Abstract
The exact grand-canonical solution of a generalized interacting self-avoiding walk (ISAW) model, placed on a Husimi lattice built with squares, is presented. In this model, beyond the traditional interaction $\omega_1 = e^{\epsilon_1/k_BT}$ between (nonconsecutive) monomers on nearest-neighbor (NN) sites, an additional energy $\omega_2$ is associated to next-NN (NNN) monomers. Three definitions of NNN sites/interactions are considered, where each monomer can have, effectively, at most two, four, or six NNN monomers on the Husimi lattice. The phase diagrams found in all cases have (qualitatively) the same thermodynamic properties: a non-polymerized (NP) and a polymerized (P) phase separated by a critical and a coexistence surface that meet at a tricritical ($\theta$-) line. This $\theta$-line is found even when one of the interactions is repulsive, existing for $\omega_1$ in the range $[0, \infty)$, i.e., for $\epsilon_1/k_BT$ in the range $[-\infty, \infty)$. Thus, counterintuitively, a $\theta$-point exists even for an infinite repulsion between NN monomers ($\omega_1 = 0$), being associated to a coil–‘soft globule’ transition. In the limit of an infinite repulsive force between NNN monomers, however, the coil–globule transition disappears, and only NP–P continuous transition is observed. This particular case, with $\omega_2 = 0$, is also solved exactly on the square lattice, using a transfer matrix calculation where a discontinuous NP–P transition is found. For attractive and repulsive forces between NN and NNN monomers, respectively, the model becomes quite similar to the semiflexible-ISAW one, whose crystalline phase is not observed here, as a consequence of the frustration due to competing NN and NNN forces. The mapping of the phase diagrams in canonical ones is discussed and compared with recent results from Monte Carlo simulations on the square lattice.

Keywords: polymer, coil-globule transition, exact solution, Husimi lattice

1. Introduction

A polymer in solution usually may exist in three different conformations, depending on temperature $T$ or solvent quality: (i) extended: coil-like chains (high $T$ and/or good solvents); (ii) collapsed: the chains have globule-like shapes (low $T$ and/or poor solvents); and (iii) this point marks the (continuous/tricritical (TC) [1, 2]) transition between the coil and globule phases (occurring at $T_0$ and in a ‘$\theta$-solvent’) [3, 4]. The differences among these phases can be characterized, for example, through the metric exponent $\nu$—from the scaling of the gyration radio $R_g$ with the number $N$ of monomers, $R_g \sim N^\nu$, being $\nu_{\text{coil}} > \nu_0 > \nu_{\text{globule}}$.

For linear polymers, the coil phase can be modeled by self-avoiding walks (SAWs), where the excluded volume is the only interaction present (athermal system). Generalizing this model, by including self-attraction in the chain, the globule phase as well as a coil–globule transition arise. When the polymer is placed on a lattice, the standard interacting SAW (ISAW) model consists in assigning an energy $\epsilon$ (yielding an attractive force) between monomers on nearest-neighbor (NN) sites nonconsecutive in the walk [2, 4, 5]. Coil and globule phases, separated by a TC (0)-point, are indeed observed in this model. In two dimensions, the exponents $\nu_{\text{coil}} = 3/4$, $\nu_0 = 4/7$, and $\nu_{\text{globule}} = 1/2$ are exactly known [3, 5, 6]. The more general case of semiflexible polymers has been modeled by introducing a bending energy $\epsilon_b$ in the ISAW model (see, for instance, references [7–10]). In this semiflexible-ISAW (sISAW) model, a stable crystalline (solid-like) phase also exists in the system (for low $T$ and large $\epsilon_b$), in addition to the coil and globule ones.

Lee et al [11, 12] have proposed another interesting generalization of the ISAW model by associating different energies $\epsilon_1$ and $\epsilon_2$ with monomers on NN and next-NN (NNN) sites, respectively. From exact enumeration of walks with up to 38 monomers on the square lattice, a line of $\theta$-points (a $\theta$-line) separating the coil and globule phases was found. Similar results were also observed in recent Monte Carlo simulations of this model on the square and cubic lattices [13]. Interestingly, this last study showed that the $\theta$-line exists even for competing interactions between monomers ($\epsilon_1 < 0$ and $\epsilon_2 > 0$ or $\epsilon_1 > 0$ and $\epsilon_2 < 0$). Actually, a $\theta$-line and the absence of other phases (beyond the coil and globule ones) is quite expected when both forces are attractive ($\epsilon_1 > 0$ and $\epsilon_2 > 0$), but for competing interactions this is not necessarily the case, due to the frustration arising from such competition, which might change the critical properties of the system. As a classical example of this, one may cite the Ising model on the square lattice with competing NN and NNN interactions, where different ordered phases, transitions, and universality classes are observed. (For a recent survey see [14].) In polymers, competing (on-site) interactions in the multiple monomer per site (MMS) model by Krawczyk et al [15] are known to change the coil–globule transition in a certain region of its phase diagram, but the order of transition still remain unclear [16].

Another interesting feature of the ISAW model when the force between NNN monomers is repulsive is its semiflexibility, because $\epsilon_2 < 0$ acts as a bending energy, though it also repels NNN monomers that are not part of a bend. Anyway, for large enough $\epsilon_1 > 0$ and $\epsilon_2 < 0$, a crystalline phase could be expected in this model. However, at least in the range of energies analyzed in reference [13], this crystalline phase was not observed.

In order to analyze in more detail whether competing forces between monomers can or cannot change the coil–globule transition, as well as whether or not it yields an ordered (crystalline) phase in the ISAW with NNN interactions, here we solve this model on a Husimi lattice built with squares. Different definitions of NNNs (and interactions between monomers
on them) on this lattice are analyzed, but in all cases the same qualitative results are obtained: no crystalline phase is found, and the θ-line extends over the whole phase diagram for $\epsilon_1$ in the range $[-\infty, \infty)$, which includes the regions of competing interactions. Only in the extreme case of an infinite repulsive force between NNN monomers is a breakdown of the coil–globule transition observed, which is quite expected, since in this case the chains are straight.

The rest of this work is organized as follows. In section 2 the model is defined on a Husimi lattice built with squares and solved in terms of recursion relations. The thermodynamic properties of the model are presented in section 3. In section 4 our final discussions and conclusion are summarized. The calculations of the free energy and of the θ-lines are demonstrated in appendices A and B, respectively.

### 2. Definition of the model and its solution in terms of recursion relations

We investigate interacting self- and mutually avoiding walks on a Husimi lattice—the core of a Cayley tree [17]—built with squares (see figure 1). The endpoints of the walks are placed on the surface of the tree. In our grand-canonical solution, the thermodynamic variables of interest are the monomer fugacity $z$ and the Boltzmann weights $\omega_1 = \exp(\epsilon_1/k_B T)$ and $\omega_2 = \exp(\epsilon_2/k_B T)$ associated with each pair of nonconsecutive monomers on NN sites and pairs of monomers on NNN sites on the lattice, respectively. Hereafter, we will refer to them as NN and NNN monomers. Then, the grand-canonical partition function of the model is given by

$$ Y = \sum z^M \omega_1^M_{\text{NN}} \omega_2^M_{\text{NNN}}, $$

where the sum runs over all configurations of the walks on the tree, and $M$, $M_{\text{NN}}$, and $M_{\text{NNN}}$ are, respectively, the total number of monomers and the number of NN and NNN monomers.

At this point, one notices that on the Husimi lattice there exists an ambiguity in definition of NNN sites:
The neighborhood of a given site, let us say \( i \), can be defined according to the chemical distance (associated with the number of steps along the lattice edges to reach a site \( j \) starting at \( i \)). So, at first, any site would have ten second neighbors, as shown in figure 1(b). However, four of these sites (7–10 in figure 1(b)) would correspond to third neighbors on the square lattice. Since our aim is to compare the Husimi solution with results for the ordinary lattice, we will consider only six NNN sites: the 1–6 ones in figure 1(b).

(b) Another option is to state that second neighbors are the sites in opposite vertices of an elementary square (e.g., sites 1–i and 2–i, in figure 1(b)). Then, each site will have two NNN ones.

Since definition a (b)—hereafter called approach A (C)—overestimates (underestimates) the number of second neighbors on a square lattice, which is four, both approaches will be analyzed in the following. It is easy to see in figure 1(b) that the overestimate in case A comes from the ‘out-square’ sites 3–6, because in the square lattice 3 and 4 (and also 5 and 6) would be a single site. So, this ‘excess’ of second neighbors can be compensated by assigning only half of NNN energy \( (\epsilon_a/2) \) for ‘out-square’ NNN monomers. In this way, the contribution to the partition function of the possible six NNN monomers is effectively the same as the one of four (regular) NNN ones (i.e., \( \omega_4^2 \)). This case will be called approach B. In order to consider all these cases in a general way, we assign a weight \( \omega_2 \) to ‘in-square’ NNN monomers and a weight \( \omega_2' \) to ‘out-square’ ones (see figure 1(a)). Thence, the approaches A, B, and C are recovered by making \( \omega_2^4 = \omega_2, \omega_2' = \sqrt{\omega_2^2}, \) and \( \omega_2'^2 = 1 \), respectively.

A subtree with generation \( M + 1 \) can be obtained by attaching three subtrees (each one with \( M \) generations) in three vertices of an elementary square. The remaining vertex is usually called the ‘root site’ and, associated to it, a partial partition function (ppf) \( g_i \) is defined. Nine root sites and, consequently, nine ppfs are required to correctly account for the NNN interactions in the homogeneous (isotropic) solution of the model, shown in figure 2(a). The ppf \( g_i \)

(a) The neighborhood of a given site, let us say \( i \), can be defined according to the chemical distance (associated with the number of steps along the lattice edges to reach a site \( j \) starting at \( i \)). So, at first, any site would have ten second neighbors, as shown in figure 1(b). However, four of these sites (7–10 in figure 1(b)) would correspond to third neighbors on the square lattice. Since our aim is to compare the Husimi solution with results for the ordinary lattice, we will consider only six NNN sites: the 1–6 ones in figure 1(b).

(b) Another option is to state that second neighbors are the sites in opposite vertices of an elementary square (e.g., sites 1–i and 2–i, in figure 1(b)). Then, each site will have two NNN ones.

Since definition a (b)—hereafter called approach A (C)—overestimates (underestimates) the number of second neighbors on a square lattice, which is four, both approaches will be analyzed in the following. It is easy to see in figure 1(b) that the overestimate in case A comes from the ‘out-square’ sites 3–6, because in the square lattice 3 and 4 (and also 5 and 6) would be a single site. So, this ‘excess’ of second neighbors can be compensated by assigning only half of NNN energy \( (\epsilon_a/2) \) for ‘out-square’ NNN monomers. In this way, the contribution to the partition function of the possible six NNN monomers is effectively the same as the one of four (regular) NNN ones (i.e., \( \omega_4^2 \)). This case will be called approach B. In order to consider all these cases in a general way, we assign a weight \( \omega_2 \) to ‘in-square’ NNN monomers and a weight \( \omega_2' \) to ‘out-square’ ones (see figure 1(a)). Thence, the approaches A, B, and C are recovered by making \( \omega_2^4 = \omega_2, \omega_2' = \sqrt{\omega_2^2}, \) and \( \omega_2'^2 = 1 \), respectively.

A subtree with generation \( M + 1 \) can be obtained by attaching three subtrees (each one with \( M \) generations) in three vertices of an elementary square. The remaining vertex is usually called the ‘root site’ and, associated to it, a partial partition function (ppf) \( g_i \) is defined. Nine root sites and, consequently, nine ppfs are required to correctly account for the NNN interactions in the homogeneous (isotropic) solution of the model, shown in figure 2(a). The ppf \( g_i \)
in generation $M + 1$ is determined, counting all possible configurations produced by attaching three ($M$-generation) subtrees in a square with a root site of type $i$. Instead of doing this directly, it is convenient to determine first the contribution coming from each type of vertex of the elementary square (depicted in figure 2(b)), being

\begin{align*}
  v_{0,0} &= g_{0,0} + 2g_{0,1} + g_{0,2}, \\
  v_{0,1} &= g_{0,0} + (1 + \omega_2')g_{0,1} + \omega_2'^2 g_{0,2}, \\
  v_{0,2} &= g_{0,0} + 2\omega_2' g_{0,1} + \omega_2'^2 g_{0,2}, \\
  v_{1,0} &= z g_3, \\
  v_{1,1} &= \omega_2'^2 g_3, \\
  v_{1,2} &= 2\omega_2'^2 g_3, \\
  v_{2,0} &= z[(1 + \omega_2')g_{2,0} + 2\omega_2' g_{2,1}], \\
  v_{2,1} &= 2z(\omega_2' g_{2,0} + \omega_2'^2 g_{2,1}), \\
  v_3 &= z(g_{0,0} + 2\omega_2' g_{0,1} + \omega_2'^2 g_{0,2}).
\end{align*}

In terms of these expressions, it is quite simple to determine the recursion relations for the ppfs of the model, given by

\begin{align*}
  g'_{0,0} &= v_{0,0}^3 + v_{0,1}^2 v_{1,0}, \\
  g'_{0,1} &= v_{0,0} v_{0,1} v_{1,0} + \omega_1 v_{0,1} v_{1,1} + v_{0,1} v_{2,0}^2, \\
  g'_{0,2} &= \omega_2 [v_{0,2} v_{1,0}^2 + \omega_1^2 v_{1,1} v_{1,2} + 2\omega_1 v_{1,1} v_{2,0} v_{2,1} + v_{2,0}^2 v_{3}], \\
  g'_{1,0} &= v_{0,0} v_{0,1}^2 + 2\omega_1 v_{0,2}^3, \\
  g'_{1,1} &= \omega_1 [v_{0,1} v_{1,1} + \omega_1 \omega_2 v_{0,2} v_{1,1} v_{1,2} + \omega_2 v_{0,2} v_{2,0} v_{2,1}], \\
  g'_{1,2} &= \omega_1^2 \omega_2 [v_{0,2} v_{1,1}^2 + \omega_1^2 v_{1,2} v_{1,3} + 2\omega_1 v_{1,2} v_{2,1} v_{2,3} + \omega_2 v_{2,1} v_{3}], \\
  g'_{2,0} &= v_{0,1} v_{2,0} + \omega_1 v_{0,2} v_{1,1} v_{2,1} + \omega_2 v_{0,2} v_{2,0} v_{3}, \\
  g'_{2,1} &= \omega_1 \omega_2 [v_{0,2} v_{1,1} v_{2,0} + \omega_2 \omega_2 v_{1,2} v_{2,1} + \omega_1 \omega_2 (v_{2,1}^2 + v_{1,2} v_{1,3}) + \omega_2 v_{2,1} v_{3}], \\
  g'_{3} &= \omega_2 [v_{0,2} v_{2,0} + \omega_1^2 \omega_2 v_{1,2} v_{2,3} + 2\omega_1 \omega_2 v_{2,1} v_{3}],
\end{align*}

where $g_i$ and $g'_i$ are in generations $M$ and $M + 1$, respectively.

In a similar way, the partition function of the model on the Cayley tree can be found by attaching four subtrees in a central square, which yields

\begin{align*}
  Y &= 4v_{0,0}^4 + 4v_{0,0} v_{0,1} v_{1,0} + 4\omega_1 v_{0,1}^2 v_{1,1} + 2\omega_2 v_{0,2} v_{1,0}^2 + 4\omega_2^3 v_{0,2} v_{1,1} v_{1,2} \\
  &+ \omega_1^2 v_{2,1}^2 + 4v_{0,1} v_{2,0}^2 + 8\omega_1 \omega_2 v_{0,2} v_{1,1} v_{2,0} v_{2,1} + 4\omega_2 v_{0,2} v_{2,0} v_{3} \\
  &+ 4\omega_1^3 v_{1,2} v_{2,1}^2 + 2\omega_1^2 \omega_2 (v_{2,1}^4 + v_{1,2} v_{2,1} v_{3}) + 4\omega_1 \omega_2^2 v_{2,1} v_{3}^2.
\end{align*}
Then, the densities of monomers ($\rho$) and of NN ($\rho_{NN}$) and NNN ($\rho_{NNN}$) monomers are

$$\rho = \frac{z}{4Y} \left( \frac{\partial Y}{\partial z} \right), \quad \rho_{NN} = \frac{\omega_1}{4Y} \left( \frac{\partial Y}{\partial \omega_1} \right)$$

and

$$\rho_{NNN} = \frac{\omega_2}{S} \left( \frac{\partial Y}{\partial \omega_2} \right).$$

where $S = 10, 6, 2$ are used in approaches A, B, and C, respectively, to make the maximum value of $\rho_{NN}$ equal 1 in all cases.

In the thermodynamic limit, when the number of generations of the tree and, consequently, the length of the polymers reaching the core of the tree tend to infinity, the ppfs diverge, so we will work with ratios of them, defined as $R_1 = g_{0,1}/g_{0,0}$, $R_2 = g_{0,2}/g_{0,0}$, $R_3 = g_{1,2}/g_{1,0}$, $R_4 = g_{1,3}/g_{1,0}$, $R_5 = g_{2,3}/g_{2,0}$, $R_6 = g_{2,4}/g_{2,0}$, and $R_7 = g_{3,4}/g_{3,0}$.

This leads to the recursion relations (RRs):

$$R_1' = (zABR_0 + z^2\omega_1\omega_2^2BR_0^2 + z^2BD^2)/R_0, \quad (6a)$$

$$R_2' = \omega_2(z^2CR_0^2 + z^3\omega_1\omega_2^2BR_0^2 + 4z^3\omega_1\omega_2^2DER_0^2 + z^3D^2F)/R_0, \quad (6b)$$

$$R_3' = (AB^2 + z\omega_2C^2R_0^2)/R_0, \quad (6c)$$

$$R_4' = \omega_1(\omega_2^2BR_0^2 + z\omega_1\omega_2^{3+1}CR_0^2 + 2z\omega_2CDE)/R_0, \quad (6d)$$

$$R_5' = \omega_2^2(z^2\omega_1\omega_2^2BR_0^2 + z^3\omega_1\omega_2^2BR_0^2 + 8z^3\omega_1\omega_2^{3+1}E^2R_0 + 4z^3\omega_2^2E^2F)/R_0, \quad (6e)$$

$$R_6' = (z^2D^2 + 2z^2\omega_1\omega_2^{3+1}CR_0^2 + z^2\omega_2CDF)/R_0, \quad (6f)$$

$$R_7' = \omega_1\omega_2(z^2\omega_1\omega_2^2CDR_0 + z^3\omega_1\omega_2^2BR_0^2 + \omega_1\omega_2(8z^2E + 2z^3\omega_1^2EFR_0) + 2z\omega_1\omega_2E^2F)/R_0, \quad (6g)$$

with

$$R_0 = (1 + 2R_1 + R_2)^3 + z[1 + (1 + \omega_2)R_1 + \omega_2^2R_2]^2R_0, \quad (6h)$$

$$A = 1 + 2R_1 + R_2, \quad (6i)$$

$$B = 1 + (1 + \omega_2^2)R_1 + \omega_2^2R_2, \quad (6j)$$

$$C = 1 + 2\omega_2^2R_1 + \omega_2^2R_2, \quad (6k)$$

$$D = (1 + \omega_2^2)R_5 + 2\omega_2^2R_7, \quad (6l)$$

$$E = \omega_2^2R_6 + \omega_2^2R_7, \quad (6m)$$

$$F = R_3 + 2\omega_2R_4 + \omega_2^2R_5, \quad (6n)$$

where $\alpha = 1, 1/2$, and 0 in cases A, B, and C, respectively. In the case C ($\omega_2 = 1$), it is easy to see that $v_{1,0} = v_{0,1} = v_{0,2} = (g_{0,0} + 2g_{0,1} + g_{0,2})$, $v_{1,0} = v_{1,1} = v_{1,2} = zg_3$, $v_{2,0} = v_{2,1} = 2z(g_{1,0} + g_{1,1})$, and $v_3 = z(g_{1,0} + 2g_{1,1} + g_{1,2})$, and thus only the combinations $g_0 \equiv (g_{0,0} + 2g_{0,1} + g_{0,2})$, $g_1 \equiv (g_{1,0} + 2g_{1,1} + g_{1,2})$, and $g_2 \equiv (g_{2,0} + g_{2,1})$ appear in the RRs. Thus, one may work with simplified ratios of ppfs, defined as $R_0 = g_{1,0}/g_{0,0}$, $R_2 = g_{2,0}/g_{0,0}$, and $R_3 = g_{3,0}/g_{0,0}$, yielding

$$R_1' = [1 + z(2\omega_1 + \omega_2)R_3 + 3z^2\omega_1\omega_2^2R_0^2 + 2z^3\omega_1^2\omega_2^2R_3 + 8z^2\omega_1\omega_2R_2^2 + 8z^3\omega_1\omega_2^2R_3 + 4z\omega_1\omega_2^2R_3] / R_0, \quad (7a)$$

J. Phys. A: Math. Theor. 49 (2016) 155001

T J Oliveira
\[ R'_2 = 2zR_3(1 + 2z\omega_1\omega_2 R_3 + z^2\omega_1^2\omega_2^2 R_3^2 + 4z^2\omega_1^2\omega_2^2 R_3^2 + \omega_2 R_1) \]
\[ + z^3\omega_1^2\omega_2^2 R_3 R_5 + z^3\omega_1\omega_2^2 R_3^2)/R_0, \]  
\[ (7b) \]
\[ R'_1 = 4z^2 R_2^2 R_5(1 + z\omega_1 \omega_2 R_3 + 2z\omega_1 \omega_2 R_1)/R_0, \]  
\[ (7c) \]
with
\[ R_0 = 1 + 3zR_3 + z^2(2\omega_1 + \omega_2)R_3^2 + z^3\omega_1^2\omega_2^2 R_3^3 + 8z^2R_2^2 \]
\[ + 8z^3\omega_1\omega_2 R_3^2 R_5 + 4z^3\omega_2 R_1 R_2^2. \]  
\[ (7d) \]

It is worth noting that the partition functions (equation (4)) for approach X, with X = A, B, or C, can be written as \( Y_X = g_{0,0}^4 Y_X \), where \( y_X \) is finite (since is depends only on the ratios \( R_x \), beyond \( z, \omega_1, \) and \( \omega_2 \)), while \( Y_X \) diverges as \( g_{0,0}^4 \) in the thermodynamic limit. Notwithstanding, the densities (equation (5)) remain finite, because they are in fact functions of \( y_X \) instead of \( Y_X \).

### 3. Thermodynamic properties of model

The thermodynamic phases of the model on the Husimi lattice are given by the real and positive fixed points of RRs (equations (6)). Similarly to the classical ISAW model (\( \omega_2 = 1 \)), the grand-canonical phase diagram for general \( \omega_2 \) presents only two phases: (i) a non-polymerized (NP) phase, where \( R_3 = 1 \) and \( R_1 = 0 \) otherwise; and (ii) a polymerized (P) phase, with \( R_i = 0 \) for \( i = 1, \ldots, 8 \). In the former, the density of the monomers vanishes (\( \rho = 0 \)), and, consequently, \( \rho_{NN} = \rho_{NNN} = 0 \). On the other hand, in the P phase these densities are, in general, non-null and depend on the parameters \( z, \omega_1, \) and \( \omega_2 \). Obviously, working with the reduced set of RRs (equations (7)) in approach C, one finds a similar behavior, with \( R_1 = 1, R_5 = R_3 = 0 \) in the NP phase and \( R_i = 0 \) in the P one.

Each phase is stable in the region of the parameter space \((z, \omega_1, \omega_2)\), where the largest eigenvalue \( \lambda \) of its Jacobian matrix \( (J_{ij} = \frac{\partial R_i}{\partial R_j}) \) is smaller than \( 1 \). The condition \( \lambda = 1 \) gives the thermodynamic stability limit (the spinodal) of the respective phase, which is easy to calculate in the NP phase, being
\[ \omega_1 = \frac{1}{2z^3\omega_2^2\omega_1(\alpha+1)} \left( \frac{-1 + z + z\omega_2^2 + z^2\omega_2 + z^3\omega_2^{2+1}}{-1 - z + z\omega_2^2 - z^2\omega_2 + z^3\omega_2^{2+1}} \right), \]  
\[ (8) \]
recalling that \( \alpha = 1, 1/2, \) and \( 0 \) in approaches A, B, and C, respectively. For the P phase, the stability limit is determined numerically. In a certain region of the phase diagram, the NP and P spinodals are coincident, forming a critical surface.

There exists also a coexistence region in the phase diagram—where the spinodals do not match, and both phases are stable—with a coexistence surface separating the NP and P phases there. A simple way to determine this surface is through the free energy of the model, which can be calculated using Gujrati’s prescription [18]. The derivation of this free energy for the Husimi lattice built with squares is presented in appendix A, leading to
\[ \phi_b = -\frac{1}{2}(2 \ln R_{0,X} - \ln y_X) \]  
\[ (9) \]
with \( X = A, B, \) or \( C, \) and \( R_{0,X} \) and \( y_X \) defined as above and calculated at the fixed point. In the NP phase, \( R_{0,X} = y_X = 1 \), so that \( \phi_b^{NP} = 0 \), and then the coexistence surface—where the free energies of both phases are equal—is given by \( \phi_b^P = \phi_b^{NP} = 0 \).
These critical and coexistence surfaces meet (tangentially) at a TC line, which was calculated exactly by locating the points along the spinodal of the NP phase, where the solution of the RRs is triply degenerate. This is demonstrated in detail in appendix B.

Let us first discuss the thermodynamic behavior for approach A. Figure 3(a) shows phase diagrams for several values of (fixed) $\omega_2$ in the range $[0.4, 2.2]$. For any $\omega_2 < 1.9217692$, the same properties of the classical ISAW model ($\omega_2 = 1$) are found: there is a continuous NP–P transition at small $\omega_1$ that becomes discontinuous at a TC ($\theta$) point. The location of the $\theta$ point, however, strongly depends on $\omega_2$, forming a continuous $\theta$-line.

In general, a decrease in the coordinates $(z, \omega_1')$ of the TC point is observed as $\omega_2$ increases. In fact, for attractive forces between the NN and NNN monomers, this is quite expected, since $\epsilon_2/k_B T > 0$ will facilitate the collapse and, thus, $\epsilon_1/k_B T$ becomes smaller. When $\omega_2 = 1.1553956$, the NN energy is null at the $\theta$ point; i.e., $\omega_1' = 1$ (and $z' = 0.3085453$), so that the collapse transition happens due solely to the NNN interaction. For larger $\omega_2$, the $\theta$-line still exists, but for $\omega_1' < 1$, meaning that the NN monomers repel each other. The value of $\omega_1'$ decreases for increasing $\omega_2$ until it reaches the 0 at $\omega_2 = 1.9217692$. Therefore, even for an infinite repulsive force between NN monomers, a coil–globule transition exists for a finite (attractive) interaction between the NNN ones. This will be discussed in more detail in the following. For $\omega_2 > 1.9217692$, only a NP–P coexistence surface is found.

The $\theta$-line extends also to the region of repulsive NNN interactions ($\omega_2 < 1$), where, again, increasing $z'$ and $\omega_1'$ are observed as $\omega_2$ decreases. When $\omega_2$ approaches the 0, one finds $\omega_1' \rightarrow \infty$ and $z' \rightarrow 1$. This is quite reasonable, since $\omega_2 \ll 1$ will prevent the formation of bends in the walks and, consequently, of a globular phase. Notwithstanding, if $\omega_1 \gg 1$, the attractive NN force can overcome the NNN repulsion, yielding this phase.

Phase diagrams for approach C are presented in figure 3(b), where the same qualitative behavior of A is observed with a $\theta$-line existing, since $\omega_1 = 0$ until $\omega_1 \rightarrow \infty$. Analogous phase diagrams are also found for the intermediate approach B (not shown). These similarities are more evident in the comparison of the $\theta$-lines for all approaches, which is presented in

![Figure 3. Phase diagrams in the variables $\omega_1$ versus $z$ for approaches (a) A and (b) C. In (a) diagrams for $\omega_2$ varying by 0.2 in the range [0.4, 2.2] are shown, while in b) they are for $\omega_2 = 0.2, 0.4, 0.6, 0.8, 1.0, 2.0, 4.0, 8.0, \text{and } 16.0$. The full (red) and dashed (blue) lines are the critical and coexistence lines, respectively. The black dots indicate the $\theta$ points, and the $\theta$ line is given by the dotted (black) line.](image)
In case A (B), the $\theta$-line starts at $z_0 = 0.235592 (0.208304)$—where $\omega_1^0 = 0$ and $\omega_2^0 = 1.921769 (3.345581)$—and ends at $z^\theta \to 1$, where $\omega_1^0 \to \infty$ and $\omega_2^0 \to 0$. On the other hand, in case C a quite different $z$-range is found for the $\theta$-line, which starts at $z_0 = 0.16447819$—where $\omega_1^0 = 0$ and $\omega_2^0 = 12.40235262$—and ends at $z^\theta \to 1/2$, where $\omega_1^0 \to \infty$ and $\omega_2^0 \to 0$. Notice that $\omega_2^0(C) > \omega_2^0(B) > \omega_2^0(A)$ for attractive NNN interactions, and $\omega_2^0(C) < \omega_2^0(B) < \omega_2^0(A)$ for repulsive ones is quite expected, since the effective number of possible NNN monomers decreases from A to C.

We notice that in approach C a repulsive (attractive) NNN interaction introduces an energetic penalty (advantage) whenever the polymer is bending within an elementary square but doing not when it bends in the opposite direction. This unrealistic feature of the Husimi lattice in case C certainly explains why $z^\theta \to 1$ (in cases A and B) and $z^\theta \to 1/2$ (in C), when $\omega_2^0 \to 0$ (with $\omega_1^0 \to \infty$).

It is important to remark that when NNN monomers repel each other, the polymer is semiflexible, and thus a crystalline phase could be expected in the phase diagrams for large enough $\omega_1$. However, we have exhaustively looked for any new stable phase in this region and did not find any. One recalls that the crystalline phase is dense ($\rho = 1$)—it is a quasi-Hamiltonian walk—featured by straight parallel chains, maximizing the number of NN monomers and minimizing the bending. Therefore, to correctly analyze this phase—with chains aligned in one direction of the lattice—at first, more general RR’s are required, defining the root sites (and pps) to account for the directional anisotropy (as done for the sISAW in [9], for example). In the homogeneous solution we are considering (equations (6)), both directions are assumed to be equivalent, and thus the symmetry-breaking of the phase cannot arise. In any case, however, a dense phase should appear as a diverging fixed point of the RRs, because they were defined as $R_i = g_i/g_{0,0}$, and configurations of type $g_{0,0}$ (see figure 2) do not exist in a fully occupied lattice, so that $g_{0,0} \to 0$, and, consequently, $R_i \to \infty$. Thus, although we are analyzing only the homogeneous solution, the absence of a divergence in the RRs strongly suggests that no stable crystalline phase exists in the model on the Husimi lattice. In fact, in contrast to the bending energy in the sISAW, in our model the repulsive NNN force acts also between monomers that are not part of a bending (see figure 1(a)) and, in a phase formed by aligned chains, the NNN repulsion would be maximized, together with the
NN attraction. This frustration in the system is certainly responsible for the absence of the ordered (crystalline) phase.

3.1. Infinite repulsion between NN monomers ($\omega_1 = 0$)

Now, we consider the case where NN monomers are forbidden ($\omega_1 = 0$). As noted above, phase diagrams similar to the ones for a finite NN interaction are found also in this limit. Indeed, from equation (8), the NP spinodal can be written as

$$z = \frac{-1 - \omega_2^0 + \sqrt{1 + 2\omega_2^0 + \omega_2^{2n} + 4\omega_2 + 4\omega_2^{2n+1}}}{2(\omega_2 + \omega_2^{2n+1})}.$$  

(10)

For $\omega_2 < \omega_2^0$, this expression defines also the critical line. Once more, $\alpha = 1$ (in case A), $\alpha = 1/2$ (in B), and $\alpha = 0$ (in C). From the analysis in appendix B, the values of $\omega_2^0$ are given by the real positive root of the polynomial

$$7 + 29\omega_2 + 26\omega_2^2 - 2\omega_2^3 + 74\omega_2^{2n+1} + 33\omega_2^{2n} - 6\omega_2^{2n+1} + 12\omega_2^{3n} - 7\omega_2^{4n} - 6\omega_2^{n+2} + 46\omega_2^{2n+1} - 2\omega_2^{3n+2} - 2\omega_2^{5n+1} + 16\omega_2^{3n+1} - 19\omega_2^{4n+1} + 6\omega_2^{n+2} + b(\omega_2^{2n+1} + \omega_2^{2n} + \omega_2 + 1 - 2\omega_2^{2n} + 3\omega_2^{2n+1} - 2\omega_2^{2n} + \omega_2^{3n+1} + 3\omega_2^{4n+1}) = 0,$$

(11)

with $b = \sqrt{1 + 2\omega_2^0 + \omega_2^{2n} + 4\omega_2 + 4\omega_2^{2n+1}}$. Actually, in each approach there are two such roots, but one of them leads to inconsistent values of $z$, being $\omega_2^0 = 1.921 7693$ (A), $\omega_2^0 = 3.345 5816$ (B), and $\omega_2^0 = 12.402 3526$ (C), the physical ones. Inserting these values in equation (10), one readily finds $z^0 = 0.235 5927$ (A), $z^0 = 0.208 3038$ (B), and $z^0 = 0.164 4782$ (C). In the region $z < z^0$ (where $\omega_2 > \omega_2^0$), both phases coexist. One example of this phase behavior is presented in figure 5 for case A, and analogous ones are obtained in other approaches (not shown).

Although a coil–globule transition is present in this case, the globule phase is different from the one for $\omega_1 > 0$, since $\omega_1 = 0$ forbids NN monomers in the system (i.e., $\rho_{NN} = 0$). For instance, from the expressions for the densities of monomers $\rho$ and NNN monomers $\rho_{NNN}$ (not shown explicitly here), it is possible to demonstrate that $\rho \to 1$ and $\rho_{NNN} \to 1$, in the limit $z \to \infty$ and $\omega_2 \to \infty$, for any approach when $\omega_1 > 0$. On the other hand, for $\omega_1 = 0$, diverging $z$ and $\omega_2$ lead to $\rho \to 3/4$ and $\rho_{NNN} \to 7/10$ (in case A), $\rho \to 3/4$ and $\rho_{NNN} \to 2/3$ (in B), and $\rho \to 3/4$ and $\rho_{NNN} \to 1/2$ (in C), which corresponds to ‘soft’ P phases (and respective ‘soft globules’), since the maximal occupation of the lattice is smaller than 1. In a canonical situation (with polymers with fixed size), this ‘soft’ phase (for $\omega_1 = 0$) shall occupy a volume larger than the ‘regular’ globule phase (for $\omega_1 > 0$).

We claim that this ‘soft’ globule phase is not a feature of the Husimi lattice, but it might exist also in the square (and other regular) lattices. In fact, although NN monomers are forbidden, the attractive force between NNN monomers that are not part of a bending can act to collapse the chains, in a similar way as the NN one in the ordinary ISAW model. Moreover, the NNN interaction enhances the formation of bends and, consequently, the formation of globules. Anyhow, more studies are necessary to confirm this.

3.2. Infinite repulsion between NNN monomers ($\omega_2 = 0$)

Now, we turn to the analysis of the case of forbidden NNN monomers. By making $\omega_2 = 0$ in the RR’s (equations (6)), it is possible to find their solution exactly for the P phase, being $R_2 = R_4 = R_5 = R_7 = R_8 = 0$, and $R_i = a/24 + (z + z^2/24)/a + z/24 - 1/2$, with
In approaches A and B, the only non-null eigenvalue of the Jacobian matrix in the NP phase is \( \lambda = z \), so this phase is stable for \( z \leq 1 \), and its spinodal is at \( z = 1 \). The fixed point above for the P phase is physical (and stable) for \( z \geq 1 \), and its stability limit is at \( z = 1 \). Therefore, the phase diagrams in both approaches present only a critical line at \( z = 1 \), separating the NP and P phases, which is consistent with a \( \theta \)-point located at \( z^\theta = 1 \) and \( \omega_1^\theta \to \infty \), as already discussed. In case C, one finds the same scenario, but the critical line is at \( z = 1/2 \).

Notice that \( \omega_2 = 0 \) leads to \( \rho_{\text{NNN}} = 0 \), so that all polymer chains are straight in cases A and B. As already noticed, in case C, the chains are not necessarily straight, since they can bend out the elementary squares and still have \( \rho_{\text{NNN}} = 0 \). In all cases, \( \rho_{\text{NN}} = 0 \) is also found, as expected, since the infinite repulsion between NNN monomers also forbids NN ones. The density of monomers \( \rho \), in the P phase, is a monotonic increasing function of \( z \), being \( \rho = (2z - 1)/(4z - 1) \), for \( z \geq 1/2 \), in approach C. In the other approaches the expressions are too long to be given here, but one also finds \( \rho = 0 \) at \( z = 1 \) and \( \rho \to 1/2 \) for \( z \to \infty \). On the square lattice this shall correspond to a ‘soft crystalline’ phase, where half of the rows (or columns) of the lattice are alternately occupied by straight (parallel) chains. Indeed, placing such aligned (repulsive) polymer chains on a square lattice is analogous to the athermal problem of placing infinite rigid rods with (infinite) NNN exclusion. We remark that athermal lattice gases with exclusion of neighbors have been considered in the literature for several ranges of exclusion (or particle sizes) [19, 20], as well as mixtures of them [21]. Furthermore, isotropic–nematic transitions in rigid rods are a problem largely studied. (see, e.g, [22, 24] for recent surveys.) However, for the best of our knowledge, rigid rods with neighbor exclusion have been considered only in the case of dimers with NN exclusion [23].

Anyhow, the case of infinite rods with NNN exclusion can be solved on the square lattice, for example, following the recent transfer matrix (TM) calculation by Stilck and Rajesh [24]. Considering the limit of infinite rods, without neighbor exclusion, on a rotated square lattice yielding a diagonal TM, those authors showed that the (degenerated) spectrum

\[
a = (36z^2 + 216z + z^3 + 24\sqrt{3z^3 + 81z^2})^{1/3},
\]

\[
R_3 = (1 + 2R_1)/z,
\]

and \( R_6 = \sqrt{R_1(1 + R_1)}/z \), in approaches A and B. In case C, one finds \( R_1 = z - 1/2 \), \( R_3 = 1 \), \( R_6 = \sqrt{4z - 2}/2 \), and \( R_1 = 0 \) otherwise. It is noteworthy that these fixed points are independent of \( \omega_1 \), demonstrating that the thermodynamic properties of the model do not depend on this parameter, as expected.

Figure 5. Phase diagram for approach A and \( \omega_1 = 0 \). The full (red) and dashed (blue) lines are the critical and coexistence lines, respectively. The black dot indicate the TC point.
of eigenvalues of the TM is given by $k_m = \frac{mL}{2\pi}$, with $m = 0, 1, \ldots, \pi$ or $0 \leq k_L \leq \frac{\pi}{L}$. This result is for an infinite stripe (in the vertical) with width $L$ and periodic boundary conditions in the horizontal. (For more details see [24].) One notices that all rods are parallel in this limiting case and that an eigenvalue of type $k_m$ is associated to a state of the system with $m$ parallel rods in the horizontal direction. So, it is easy to particularize these results for the case with finite $N$ repulsion by imposing that two rods cannot occupy adjacent columns (or rows) of the lattice, which simply reduce the number of states of the TM. Consequently, the spectrum of eigenvalues is also reduced to $k_m = \frac{mL}{2\pi}$, with $m = 0, 1, \ldots, \pi$ or $0 \leq k_L \leq \frac{\pi}{L}$, since on a stripe of (even) width $L$ it is possible to exist at most $L/2$ parallel rods/chains, due to exclusion. Hence, the largest eigenvalue $\lambda_1$ and, consequently, the free energy $f = \frac{1}{L} \ln \lambda_1$ and the density of monomers $\rho = \frac{z}{(\partial z)}$ are: $\lambda_1 = 1$, $f = 0$, and $\rho = 0$ for $z \leq 1$; and $\lambda_1 = z^{L/2}$, $f = \frac{1}{2} \ln z$, and $\rho = 1/2$ for $z > 1$. Namely, the system undergoes a discontinuous transition at $z = 1$ from an empty lattice (the NP phase—for $z \leq 1$) to a low-density nematic phase (the ‘soft crystalline’ P phase—for $z > 1$).

Although the Husimi solution yields the correct transition point $z = 1$ (at least in the more realistic A and B approaches), the nature of the transition (continuous) is different from the one in the square lattice. At first, it seems unexpected to find a continuous transition in a mean-field calculation, whereas the real transition is discontinuous. A possible cause of this inconsistency may be the fact that our homogeneous solution (on the Husimi lattice) does not capture correctly the anisotropy/structure of the ‘soft crystalline’ phase. One recalls, notwithstanding, that similar scenarios, with discontinuous transitions observed in simulations on ordinary lattices and continuous ones in exact solutions on hierarchical lattices, have been observed in other models for $\theta$-polymers without structured phases [15, 16, 25].

4. Final discussions and conclusions

In summary, we have studied a generalized ISAW model—where different forces exist between NN and NNN monomers—on a Husimi lattice built with squares. Three definitions of second neighbors—or interactions between them—have been considered, which effectively overestimate, match, or underestimate the number of NNN monomers, compared with a
square lattice. Since all approaches lead to analogous thermodynamic behaviors, this suggests that a similar scenario can exist also on the regular lattice.

Indeed, our findings are in good agreement with the ones from Monte Carlo simulations on square and cubic lattices [13], where only a $\theta$-line was observed, as well as with previous results from exact enumerations [12]. Interestingly, approximately linear $\theta$-lines were found in the canonical phase diagrams reported in those works, around the region of positive energies. Figure 6 shows the mapping of our grand-canonical phase diagrams in the canonical variables $K_{2k} T b^{-2} \ln 2(\omega_{A})$, and, indeed, almost linear behaviors are found around the first quadrant of the diagrams, but the whole $\theta$-lines are curved. For comparison, the $\theta$-line found in simulations of the model on a square lattice, $K_{2} \simeq -0.6099K_{1} + 0.4066$ [13], is also shown in figure 6. In the region corresponding to attractive interactions (highlighted in the inset), the $\theta$-lines from approaches A and B are always below the one from simulations, which is expected, since mean-field results generally underestimate the (tri)critical points. A similar behavior is observed for small $K_{2}$ in approach C, but as this parameter increases, the corresponding $\theta$-line crosses the one from simulations, which is simply due to the underestimate in the number of NNN sites/monomers in this approach. Linear fits of the $\theta$-lines in the attractive region return the slopes $-0.333$ (in case A), $-0.522$ (in B), and $-1.221$ (in C), which are approximately 55%, 86%, and 200% of the value found in simulations. These behaviors are physically reasonable, because in a collapsing chain each monomer can have at most two NN monomers, while in approaches A, B, and C it can have effectively a maximum of six, four, and two NNN monomers, respectively, which is consistent with $K_{2} \sim -K_{1}/3$ (in A), $K_{2} \sim -K_{1}/2$ (in B), and $K_{2} \sim -K_{1}$ (in C).

This work was supported by CNPq and FAPEMIG (Brazilian agencies). The author thanks JF Stilck for a critical reading of this manuscript and the kind hospitality of the group of Prof. James Evans at Iowa State University, where part of this work was done.

Appendix A. Free energy

The grand-canonical free energy of the model on the Cayley tree with $M$ generations is $\Phi_{M} = -k_{B} T \ln Y_{M}$, and one may, conveniently, define the adimensional free energy as $\Phi_{M} = \Phi_{M}/k_{B} T$. Assuming that each surface site has a free energy $\phi_{s}$, while the ones in bulk have $\phi_{b}$ [18], it reads

$$\Phi_{M} = N_{s}^{M} \phi_{s} + N_{b}^{M} \phi_{b},$$

(A1)

where $N_{s}^{M}$ and $N_{b}^{M}$ are the number of sites at surface and bulk, respectively, in generation $M$. Considering a Cayley tree built with squares and ramification $\sigma$ (coordination number $q = 2(\sigma + 1)$), these numbers are

$$N_{s}^{M} = 4(3\sigma)^{M-1} \quad \text{and} \quad N_{b}^{M} = \frac{4(3\sigma)^{M-1} - 1}{3\sigma - 1}. \quad (A2)$$

From these equations, one finds

$$\phi_{b} = \frac{1}{4} \left[ 4\Phi_{M+1} - 3\sigma \Phi_{M} \right] = -\frac{1}{4} \ln \left[ \frac{Y_{M+1}}{Y_{M}} \right]. \quad (A3)$$
which is the reduced free energy in the bulk of the Cayley tree built with squares, i.e., the Husimi lattice.

As discussed in section 2, in general, one may write \( Y_M = (g_0^M)^{\delta y} \), and so \( Y_M = (g_0^{M-1})^{\delta y} \) (where \( y = y_c, y_b \), or \( y_c \), depending on the approach). In addition, it is easy to see that \( g_0^{M+1} = (g_0^M)^{\delta y} g_0 \), then

\[
\lim_{M \to \infty} \frac{Y_{M+1}}{Y_M} = \frac{R_0^{1/\delta y}}{y^{1/\delta y - 1}},
\]

leading finally to

\[
\phi_b = -\frac{1}{4}[4\sigma \ln R_0 - (3\sigma - 1)\ln y].
\]

For the case \( \sigma = 1 \) considered in this work, the expressions for \( R_0 \) are given in equation (6h), while \( y = Y / \delta y \) can be easily calculated from equation (4), setting \( \alpha = 1 \) (in approach A), \( \alpha = 1/2 \) (in B), or \( \alpha = 0 \) (in C).

### Appendix B. Tricritical lines

At the TC condition the solution of the recursion relations (RRs, equations (6) and (7)) must be triply degenerated. Then, one may find the points at the parameter space where this happens, bearing in mind that they shall be on the NP spinodal.

In the NP phase \( R_i = 1 \) for \( i = 3 \) and \( R_i = 0 \) otherwise, so, near the critical surface (and the TC line), one may expand the RRs around, for example, \( R_b \) keeping only the terms up to the third order. A simple inspection of the RRs (equation (6)) shows that \( R_i \approx a_i R_0^2 \) for \( i = 1, 2, 4, 5, \) and \( 8, R_i \approx 1 + a_1 R_0^2, \) and \( R_i \approx a_7 R + a_7 R_0^2. \) Inserting this in the RR’s and expanding them up to order \( R_0^3, \) one finds

\[
D \approx 1 + C_0 R_0^2
\]

\[
D a_1 R_0^2 \approx C_1 R_0^2
\]

\[
D a_2 R_0^2 \approx C_2 R_0^2
\]

\[
D (1 + a_3 R_0^2) \approx 1 + C_3 R_0^2
\]

\[
D a_4 R_0^2 \approx C_4 R_0^2
\]

\[
D a_5 R_0^2 \approx C_5 R_0^2
\]

\[
D R_0 \approx C_6 R_0 + C_6 R_0^3
\]

\[
D (a_7 R_0 + a_7 R_0^2) \approx C_7 R_0 + C_7 R_0^3
\]

\[
D a_8 R_0^2 \approx C_8 R_0^2
\]

where

\[
C_0 = 6a_1 + 3a_2 + za_8
\]

\[
C_1 = za_8 + z^2 b^2
\]

\[
C_2 = z^3 \omega_2 b^2
\]
\[ C_3 = 2(1 + \omega_2^2) a_1 + 2\omega_2^2 a_2 + 2a_1 + a_2 + z\omega_2 a_8 \]  
\[ C_4 = \omega_1[z\omega_2^2 a_8 + 2\omega_2 z^2b(\omega_2^2 + \omega_2^2 a_{1,1})] \]  
\[ C_5 = 4\omega_1^2 \omega_2^2 z^3(\omega_2^2 + \omega_2^2 a_{1,1})^2 \]  
\[ C_{6,1} = zb + \omega_2 z^2b \]  
\[ C_{6,2} = \omega_2 z^2b(a_1 + 2\omega_2^2 a_4 + z\omega_2^2 a_9) + 2\omega_2^2 z^2 a_{1,2} + \omega_2 (2\omega_2^2 a_1 + \omega_2^2 a_2)z^2b \]  
\[ + 2\omega_1 z^2\omega_2^2 a_8(\omega_2^2 + \omega_2^2 a_{1,1}) + 2z\omega_2 a_{1,2} + [(2(1 + \omega_2^2))a_1 + 2\omega_2^2 a_2]zb \]  
\[ C_{7,1} = 2\omega_1^2 \omega_2^2 z^3(\omega_2^2 + \omega_2^2 a_{1,1}) \]  
\[ C_{7,2} = \omega_1^2 \omega_2^2 z^3 a_{1,1}b + \omega_2 z^3(\omega_2^2 + \omega_2^2 a_{1,1})(2a_1 + 4\omega_2^2 a_4 + 2\omega_2^2 a_8) + 2\omega_2^2 z^3 a_{1,2} + 2\omega_1^2 \omega_2 z^3 a_{1,1}z^2b \]  
\[ + \omega_1 \omega_2 (8\omega_2^3(\omega_2^2 + \omega_2^2 a_{1,1})^2 + 2z\omega_2^2 a_{1,1}a_{8}(\omega_2^2 + \omega_2^2 a_{1,1})) \]  
\[ C_6 = \omega_2[z^2b^2 + 8\omega_1 z^2\omega_2(\omega_2^2 + \omega_2^2 a_{1,1})^2] \]

with \( b \equiv 1 + \omega_2^2 + 2\omega_2^2 a_{1,1} \) and \( \alpha = 1 \) (in case A), \( \alpha = 1/2 \) (in B), or \( \alpha = 0 \) (in C).

Equating the terms of the same order in equations (B1a)-(i), the relations \( a_i = C_i \) for \( i = 1, 2, 4, 5, 8, \) and \( a_1 + C_0 = C_2, a_{1,1} = C_{7,1}, \) and \( a_{1,2} + a_{1,1}C_0 = C_{7,2} \) are obtained, allowing us to determine all \( a_i \) as functions of \( z, \omega_1, \) and \( \omega_2. \) Using these functions in the two additional equations \( C_{6,1} = 1 \)—which leads to the same expression for the stability limit of the NP phase (equation (8))—and \( C_{6,2} = C_0, \) the TC line is found. Although we do not find a closed expression for this line, it can be easily calculated with the help of an algebra software.
