A prime goal of ultrarelativistic heavy-ion collisions (URHICs) is the production and investigation of the quark-gluon plasma (QGP), a state of matter with quarks and gluons as the relevant degrees of freedom. The suppression of heavy-quarkonium production in URHICs, relative to proton-proton (p-p) reactions, has long been considered as a signature of QGP formation [1]. However, more recent observations at the Relativistic Heavy-Ion Collider (RHIC) suggest that the created matter is a strongly interacting QGP (sQGP), which allows for the existence of heavy-quark bound states as suggested by lattice QCD [2]. Thus, with copious production of charmquarks at RHIC, secondary formation of charmonia via $c$-$\overline{c}$-coalescence might dominate their yield in central Au-Au collisions [3,4], contrary to the situation in Pb-Pb collisions at the CERN Super Proton Synchrotron (SPS), where $J/\psi$ suppression is the main effect.

In the present work [5], we study consequences of this picture for bottomonium ($Y$) production at RHIC and the Large Hadron Collider (LHC). We assess the time evolution of $Y$ states in A-A collisions via a kinetic rate equation,

$$\frac{dN_Y}{dt} = -\Gamma_Y (N_Y - N_Y^{eq})$$

($N_Y$: number of $Y$, $\Gamma_Y$: $Y$-dissociation rate, $N_Y^{eq}$: $Y$-equilibrium number), which is valid if $b$-quarks (open-bottom states) are in thermal equilibrium with the surrounding QGP [6].

The dissociation rates for the various $Y$ states are evaluated using dissociation cross sections with thermal quarks and gluons. Since the commonly employed gluo-dissociation process [7], $g+Y\rightarrow b+b\overline{b}$, becomes inefficient for small $Y$ binding energies, we use the quasi-free breakup mechanism, $g(q)+Y\rightarrow b+b\overline{b}+g(q)$, as suggested for charmonia [4]. The in-medium $Y$ binding energies are taken from solutions of a Schrödinger equation with a color-screened Cornell potential [8]. We furthermore assume that the quarkonium masses are temperature independent, which implies that the $b$-quark mass also decreases with temperature (as indicated by lattice QCD as well).

Due to their large mass, $b$-quarks are not expected to kinetically equilibrate in A-A collisions. We account for this by multiplying the gain term of the rate equation with a schematic correction factor, $R = 1 - \exp(-\int_{0}^{\infty} d\tau / \tau_{eq})$, with $\tau_{eq}$ denoting the thermal relaxation time for $b$-quarks which we take from a recent resonance-scattering model [9].

The total number of $b$-$\overline{b}$ pairs in the system (which determines the $Y$-equilibrium number) is obtained from binary collision scaling (secondary production is expected to be negligible [10]) according to

$$N_{b\overline{b}} = \frac{\sigma_{pp\rightarrow b\overline{b}}}{\sigma_{pp}^{inelastic}} N_{coll}(b) R_y,$$
with $\sigma_{pp}^{inelastic}=42(78)$ mb: total inelastic p-p cross section at RHIC (LHC) [11], $N_{coll}(b)$: number of primordial N-N collisions at impact parameter $b$, $\sigma_{pp\rightarrow b\bar{b}}=2(160)$μb at RHIC (LHC) [12]. $R_y=0.52(0.29)$ for RHIC (LHC) denotes the fraction of $b-b\bar{b}$ pairs in the considered rapidity range [13]. The primordial numbers of bottomonia are taken to be proportional to the $b-b\bar{b}$ number with a p-p production cross section of $3.5(152)$nb at RHIC (LHC, including shadowing corrections) [14]. The initial bottomonium number in the rate equation, $N_{y}(0)$, also incorporates (pre-equilibrium) nuclear absorption effects with a dissociation cross section of $3.1(4.6)$mb at RHIC (LHC).

With the above ingredients we solve the rate equation for different impact parameters for A-A collisions at RHIC and LHC energies; the pertinent centrality dependencies for $Y(1S)$ production are summarized in Fig. 1, including feeddown from excited bottomonia. A rather strong suppression turns out to be the main effect at both RHIC and LHC, mostly driven by the reduction in binding energies due to color-screening. This is in contrast with the findings of similar studies for charmonia [14], where $J/\psi$ suppression is the prevalent effect at SPS, while regeneration takes over and becomes the dominant source at RHIC energies and above. Thus, the simultaneous observation of appreciable $Y(1S)$ suppression and the absence of $J/\psi$ suppression emerges as a promising signature of the sQGP at collider energies.
