flowstone (Figure 4b) and placed on the floor of a currently flooded gallery. It had a total length of 247 mm (head and body length measured adding the skull length to the body length from the atlas to the end of the last sacral: 150 mm; tail length along caudal vertebrae: 97 mm). The tail (TaL) was relatively much shorter (c.65% of HBL) than in Eliomys quercinus (c.88% of HBL in adult specimens). Assuming that body proportions have not

changed substantially along the *Hypnomys* evolution in Mallorca (an unproved assumption), an estimation of body size in the *H. morpheus* from Cova des Coral-loides can be presented on the basis to its CBL. Total length of this specimen was estimated as c. 295 mm (HBL: 179 mm; TaL: 116 mm), an estimate that agrees with the HBL of 180 mm established by Mills (1976)[24].

Slope and intercept values obtained from the different methods which we used to estimate body weight for the specimen CDC-2 of *H. morpheus* from Cova des Coral-loides are shown in Table S1. Using best proxies (according to the previous evaluation of approaches), values between 173 and 284 g for the specimen *Hypnomys morpheus* CDC-2 from Cova des Coral-loides were obtained. Values obtained from tooth-based models gave estimates between 173 and 260 g, while those based on CBL produced estimates of 214 and 284 g. Nevertheless, it has been established that skull and teeth measurements often produce underestimates of body weight [39]. The relation between head and the body shape will be explored later to check the reliability of these approaches.

**Skull**

*E. q. ophiusae* had greater values of indexes related to the proportional elongation of the rostral part of the skull (elongated rostrum, nasal, foramina incisivi and diastema), while corresponding values of *H. morpheus* fell in the range of *E. quercinus* from Mallorca and Menorca, except for index RoL/CBL in which the fossil species showed the greatest value. *E. q. ophiusae* and *H. morpheus* had smaller values for relative braincase length (BNL/CBL)(Table S2, Figure 2).

Limbs

_Hypnomys morpheus_ had robust limbs, with an elongated zygapodium for both fore- and hindlimbs (Tables S3, S4 and S5; Figure 3[24]). To estimate the body shape design, a series of bone ratios were explored. These ratios were then compared with the corresponding ratios in the populations of _Eliomys quercinus_.

The obtained indexes were split here in (1) robustness indexes, (2) morphofunctional indexes, and (3) proportion indexes to facilitate their interpretation.

Robustness indexes: HRI, URI, FRI and TRI. Among _Hypnomys_ and all the studied populations of _Eliomys quercinus_, the greatest values for all indexes related to robustness were displayed by _H. morpheus_ and _E. q. ophiusae_, with the highest values for stylopodium in _H. morpheus_ (Table S3).

In _Hypnomys morpheus_ the range of values of humerus robustness, HRI (0.106–0.116) displayed a slight overlap with _E. q. ophiusae_ (0.098–0.110). Average values for _E. quercinus_ are 0.095 and 0.091 for the Mallorcan and Menorcan populations respectively, and value range of the Menorcan sample was included in the range of the Mallorcan one. The greatest ulna robustness values were those of _E. q. ophiusae_ (average 0.043, range: 0.039–0.049). _Hypnomys_ presented an ulna slightly more slender than that of _E. q. ophiusae_ (average 0.041, range: 0.038–0.042).

The highest values for the robustness index of the femur (FRI) were displayed by _H. morpheus_ (average 0.098, range 0.083–0.112) while the relatively robust _E. q. ophiusae_ showed a smaller average value (average 0.082, range 0.078–0.084). _E. q. gymnesicus_ presented slender femora, with average values close to 0.071 and a range smaller than in _E. q. ophiusae_. Similarly to the ulna, _E. q. ophiusae_ displayed the greatest value for tibia robustness index (TRI) among populations studied (average 0.066, range 0.062–0.068). _H. morpheus_ presented more slender tibiae than _E. q. ophiusae_ (average 0.06, range 0.059–0.063). No differences in limb bone robustness were observed between the normal sized populations of _E. quercinus_.

Morphofunctional indexes: OLI, TSI, SMI, GI, HEB, FEB. In two of the morphofunctional indexes (OLI and TSI) all groups had similar values and no remarkable differences were observed (Table S4). Roughly, both olecranon process and tibial tuberosity were similarly positioned (same proportional distance from proximal extreme) in _Hypnomys_ and _Eliomys_. For two other indexes (SMI and GI) _Hypnomys morpheus_ had similar average or range values than _E. q. ophiusae_, while both were larger than Mallorcan and Menorcan populations of _E. quercinus_. The ranges of values of _Hypnomys_ and _E. q. ophiusae_ were larger than the range observed in the populations which individuals have the size of the mainland garden dormice (except for a slight overlap in GI range values of large glirids and _E. q. gymnesicus_ from Mallorca). These indexes indicated a proportionally longer deltopectoral crest (SMI) and distal extension of femoral greater trochanter (GI) in _Hypnomys_ and _E. q. ophiusae_.

Remarkable differences in indexes, in which epicondylar breadth of the long bone is involved (HEB and FEB), could be observed in the stylopodium of _H. morpheus_ and the extant _Eliomys_. _Hypnomys_ had greater average and range values than _Eliomys_, documenting a wider medio-lateral distal breadth in the humerus and femur of _H. morpheus_.

Proportion indexes BI, CI, IM. _H. morpheus_ had higher values of BI and CI than extant _Eliomys_ indicating a proportional elongation of the zygapodium bones, i.e., ulna, radius and tibia (Table S3). These higher indexes, together with URI and TRI, should be interpreted as if _Hypnomys_ possessed relatively more elongated zygapodes than _E. q. ophiusae_, a peculiar trait of the genus. Differences could also be observed in the IM index, with

In general, index values involving the rostrum width (sensu lato, including zygomatic, interorbitary, rostral and M2-M2 widths) were similar in _H. morpheus_ and normal-sized Mallorcan and Menorcan populations of _E. quercinus_, while _E. q. ophiusae_ displayed a proportionally narrower zygomatic and interorbital breadth. On the other hand, _H. morpheus_ and _E. q. ophiusae_ had smaller values of indexes related to proportional width of the braincase part of the skull (mastoid and braincase width) than _E. quercinus_ s.l., indicating a proportionally narrower braincase in the two large-sized taxa. Mastoid width of _H. morpheus_ was even proportionally smaller than _E. q. ophiusae_. _H. morpheus_ and _E. q. ophiusae_ showed lower values of index BNH/CBL than in the other _E. quercinus_ populations, indicating a proportionally lower braincase in the first two taxa.

According to the indexes TBL/CBL, TBW/CBL, TBw/CBL and TBL/BNI, the tympanic bulla of _H. morpheus_ was shorter but proportionally wider than in _E. quercinus_. This could be related to an adaptation to a more abrasive diet already hypothesized for the fossil species [25].

Figure 4. Articulated skeletons of _Hypnomys morpheus_ covered by flowstone found in the Cova des Pas de Vallgornera (Llucmajor, Mallorca). A) Skeleton located in a dry passage of the cave. B) Skeleton found in the bottom of a lake (see diver in insert). Photos by G. Mulet (a) and M.A. Perelló (b).

doi:10.1371/journal.pone.0015817.g004
lower values in *H. morpheus*, indicating that it had proportionally longer hind limbs than *Eliomys*. Compared to *E. quercinus ophiusae*, in *Hypnomys* the increase of the fore limb zygodactyl was greater than the increase in the hind limb zygodactyl. Limb proportions were similar in all populations of *Eliomys quercinus* studied, independently of individual size.

When limb bone lengths were compared to the CBL (a proxy of overall size) of the same individual (Table S6), remarkable differences appeared between *Hypnomys* and *Eliomys*. Analyses of these ratios allowed to describe how morphology changed along the *Hypnomys* lineage. In agreement with the conclusions of the analyses of the limb indexes, the higher values of the ratios RL/CBL, FUL/CBL and TL/CBL and similar values of the ratios HL/CBL, FL/CBL and SL/CBL reflected the elongation of the zygodactyl bones in *Hypnomys*. Additionally, no remarkable differences could be observed between *Hypnomys* and *Eliomys* in the values of two of the morphofunctional indexes studied (OLI, proportional olecranon process length, and TSI, proportional distal extension of the tibial tuberosity), indicating that an elongation of the zygodactyl affected the whole bone (ulna and tibia).

**Statistical approach.** As Samuels and Van Valkenburgh (2008) previously showed, MANOVS on robustness, morphofunctional and proportion indexes indicated a significant differentiation of the morphology within the dataset involving lifestyle (Wilk’s Lambda test: Value = 0.00290, F = 78.265, *p* < 0.001). A factorial discriminant analysis, with the addition of extinct taxa as unclassified cases, allowed a complete discrimination among groups of different locomotory habits (Figures 6 and 7). Morphologies in relation with these locomotory habits could be separated on the first three discriminant axes (comprising 95% of among-group variance [Figures 6 and 7]).

The first discriminant axis (LD1) accounted for 53.5% of variance and was positively correlated with brachial index (BI) and...
crurial index (CI), and negatively correlated with intermembral index (IM). Fossorial, gliding and arboreal rodents tended to have negative scores for LD1 whereas ricochetal rodents showed strongly positive DF1 scores (Figure 6). On the other hand, 27.2% of among-group variance is explained by the second discriminant axis (LD2). This axis was negatively correlated with shoulder moment index (SMI), humeral robustness index (HRI), humeral epicondylar index (HEB), ulnar robustness index (URI), and olecranon length index (OLI). LD2 distinguished gliding and fossorial taxa that tended to have positive and negative sores for this axis. In the shape space defined by LD1 and LD2, the location of Balearic *Eliomys* remained close to arboreal as well as terrestrial rodents whereas *Hypnomys* was located near to semifossorial rodents. The third axis (LD3 - 14.2% of among-group variance - Figure 6) included components positively related to femoral robustness index (FRI), femoral epicondylar index (FEB) and tibial spine index (TSI), and mainly separated semi-aquatic rodents from all other groups. The morphological characteristics of *Hypnomys* and *Eliomys* were less discriminated on the third discriminant axis.

The discriminant model used to separate the locomotor groups was primarily checked using a classification phase and then used on extinct taxa to assess their locomotor habit. This classification showed 89.4% correct classification of species. Fossorial, gliding and ricochetal groups had 100% correct classification. All other groups had <90% correct classification but >75%: 88.9% for semifossorial, 87.5% for semiaquatic, 78.6% for terrestrial, and 77.8% for arboreal. Most misclassifications were with arboreal and terrestrial taxa. Their skeletal proportions were more variable but nevertheless compatible with these two modes of life, contrary to the other modes. The four Balearic representatives of gliroids (*i.e.* *Hypnomys morpheus*, and the three *E. quercinus* from Formentera, Mallorca and Menorca) were included as ungrouped cases in the classification phases of the analysis. Using this procedure, *H. morpheus* was first classified as arboreal (probability *a posteriori*: p = 74.6% - see Table S7) and should be secondly considered as semifossorial (p = 22%). The situation appeared to be more complex for the three Balearic *E. quercinus* because two were classified as arboreal (Formentera, p = 49.2%; Menorca, p = 69.7%) and one as terrestrial (Mallorca, p = 70.8%). As a matter of fact, it was noticed that both terrestrial and arboreal groups showed the lowest percentage of correct classification. Mahalanobis distances indicated that the morphological features of *Hypnomys* were very close to that of arboreal and semifossorial...
groups (d [Hypnomys-arboreal] = 19, and d [Hypnomys-semifossorial] = 21.4 – see Table S8).

Body shape

After the reconstruction of Mills (1976)[24], the general body shape of *Hypnomys morpheus* is that of a heavily built dormouse. Our results agree with this approach. From the previous sections it is clear that *Hypnomys morpheus* was larger and displayed different body proportions than its closest living relative, *Eliomys quercinus*. In relation to the length of the skull, some long bones of the limbs were longer in *Hypnomys morpheus* than in *Eliomys quercinus*, mainly the zygopodium bones and the pelvis. Consequently, the estimates for body weight of *Hypnomys* based on skull and dental measurements should be considered as underestimations.

The increase of body size is a clear trend in the *Hypnomys* evolution, identified long ago [23], [24], [40]. Unfortunately nothing is known about bone ratios in the earliest *Eliomys* (i.e., *E. truci* and closest relatives). Thus, comparisons had to be made with recent *E. quercinus*. If *Hypnomys* had a proportionally reduced head or a proportionally increased length of limb bones, a classical measurement as the ratio head/body length cannot be measured accurately without using some reference of the body trunk. We excluded the direct comparison with waist bones, because the main waist bones (scapula, clavicle and pelvis) are directly related to locomotion, and their size is related to the limb bone size.

To calculate the ratio between head and body length in a *Hypnomys* species we used one of the two skeletons found in Cova des Pas de Vallgornera. This ratio was compared with that of recent populations of *Eliomys quercinus* (see Table S7). In comparison to body length, the head became increasingly smaller when *Eliomys* became elder. The specimen of *Hypnomys* from Vallgornera had a proportionally slightly smaller head than the living garden dormice. Consequently, it is the skull of *Hypnomys* that appears as relatively reduced. Thus, again we can conclude than our initial estimation of body mass should be considered as an underestimate.

**Discussion**

Mills (1976)[24] stated that *Hypnomys* was a robust and probably powerfully muscled dormouse. This author studied non-associated material and established that the relative lengths of the antebrachium and tibia compared to the humerus and femur suggest that *Hypnomys* was less cursorial than other dormice.
Tracks and trackways of Hypnomys were found on aeolianites in two Menorcan deposits [41], [42]. Data yielded from the Cova de Sa Duna deposit (Alaior), and the lack of tail tracks was taken as evidence that Hypnomys did not drag the tail [42], contrary to [24].

The results obtained from the statistical analyses showed a complex situation that does not drive to clear-cut conclusions. That situation cannot be understood unless it is first considered the fact that the individuals integrate the selective effects of the many components of the environment, and second, that are unknown the early conditions of any insular evolution. In our analysis, the three living Balearic Garden Dormice depicted an original case of differentiation. One of them (Formentera population) showed a more terrestrial way of life. Eliomys is known to inhabit macchias, but also lives on the floor of rocky areas with blocks of rocks in vegetated areas and it can be expected that populations may become more specialized in one or another component of this bivalent mode of life (i.e., arboreal vs terrestrial). The difference between the Eliomys from Formentera and Menorca, and the Eliomys from Mallorca already illustrated insular divergences involving the whole morphology of the cranial and post-craniad skeleton. Hypnomys illustrates a different case. The results showed that Hypnomys was able to climb in the tree as well as to live on the ground. However, we should note from the classification procedure the very low percentage observed for Hypnomys as a typical terrestrial rodent (probability a posteriori: p = 0.03%). Thus, we have to take into consideration that Hypnomys was able to dig. This hypothesis is in agreement with the fact that all the specimens of H. morpheus showed a high number of pits and large pits [25]. Such a high frequency of coarse features could indicate the intake of grit into the diet [43]. Contrary to Eliomys, Hypnomys might have developed a more fossorial behaviour. As Hypnomys lived under a Mediterranean climate and flora, it would be possible to consider that it may have lived on some vegetal matter provided by geophytes, at least when conditions were extreme.

Little is known about the environment which Hypnomys inhabited. Climate and vegetation in the Western Mediterranean during Early Pliocene was markedly subtropical [44], [45]. It is assumed that since the late Pliocene the subtropical vegetation evolved to a Mediterranean one, with a more arid character than the previous one [46]. In some of the interglacial periods the climate of the Balearic Islands showed a wide seasonal range of temperature, moisture and precipitation, including recorded periods with a mean annual temperature about 2°C higher than today, with very dry moisture regimes, limited plant biomass [47], [48], and important sea-level rises [49], [50]. The available data on the Late Pleistocene-Holocene vegetation from Mallorca and Menorca revealed the presence of abundant plant taxa with scoriaceous leaves and containing toxic alkaloids (e.g., Buxus, Graphiurus, Nuxia, Euphorbia) [51], [52]. Nevertheless, it still remains unclear how this vegetation, supposedly modelled by climate and Myotragus, could have influenced the evolution of Hypnomys.

It is difficult to find parallels to the Hypnomys body shape and proportions. We have been unable to find clear analogies to the zygodipodium elongation in living Sciurognaths. This elongation suggests a peculiar way of locomotion, which should have been unusual for Sciurognaths. Similar, but not identical, body proportions are present in the fossil insular rat Canarianos morpheus from Gran Canaria [53], but not in Canarianos balearicus from Tenerife. C. tamarani also displays a proportionally longer radius and tibia and a wider distal humerus. The bone proportions of C. tamarani have been interpreted as an adaptation to a more terrestrial life style with greater cursorial and fossorial abilities than in C. balearicus [53]. It is currently unknown whether the limb proportions observed in Hypnomys and C. tamarani are shared by other insular rodents, and are consequently a result of an insular evolutionary trend.

Isolation on islands is a well-known factor to induce evolutionary change and a rather frequent event is the origination of giant forms in small mammals like rodents, and the study of the skeleton not only provides a good illustration of the increase in size, but also of changes in shape [54]–[57]. The singularity of Hypnomys in relation to Eliomys illustrates that aside size, differences in shape resulted of an adaptive process in relation with several aspects of the lifestyle that included the modes of locomotion, of foraging, and of food processing. Because of the lack of competitors, Hypnomys was able to become more a burrower and thus to diverge from its ancestral condition, presumed to be that of Eliomys (i.e. forest and floor of rocky areas).

Within the 30 living species of Gliridae, only the West African Graphiurus crassicaudatus has a tail as short (relative tail length 65.7%)[58] as in Hypnomys (64.7%). Species with moderately short tails are Graphiurus surdus (72.9%), and Myomys roachi (77.3%)[59]. Other glirids have relative tail lengths over 80%. Myomys roachi lives on the ground, with no morphological adaptations for a scansional or fossorial life style [59]. The ecology of Graphiurus crassicaudatus is poorly known. It would be promising to study skeletons of these rare species in the future.

Finally, we want to emphasize on opposite trends recorded in the evolution of two herbivorous mammals which inhabited the Gymnesic Islands until the human arrival. Myotragus balearicus was a dwarfed ruminant that displayed a reduction of the distal part of limbs, with an extremely reduced ability for running [9]. Hypnomys morpheus was an enlarged dormouse derived from an Eliomys ancestor, with elongated limbs, and perhaps an increased cursorial ability.

Supporting Information

Appendix S1 List of extant and extinct rodent skeletons measured in this paper.

(DOC)

Appendix S2 Postcranial indexes used in this paper (obtained from [33] and [60]).

(DOC)

Table S1 Body weight estimates of H. morpheus from Cova des Coral loides.

(DOC)

Table S2 Eliomys versus Hypnomys skull indexes.

(DOC)

Table S3 Eliomys versus Hypnomys robustness indexes (limb bones).

(DOC)

Table S4 Eliomys versus Hypnomys morphofunctional indexes (limb bones).

(DOC)

Table S5 Limb bone proportion indexes and comparison with ranges (95% interval) for terrestrial, arboreal and semifossorial rodents (according to [33]).

(DOC)

Table S6 Limb versus skull indexes in Eliomys and Hypnomys.

(DOC)
Table S7 Probability a posteriori (%) for the locomotor habit of Balearic dormice.

(DOC)

Table S8 Mahalanobis distances between the morphological proportions of Eliomys quercinus and Hypnomys morpheus vs different types of locomotor habit.
