Improved Approximation Algorithms for Matroid and Knapsack Median Problems and Applications

CHAITANYA SWAMY, University of Waterloo

We consider the matroid median problem [Krishnaswamy et al. 2011], wherein we are given a set of facilities with opening costs and a matroid on the facility-set, and clients with demands and connection costs, and we seek to open an independent set of facilities and assign clients to open facilities so as to minimize the sum of the facility-opening and client-connection costs. We give a simple 8-approximation algorithm for this problem based on LP-rounding, which improves upon the 16-approximation in [Krishnaswamy et al. 2011]. We illustrate the power and versatility of our techniques by deriving: (a) an 8-approximation for the two-matroid median problem, a generalization of matroid median that we introduce involving two matroids; and (b) a 24-approximation algorithm for matroid median with penalties, which is a vast improvement over the 360-approximation obtained in [Krishnaswamy et al. 2011]. We show that a variety of seemingly disparate facility-location problems considered in the literature—data placement problem, mobile facility location, $k$-median forest, metric uniform minimum-latency UFL—in fact reduce to the matroid median or two-matroid median problems, and thus obtain improved approximation guarantees for all these problems. Our techniques also yield an improvement for the knapsack median problem.

1. INTRODUCTION

We investigate facility location problems wherein the set of open facilities have to satisfy some matroid independence constraints or knapsack constraints. Specifically, we consider the matroid median problem, which is defined as follows. As in the uncapacitated facility location problem, we are given a set of facilities $F$ and a set of clients $D$. Each facility $i$ has an opening cost of $f_i$. Each client $j \in D$ has demand $d_j$ and assigning client $j$ to facility $i$ incurs an assignment cost of $d_j c_{ij}$ proportional to the distance between $i$ and $j$. Further, we are given a matroid $M = (F, I)$ on the set of facilities. The goal is to choose a set $F \in I$ of facilities to open that forms an independent set in $M$, and assign each client $j$ to a facility $i(j) \in F$ so as to minimize the total facility-opening cost.

A preliminary version [Swamy 2014] appeared in the Proceedings of the 17th APPROX, 2014. and client-assignment costs, that is, \( \sum_{i \in F} f_i + \sum_{j \in D} d_j c_{i(j)} \). We assume that the facilities and clients are located in a common metric space, so the distances \( c_{i(j)} \) form a metric.

The matroid median problem is a generalization of the metric \( k \)-median problem, which is the special case where \( M \) is a uniform matroid (and there are no facility-opening costs), and is thus, \( NP \)-hard. The matroid median problem without facility-opening costs was introduced recently by Krishnaswamy et al. [Krishnaswamy et al. 2011], who gave a 16-approximation algorithm for this problem.

Our contributions are threefold.

- We devise an improved 8-approximation algorithm for the matroid-median problem (Section 3). Moreover, notably, our algorithm is significantly simpler and cleaner than the one in [Krishnaswamy et al. 2011], and satisfies the stronger property that it is a \emph{Lagrangian-multiplier-preserving} 8-approximation algorithm (see Remark 3.9). The effectiveness and versatility of our simpler approach for matroid median is further highlighted when we consider some natural extensions of matroid median in Section 4. We leverage the techniques underlying our simpler and cleaner algorithm for matroid median to devise: (a) an 8-approximation algorithm for the \emph{two-matroid median} problem (Section 4.1), which is an extension that we introduce involving two matroids that captures some interesting facility-location problems considered in the literature; and (b) a 24-approximation algorithm (Section 4.2) for the \emph{matroid median problem with penalties}, wherein we are allowed to leave client unassigned and incur a penalty for each unassigned client; this constitutes a vast improvement over the approximation ratio of 360 obtained by Krishnaswamy et al. [Krishnaswamy et al. 2011].

- We show that the matroid median and two-matroid median problem turn out to be rather fundamental problems by showing in Section 5 that a variety of facility location problems that have been considered in the literature can be cast as instances of matroid median or two-matroid median. These include the data placement problem [Baev and Rajaraman 2001; Baev et al. 2008], mobile facility location [Friggstad and Salavatipour 2011; Ahmadian et al. 2013], \( k \)-median forest [Gørtz and Nagarajan 2011], and metric uniform minimum-latency UFL [Chakrabarty and Swamy 2011]. This not only gives a unified framework for viewing these seemingly disparate problems, but also our approximation guarantee of 8 yields improved, and in some cases, the first, approximation guarantees for all these problems.

- We adapt our techniques to also obtain an improvement for the knapsack median problem [Krishnaswamy et al. 2011; Kumar 2012] (Section 6).

Our improvement for matroid median comes from an improved, simpler rounding procedure for a natural LP relaxation of the problem also considered in [Krishnaswamy et al. 2011]. We show that a clustering step introduced in [Charikar et al. 2002] for the \( k \)-median problem coupled with two applications of the integrality of the intersection of two submodular (or matroid) polyhedra—one to obtain a half-integral solution, and another to obtain an integral solution—suffices to obtain the desired approximation ratio. In contrast, the algorithm in [Krishnaswamy et al. 2011] starts off with the clustering step in [Charikar et al. 2002], but then further dovetails the rounding procedure of [Charikar et al. 2002] creating trees, then stars, and then applies the integrality of the intersection of two submodular polyhedra.

There is great deal of similarity between the the rounding algorithm of [Krishnaswamy et al. 2011] for matroid median and the rounding algorithm of Baev and Rajaraman [Baev and Rajaraman 2001] for the data placement problem, who also perform the initial clustering step in [Charikar et al. 2002] and then create trees and then
stars and use these to obtain an integral solution. In contrast, our simpler, improved rounding algorithm is similar to the rounding algorithm in [Baev et al. 2008] for data placement, who use the initial clustering step of [Charikar et al. 2002] coupled with two min-cost flow computations—one to obtain a half-integral solution and another to obtain an integral solution—to obtain the final solution. These similarities are not surprising since, as mentioned above, we show in Section 5 that the data-placement problem is a special case of the matroid median problem. In fact, our improvements are analogous to those obtained for the data-placement problem by Baev, Rajaraman, and Swamy [Baev et al. 2008] over the guarantees in [Baev and Rajaraman 2001], and stem from similar insights.

A common theme to emerge from our work and [Baev et al. 2008] is that in various settings, the initial clustering step introduced by [Charikar et al. 2002] imparts sufficient structure to the fractional solution so that one can then round it using two applications of suitable integrality-results from combinatorial optimization. First, this initial clustering can be used to derive a half-integral solution. This was observed explicitly in [Baev and Rajaraman 2001] and is implicit in [Krishnaswamy et al. 2011], and making this explicit yields significant dividends. Second, and this is the oft-overlooked insight (in [Baev and Rajaraman 2001; Krishnaswamy et al. 2011]), a half-integral solution can be easily rounded, and in a better way, without resorting to creating trees and then stars etc. as in the algorithm of [Charikar et al. 2002]. This is due to the fact that a half-integral solution is already “filtered”: if client \(j\) is assigned to facility \(i\) fractionally, then one can bound \(c_{ij}\) in terms of the assignment cost paid by the fractional solution for \(j\) (see Section 3). This enables one to use a standard facility-location clustering step to set up a suitable combinatorial-optimization problem possessing an integrality property, and hence, round the half-integral solution. The resulting algorithm is typically both simpler and has a better approximation ratio than what one would obtain by mimicking the steps of [Charikar et al. 2002] involving creating trees, stars etc.

Recently, Charikar and Li [Charikar and Li 2012] obtained a 9-approximation algorithm for the matroid-median problem; our results were obtained independently.\(^1\) While there is some similarity between our ideas and those in [Charikar and Li 2012], we feel that our algorithm and analysis provides a more illuminating explanation of why matroid median and some of its extensions (e.g., two-matroid median, matroid median with penalties; see Section 4) are “easy” to approximate, whereas other variants such as matroid-intersection median (Section 4) are inapproximable. It remains to be seen if our ideas coupled with the dependent-rounding procedure used in [Charikar and Li 2012] for the \(k\)-median problem leads to further improvements for the matroid median problem; we leave this as future work.

2. AN LP RELAXATION FOR MATROID MEDIAN

We can express the matroid median problem as an integer program and relax the integrality constraints to get a linear program (LP). Throughout we use \(i\) to index facilities in \(F\), and \(j\) to index clients in \(D\). Let \(r\) denote the rank function of the matroid \(M = (F, I)\).

\(^1\)A manuscript containing the 8-approximation for matroid median was circulated privately in 2012; the current version was posted on the arXiv in Nov. 2013.
\begin{align*}
\min & \quad \sum_{i} f_i y_i + \sum_{j} \sum_{i} d_j c_{ij} x_{ij} \\
\text{s.t.} & \quad \sum_{i} x_{ij} \geq 1 \quad \forall j \tag{1} \\
& \quad \sum_{i \in S} y_i \leq r(S) \quad \forall S \subseteq \mathcal{F} \tag{2} \\
& \quad 0 \leq x_{ij} \leq y_i \quad \forall i, j. \tag{3}
\end{align*}

Variable $y_i$ indicates if facility $i$ is open, and $x_{ij}$ indicates if client $j$ is assigned to facility $i$. The first and third constraints say that each client must be assigned to an open facility. The second constraint encodes the matroid independence constraint. An integer solution corresponds exactly to a solution to our problem. We note that (P) can be solved in polytime since (for example) a polytime algorithm for submodular-function minimization yields an efficient separation oracle.

3. A SIMPLE 8-APPROXIMATION ALGORITHM VIA LP-ROUNDING

Let $(x, y)$ denote an optimal solution to (P) and $OPT$ be its value. We first describe a simple algorithm to round $(x, y)$ to an integer solution losing a factor of at most 10. In Section 3.4, we use some additional insights to improve the approximation ratio to 8. We use the terms connection cost and assignment cost interchangeably. We may assume that $\sum_{i} x_{ij} = 1$ for every client $j$.

3.1. Overview of the algorithm

We first give a high level description of the algorithm. Suppose for a moment that the optimal solution $(x, y)$ satisfies the following property:

\begin{equation}
\text{for every facility } i, \text{ there is at most one client } j \text{ such that } x_{ij} > 0. \tag{*}
\end{equation}

Let $\mathcal{F}_j = \{i : x_{ij} > 0\}$. Notice that the $\mathcal{F}_j$ sets are disjoint. We may assume that for $i \in \mathcal{F}_j$, we have $y_i = x_{ij}$, so the objective function is a linear function of only the $y_i$ variables. We can then set up the following matroid intersection problem. The first matroid is $M$ restricted to $\bigcup_{j} \mathcal{F}_j$. The second matroid $M'$ (on the same ground set $\bigcup_{j} \mathcal{F}_j$) is the partition matroid defined by the $\mathcal{F}_j$ sets; that is, a set is independent in $M'$ if it contains at most one facility from each $\mathcal{F}_j$. Notice the $y_i$-variables yield a fractional point in the intersection of the matroid polyhedron of $M$ and the matroid-base polyhedron of $M'$. Since the intersection of these two polyhedra is known to be integral (see, e.g., [Cook et al. 1998]), this means that we can round $(x, y)$ to an integer solution of no greater cost. Of course, the LP solution need not have property $(*)$ so our goal will be to transform $(x, y)$ to a solution that has this property without increasing the cost by much.

Roughly speaking we want to do the following: cluster the clients in $\mathcal{D}$ around certain ‘centers’ (also clients) such that (a) every client $k$ is assigned to a “nearby” cluster center $j$ whose LP assignment cost is less than that of $k$, and (b) the facilities serving the cluster centers in the fractional solution $(x, y)$ are disjoint. So, the modified instance where the demand of a client is moved to the center of its cluster has a fractional solution, namely the solution induced by $(x, y)$, that satisfies $(*)$ and has cost at most $OPT$. Furthermore, given a solution to the modified instance we can obtain a solution to the original instance losing a small additive factor. One option is to use the decomposition method of Shmoys et al. [Shmoys et al. 1997] for uncapacitated facility location (UFL) that produces precisely such a clustering. The problem however is that [Shmoys et al. 1997] uses filtering which involves blowing up the $x_{ij}$ and $y_i$ values, thus violating the

ACM Transactions on Algorithms, Vol. V, No. N, Article 1, Publication date: January 2016.
matroid-rank packing constraints. Chudak and Shmoys [Chudak and Shmoys 2003] use the same clustering idea but without filtering, using the dual solution to bound the cost. The difficulty here with this approach is that there are terms with negative coefficients in the dual objective function that correspond to the primal matroid-rank constraints. Although [Swamy and Shmoys 2008] showed that it is possible to overcome this difficulty in certain cases, the situation here looks more complicated and it is not clear how to use their techniques.

Instead, we use the clustering technique of Charikar et al. [Charikar et al. 2002] to cluster clients and first obtain a half-integral solution \((\hat{x}, \hat{y})\), that is, every \(\hat{x}_{ij}, \hat{y}_i \in \{0, \frac{1}{2}, 1\}\), to the modified instance with cluster centers, losing a factor of 3. Further, any solution here will give a solution to the original instance while increasing the cost by at most \(4 \cdot \text{OPT}\). Now we use the clustering method of [Shmoys et al. 1997] without any filtering, since the half-integral solution \((\hat{x}, \hat{y})\) is essentially already filtered; if client \(j\) is assigned to \(i\) and \(i'\) in \(\hat{x}\), then \(c_{ij}, c_{i'j} \leq 2(c_{ij}\hat{x}_{ij} + c_{i'j}\hat{x}_{i'j})\). This final step causes us to lose an additive factor equal to the cost of \((\hat{x}, \hat{y})\), so overall we get an approximation ratio of \(4 + 3 + 3 = 10\). In Section 3.4, we show that by further exploiting the structure of the half-integral solution, we can get a better bound on the cost of the integer solution and thus obtain an 8-approximation.

We now describe each of these steps in detail. Let \(\bar{C}_j = \sum_i c_{ij}x_{ij}\) denote the cost incurred by the LP solution to assign one unit of demand of client \(j\). Given a vector \(v \in \mathbb{R}^F\) and a set \(S \subseteq F\), we use \(v(S)\) to denote \(\sum_{i \in S} v_i\).

### 3.2. Obtaining a Half-Integral Solution \((\hat{x}, \hat{y})\)

**Step I: Consolidating demands around centers.** We first consolidate (or cluster) the demand of clients at certain clients, that we call *cluster centers*. We do not modify the fractional solution \((x, y)\) but only modify the demands so that for some clients \(k\), the demand \(d_k\) is “moved” to a “nearby” center \(j\). We assume every client has non-zero demand (we can simply get rid of zero-demand clients).

Set \(d'_j \leftarrow 0\) for every \(j\). Consider the clients in increasing order of \(\bar{C}_j\). For each client \(k\) encountered, if there exists a client \(j\) such that \(d'_j > 0\) and \(c_{jk} \leq 4\max(\bar{C}_j, \bar{C}_k) = 4\bar{C}_k\), set \(d'_j \leftarrow d'_j + d_k\), otherwise set \(d'_k \leftarrow d_k\). Let \(D = \{j \in D : d'_j > 0\}\). Each client in \(D\) is a cluster center. Let \(\text{OPT}' = \sum_{j \in D} f_j y_j + \sum_{j \in D, i} d'_j c_{ij} x_{ij}\) denote the cost of \((x, y)\) for the modified instance consisting of the cluster centers.

**Lemma 3.1.** (i) If \(j, k \in D\), then \(c_{jk} \geq 4\max(\bar{C}_j, \bar{C}_k)\). (ii) \(\text{OPT}' \leq \text{OPT}\), and (iii) any solution \((x', y')\) to the modified instance can be converted to a solution to the original instance incurring an additional cost of at most \(4 \cdot \text{OPT}\).

**Proof.** Suppose \(k\) was considered after \(j\). Then \(d'_j > 0\) at this time, otherwise \(d'_j\) would remain at 0 and \(j\) would not be in \(D\). So if \(c_{jk} < 4\max(\bar{C}_j, \bar{C}_k)\) then \(d'_k\) would remain at 0, giving a contradiction. It is clear that if we move the demand of client \(k\) to client \(j\), then \(\bar{C}_j \leq \bar{C}_k\) and \(c_{jk} \leq 4\bar{C}_k\). So the assignment cost for the new instance, \(\sum_j d'_j \bar{C}_j\), only decreases and the facility-opening cost \(\sum_i f_i y_i\) does not change, hence \(\text{OPT}' \leq \text{OPT}\). Given a solution \((x', y')\) to the modified instance, if the demand of \(k\) was moved to \(j\) the extra cost incurred in assigning \(k\) to the same facility(ies) as in \(x'\) is at most \(d_k c_{jk} \leq 4d_k \bar{C}_k\) by the triangle inequality, so the total extra cost is at most \(4 \cdot \text{OPT}\). \(\Box\)

From now on we focus on the modified instance with client set \(D\) and modified demands \(d'_j\). At the very end we will use the above lemma to translate an integer solution to the modified instance to an integer solution to the original instance.
Step II: Transforming to a half-integral solution. We define the cluster of a client \( j \in D \) to be the set \( F_j \) of all facilities \( i \) such that \( j \) is the center in \( D \) closest to \( i \), that is, \( F_j = \{ i : c_{ij} = \min_{k \in D} c_{ik} \} \), with ties broken arbitrarily. Let \( F'_j \subseteq F_j = \{ i \in F_j : c_{ij} \leq 2C_j \} \). Define \( \gamma_j := \min_{i \in F_j} c_{ij} \), and let \( G_j = \{ i \in F_j : c_{ij} \leq \gamma_j \} \); see Fig. 1. By property (i) of Lemma 3.1, we have that \( F_j \) contains all the facilities \( i \) such that \( c_{ij} \leq 2C_j \). So \( \gamma_j \geq 2C_j, F'_j \subseteq G_j, \) and \( \sum_{i \in F'_j} x_{ij} = \sum_{i \in G_j} x_{ij} \geq \frac{1}{2} \) by Markov's inequality. Clearly the sets \( F_j \) for \( j \in D \) are disjoint.

To obtain the half-integral solution, we define a suitable vector \( y' \) that lies in a polytope with half-integral extreme points and construct a linear function \( T(.) \) such that \( T(y') \) bounds the cost of a fractional solution. We show that \( T(y') \leq 3 \cdot OPT' \). This implies that one can obtain a “better” half-integral vector \( \hat{y} \), which we then argue yields a half-integral solution \( (\hat{x}, \hat{y}) \) to the modified instance of cost at most \( T(\hat{y}) \leq T(y') \).

To motivate the definition of \( T(.) \) and the polytope, first define \( y' \in \mathbb{R}^F_+ \) as follows: set \( y'_i = x_{ij} \leq y_i \) if \( i \in G_j \), and \( y'_i = 0 \) otherwise. Clearly, \( y'(F_k) = y'(G_j) \leq 1 \) for every \( \ell \in D \). Consider some client \( j \in D \). Suppose \( \gamma_j = c_{ij} \), where \( i \in F_k, k \neq j \). It is not hard to show that \( c_{ij} \leq 3\gamma_j \) for every facility \( j' \in F'_k \) (see Lemma 3.2), and so

\[
\sum_{i \in G_j} c_{ij} y'_i + 3\gamma_j (1 - y'(G_j)) \leq 3C_j.
\]

We use the above linear function of \( y' \) as a proxy for \( j \)'s per-unit-demand assignment cost, and define \( T(v) = \sum_i f_i v_i + \sum_j d_j \left( \sum_{i \in G_j} c_{ij} v_i + 3\gamma_j (1 - \sum_{i \in G_j} v_i) \right) \) for \( v \in \mathbb{R}^F_+ \). Note that if \( v \in \mathbb{R}^F_+ \) satisfies \( v(F'_k) \geq 0.5, v(G_k) \leq 1 \) for all \( \ell \in D \), then \( d_j \left( \sum_{i \in G_j} c_{ij} v_i + 3\gamma_j (1 - v(G_j)) \right) \) is an upper bound on \( j \)'s assignment cost under \( v \) (since \( 1 - v(G_j) \leq 0.5 \leq v(F'_k) \)). Hence, we define our polytope to be

\[
\mathcal{P} := \left\{ v \in \mathbb{R}^F_+ : v(S) \leq r(S) \quad \forall S \subseteq F, \quad v(F'_j) \geq \frac{1}{2}, \quad v(G_j) \leq 1 \quad \forall j \in D \right\}. \tag{4}
\]

We claim that \( \mathcal{P} \) has half-integral extreme points. The easiest way to see this is to note that any extreme point of \( \mathcal{P} \) is defined by a linearly independent system of tight constraints comprising some \( v(S) = r(S) \) equalities corresponding to a laminar set system, and some \( v(F'_j) = \frac{1}{2} \) and \( v(G_j) = 1 \) equalities. The constraint matrix of this system thus corresponds to equations coming from two laminar set systems; such a matrix is
known to be totally unimodular, and hence the vector \( v \) satisfying this system must be a half-integral solution. (Appendix A gives another proof based on the integrality of the intersection of two submodular polyhedra.)

Clearly \( y' \in P \). Hence, we can obtain a half-integral solution \( \hat{y} \) such that \( T(\hat{y}) \leq T(y') \). For any \( j \in D \), observe that there is at least one facility \( i \in F_j' \) with \( \hat{y}_i > 0 \); we call the facility \( i \in F_j' \) nearest to \( j \) the primary facility of \( j \) and set \( \hat{x}_{ij} = \hat{y}_i \). If \( \hat{y}_i < 1 \), then let \( i' \) be the facility nearest to \( j \) other than \( i \) such that \( \hat{y}_{i'} > 0 \); we call \( i' \) the secondary facility of \( j \), and set \( \hat{x}_{ij} = 1 - \hat{x}_{i'j} \). Note that every client in \( D \) has a distinct primary facility.

**Lemma 3.2.** The cost of \((\hat{x}, \hat{y})\), that is, \( \sum_{i} f_i \hat{y}_i + \sum_{j \in D, i} d_j' c_{ij} \hat{x}_{ij} \), is at most \( 3 \cdot \text{OPT}' \leq 3 \cdot \text{OPT} \).

**Proof.** We first show that \( T(y') \leq 3 \cdot \text{OPT}' \), and then bound the cost of \((\hat{x}, \hat{y})\) by \( T(\hat{y}) = \sum_i f_i \hat{y}_i + \sum_{j \in D, i} d_j' \left( \sum_{i' \in G_j} c_{ij} \hat{y}_{i'} + 3 \gamma_j(1 - \hat{y}(G_j)) \right) \). Since \( T(\hat{y}) \leq T(y') \), this proves the lemma.

We have \( \text{OPT}' = \sum_i f_i \hat{y}_i + \sum_{j \in D} d_j' \hat{C}_j \), and for any \( j \in D \), we have \( \hat{C}_j = \sum_{i' \in G_j} c_{ij} \hat{x}_{ij} + \sum_{i \in G_j} c_{ij} x_{ij} \) by the definition of \( \gamma_j \). So

\[
T(y') \leq \sum_{i} f_i \hat{y}_i + \sum_{j \in D} d_j' \left( \sum_{i \in G_j} c_{ij} x_{ij} + 3 \gamma_j(1 - \sum_{i \in G_j} x_{ij}) \right) \leq \sum_{i} f_i \hat{y}_i + 3 \sum_{j} d_j' \hat{C}_j \leq 3 \cdot \text{OPT}.
\]

To bound the cost of \((\hat{x}, \hat{y})\), it suffices to show that the assignment cost of each client

\[
j \in D \text{ is at most } d_j' \left( \sum_{i \in G_j} c_{ij} x_{ij} + 3 \gamma_j(1 - \sum_{i \in G_j} x_{ij}) \right).
\]

If \( \hat{y}(G_j) = 1 \), then the assignment cost of \( j \) is at most

\[
d_j' \sum_{i \in G_j} c_{ij} \hat{x}_{ij} + d_j' c_{ij}(1 - \hat{y}(G_j)),
\]

where \( i' \) is the secondary facility of \( j \). We show that

\[
c_{ij} \leq 3 \gamma_j,
\]

which implies the desired bound. Let \( \gamma_j = c_{ij} \) where \( j'' \in F_k, k \neq j \). Let \( \ell \) be the primary facility of \( k \). Then, \( c_{ij} \leq c_{ij} \) and \( 4 \max(\hat{C}_j, \hat{C}_k) \leq c_{jk} \leq c_{ij} + c_{ij} \leq 2 \gamma_j \).

Also \( c_{ik} \leq 2 \hat{C}_k \) since \( \ell \in F_k \). Combining the inequalities we get that \( c_{ij} \leq 3 \gamma_j \). \( \square \)

### 3.3. Converting \((\hat{x}, \hat{y})\) to an integer solution

Define \( \hat{C}_j = \sum_i c_{ij} \hat{x}_{ij} \) and \( S_j = \{ i : \hat{x}_{ij} > 0 \} \) for \( j \in D \).

**Step III: Clustering.** We cluster the clients in \( D \) as follows: pick \( j \in D \) with smallest \( \hat{C}_j \). Remove every client \( k \in D \) such that \( S_j \cap S_k = \emptyset \); we call \( j \) the center of \( k \) and denote it by \( \text{ctr}(k) \). Recurse on the remaining set of clients until no client in \( D \) is left. Let \( D' \) be the set of clients picked — these are the new cluster centers. Note that \( \text{ctr}(j) = j \) for every \( j \in D' \).

**Step IV: The matroid intersection problem.** For convenience, we will say that every client \( j \in D \) has both a primary facility, denoted \( i_1(j) \), and a secondary facility, denoted \( i_2(j) \), with \( \hat{x}_{i_1(j)j} = \hat{x}_{i_2(j)j} = \frac{1}{2} \), with the understanding that if \( j \) does not have a secondary facility then \( i_2(j) = i_1(j) \), and so \( \hat{x}_{i_1(j)j} = 1 \). Then we have \( \hat{C}_j = \frac{1}{2}(c_{i_1(j)j} + c_{i_2(j)j}) \) and \( c_{i_1(j)j} \leq \hat{C}_j \leq c_{i_2(j)j} \leq 2 \hat{C}_j \).

For \( i \in F \), define \( \hat{y}'_i = \hat{x}_{ij} \leq \hat{y}_i \) if \( i \in S_j \) where \( j \in D' \), and \( \hat{y}_i' = \hat{y}_i \) otherwise. Then \( \hat{y}' \) lies in the polytope

\[
\mathcal{R} := \{ z \in \mathbb{R}_+^F : z(S) \leq r(S) \quad \forall S \subseteq F, \quad z(S_j) = 1 \quad \forall j \in D' \}. \tag{5}
\]

Observe that \( \mathcal{R} \) is the intersection of the matroid polytope for \( M \) with the matroid base polytope for the partition matroid defined by the \( S_j \) sets for \( j \in D' \). This polytope is known to have integral extreme points. Similar to Step II, we define a linear function
\[ H(z) = \sum_i f_i z_i + \sum_{k \in D} A_k(z), \]

where

\[ A_k(z) = \begin{cases} 
\sum_{i \in S_{\text{ctr}(k)}} d_k^i c_{ik} z_i 
& \text{if } i_1(k) \in S_{\text{ctr}(k)} \\
\sum_{i \in S_{\text{ctr}(k)}} d_k^i c_{ik} z_i + d_k^i (c_{i_1(k)k} - c_{i_2(k)k}) z_{i_1(k)} 
& \text{otherwise.}
\end{cases} \]

Here, \( A_k(z) \) is a proxy for \( k \)'s assignment cost chosen suitably so that: (a) for an integer \( \hat{y} \in R \), \( A_k(\hat{y}) \) yields an upper bound on \( k \)'s assignment cost (see Lemma 3.3); and (b) \( A_k(\hat{y}') \) is at most \( 2d_k^i \hat{C}_k \) (see Lemma 3.4). Since \( R \) is integral, we can find an integer point \( \bar{y} \in R \) such that \( H(\bar{y}) \leq H(\hat{y}') \). This yields an integer solution \((\bar{x}, \bar{y})\) to the instance with client set \( D \), where we assign each client \( j \in D' \) to the unique facility opened from \( S_j \), and each client \( k \in D \setminus D' \) either to \( i_1(k) \) if it is open (i.e., \( y_{i_1(k)} = 1 \)), or to the facility opened from \( S_{\text{ctr}(k)} \). In Lemma 3.3 we prove that the cost of this integer solution is at most \( H(\bar{y}) \), and in Lemma 3.4 we show that \( H(\bar{y}') \) is at most twice the cost of \((\bar{x}, \bar{y})\) and hence, at most \( 6 \cdot OPT \) (by Lemma 3.2). Combined with Lemma 3.1, this yields Theorem 3.5.

**Lemma 3.3.** The cost of \((\bar{x}, \bar{y})\) is at most \( H(\bar{y}) \).

**Proof.** Clearly, the facility opening cost is \( \sum_i f_i \bar{y}_i \), and the assignment cost of a client \( j \in D' \) is \( \sum_{i \in S_j} d_j^i c_{ij} \bar{y}_i \), which is exactly \( A_j(\bar{y}) \). Consider a client \( k \in D \setminus D' \) with \( \text{ctr}(k) = j \). If \( y_{i_1(k)} = 0 \), then the assignment cost of \( k \) is \( d_k^i \sum_{i \in S_j} c_{ik} \bar{y}_i \) which is equal to \( A_k(\hat{y}) \). If \( y_{i_1(k)} = 1 \), then the assignment cost of \( k \) is \( d_k^i c_{i_1(k)k} \). If \( i_1(k) \in S_j \), then \( A_k(\bar{y}) = d_k^i \sum_{i \in S_j} c_{ik} \bar{y}_i \geq d_k^i c_{i_1(k)k} \), and otherwise \( A_k(\bar{y}) = d_k^i \left( \sum_{i \in S_j} c_{ik} \bar{y}_i + c_{i_1(k)k} - c_{i_2(k)k} \right) \geq d_k^i c_{i_1(k)k} \) since \( i_2(k) \) is the second-nearest facility to \( k \), so every facility in \( S_j \) is at least as far away from \( k \) as \( i_2(k) \). \( \square \)

**Lemma 3.4.** \( H(\bar{y}') \) is at most twice the cost of \((\bar{x}, \bar{y})\).

**Proof.** Clearly \( \sum_i f_i \bar{y}_i' \leq \sum_i f_i \bar{y}_i \). For \( j \in D' \), we have \( A_j(\bar{y}') = \sum_{i \in S_j} d_j^i c_{ij} \bar{x}_j \).

Consider \( k \in D \setminus D' \) with \( \text{ctr}(k) = j \). Let \( i' = i_1(j) \) and \( i'' = i_2(j) \), so \( \hat{C}_j = \frac{1}{2}(c_{i'j} + c_{i''j}) \leq \hat{C}_k \).

If \( i_1(k) \in S_j \), then the (at most one) facility \( i \in S_j \setminus \{i_1(k)\} \) satisfies \( c_{ik} \leq c_{i'j} + c_{i''j} + c_{i_2(k)k} \), so \( A_k(\bar{y}') \leq \frac{d_k^i}{2} (2c_{i_1(k)k} + 2\hat{C}_k) \leq 2d_k^i \hat{C}_k \).

If \( i_1(k) \notin S_j \), then \( i_2(k) \in S_j \), so \( c_{i'k} + c_{i''k} \leq 2c_{i_2(k)k} + c_{i'j} + c_{i''j} \leq 2c_{i_2(k)k} + 2\hat{C}_k \). So \( A_k(\bar{y}') \) is at most \( \frac{d_k^i}{2} (2c_{i_2(k)k} + 2\hat{C}_k + c_{i_2(k)k} - c_{i_2(k)k}) = 2d_k^i \hat{C}_k \). \( \square \)

**Theorem 3.5.** The integer solution \((\bar{x}, \bar{y})\) translates to an integer solution to the original instance of cost at most \( 10 \cdot OPT \).

**Proof.** By Lemmas 3.3 and 3.4, the cost of \((\bar{x}, \bar{y})\) (for the modified instance) is at most twice the cost of \((\bar{x}, \bar{y})\), and hence, at most \( 6 \cdot OPT \) by Lemma 3.2. Applying part (ii) of Lemma 3.1 yields the theorem. \( \square \)

### 3.4. Improvement to 8-approximation

The procedure described in Section 3.3 shows that any half-integral solution can be rounded to an integral one losing a factor of 2 in the cost. We obtain an improved approximation ratio of 8 by exploiting the structure leading to the half-integral solution obtained in Section 3.2. The key to the improvement comes from the following observation (in various flavors). Consider a non-cluster-center \( k \in D \setminus D \) with \( \text{ctr}(k) = j \). Let \( i \) be a facility serving both \( j \) and \( k \). Suppose \( i \) is not the primary facility of \( k \).

Without any further information, we can only say that \( c_{ik} \leq c_{ij} + c_{ik} \leq 3\gamma_j + 3\gamma_k \). However, if we define our half-integral solution by setting the secondary facility of
Step III.

We use a different criterion for selecting a cluster center in the clustering performed in integral and integral solutions: we tailor the function $T$ (defined in Step II above) so as to allow one to bound the total cost of the final integral solution obtained. Also, we use a different criterion for selecting a cluster center in the clustering performed in Step III.

The first step is the same as Step I in Section 3.2. Recall that the new client-set is $D$ with demands $\{d'_j\}_{j \in D}$, $OPT'$ is the cost of $(x, y)$ for the modified instance, and for each $j \in D$ we define $F_j = \{ i : c_{ij} = \min_{k \in D} c_{ik} \}$, $F'_j = \{ i \in F_j : c_{ij} \leq 2\gamma_j \}$, $\gamma_j = \min_{i \notin F_j} c_{ij}$, and $G_j = \{ i \in F_j : c_{ij} \leq \gamma_j \}$.

A1. Obtaining a half-integral solution. Set $y'_{ij} = x_{ij} \leq y_i$ if $i \in G_j$, and $y'_{ij} = 0$ otherwise. We define $T(v) = \sum_i f_i v_i + \sum_j d'_j (2\sum_{i \in G_j} c_{ij} v_i + 4\gamma_j (1 - \sum_{i \in G_j} v_i))$ for $v \in \mathbb{R}^+_\mathbb{S}$ with some hindsight. Since $y'$ lies in the half-integral polytope $\mathbb{S}$ (see (4)), we can obtain a half-integral $\hat{y}$ such that $T(\hat{y}) \leq T(y')$.

For each client $j \in D$, define $\sigma(j) = j$ if $\hat{y}(G_j) = 1$, and $\sigma(j) = \arg \min_{k \in D : k \neq j} c_{jk}$ otherwise (breaking ties arbitrarily). Note that $c_{j\sigma(j)} \leq 2\gamma_j$. As before, we call the facility $i$ nearest to $j$ with $\hat{y}_i > 0$ the primary facility of $j$ and denote it by $i_1(j)$; we set $\hat{x}_{i_1(j)} = \hat{y}_{i_1(j)}$. Note that $i_1(j) \in F'_j$. If $\hat{y}_{i_1(j)} < 1$ and $\hat{y}(G_j) = 1$, let $i' = \hat{x}_{i_1(j)}$, otherwise let $i' = \hat{x}_{i\sigma(j)}$, and denote it by $i_2(j)$. Then, for convenience, we consider $j$ as having both a primary and secondary facility and $\hat{x}_{i_1(j)} = \hat{x}_{i_2(j)}$. With the understanding that if $\hat{y}_{i_1(j)} = 1$, then $i_2(j) = i_1(j)$ and $\hat{x}_{i_1(j)} = 1$. Let $S_j = \{i : \hat{x}_{ij} > 0\}$.

A2. Clustering and rounding to an integral solution. For each $j \in D$, define $C'_j = (c_{i_1(j)} + c_{j\sigma(j)} + c_{i_1(j)\sigma(j)})/2$. We cluster clients as in Step III in Section 3.3, except that we repeatedly pick the client with smallest $C'_j$ among the remaining clients to be the cluster center. As before, let $D'$ denote the set of cluster centers, and let $\text{ctr}(k) = j \in D'$ for $k \in D$ if $k$ was removed in the clustering process because $j$ was chosen as a cluster center and $S_j \cap S_k \neq \emptyset$.

Similar to Step IV in Section 3.3, for each $i \in F$, define $\hat{y}'_i = \hat{x}_{ij} \leq \hat{y}_i$ if $i \in S_j$ where $j \in D'$ and $\hat{y}'_i = \hat{y}_i$ otherwise. For $z \in \mathbb{R}^+_\mathbb{S}$, define $H(z) = \sum_i f_i z_i + \sum_{k \in D} L_k(z)$, where

$$L_k(z) = \begin{cases} \sum_{i \in S_{\text{ctr}(k)}} d'_k c_{ik} z_i & \text{if } i_1(k) \in S_{\text{ctr}(k)} \\ \sum_{i \in S_{\text{ctr}(k)}} d'_k (c_{k\sigma(k)} + c_{i\sigma(k)}) z_i + d'_k (c_{i_1(k)k} - c_{k\sigma(k)} - c_{i_1(k)\sigma(k)} + c_{i_1(k)\sigma(k)}) z_{i_2(k)} & \text{otherwise.} \end{cases}$$

As in Step IV in Section 3.3, $L_k(z)$ is a suitable proxy for $k$'s assignment cost. It coincides with $A_k(z)$ when $i_1(k) \in S_{\text{ctr}(k)}$; in the other case, we have replaced each $c_{ik}$ term for $i \in S_{\text{ctr}(k)}$ in the expression for $A_k(z)$ by the bound $c_{k\sigma(k)} + c_{i\sigma(k)}$ (note that $i_2(k) = i_1(k)\sigma(k)$). The intent is to capture the cost savings due to our new definition of $i_2(k)$ but yet ensure that $L_k(\hat{y})$ yields an upper bound on $k$'s assignment cost when $\hat{y}\in \mathbb{R}$.

Since $\hat{y}'$ lies in the integral polytope $\mathbb{R}$ (see (5)), we can obtain an integral vector $\hat{y}$ such that $H(\hat{y}) \leq H(\hat{y}')$, and a corresponding integral solution $(\hat{x}, \hat{y})$ (as in Step IV in Section 3.3).
Analysis. By mimicking the proof of Lemma 3.2, we easily obtain that $T(y') \leq 4 \cdot OPT'$. Hence, we have $T(\tilde{y}) \leq T(y') \leq 4 \cdot OPT' \leq 4 \cdot OPT$. Lemma 3.6 shows that the cost of $(\tilde{x}, \tilde{y})$ is at most $H(\tilde{y}) \leq H(y')$, and Lemma 3.7 proves that $H(y') \leq T(y)$. This shows that the cost of $(\tilde{x}, \tilde{y})$ is at most $4 \cdot OPT$. Combined with Lemma 3.1, this yields the 8-approximation guarantee (Theorem 3.8).

Lemma 3.6. The cost of $(\tilde{x}, \tilde{y})$ is at most $H(\tilde{y})$.

Proof. The facility opening cost is $\sum_{i \in S_j} f_i \tilde{y}_i$. The assignment cost of a client $j \in D'$ is $\sum_{i \in S_j} d'_j c_{ij} \tilde{y}_i = L_j(\tilde{y})$. Consider a client $k \in D \setminus D'$ with $\text{ctr}(k) = j$. Let $i' = i_1(j)$, $i'' = i_2(j)$. If $y_{i_1(k)} = 0$ or $i_1(k) \in S_j$, then $L_k(\tilde{y})$ is at least $d'_k \sum_{i \in S_j} c_{ik} \tilde{y}_i$, which is the assignment cost of $k$. So suppose $\tilde{y}_{i_1(k)} = 1$ and $i_1(k) \notin S_j$. Then the assignment cost of $k$ is $d'_k c_{i_1(k)k}$, and since $c_\sigma(k) \geq c_{i_1(\sigma(k))\sigma(k)}$ for every $i \in S_j$, we have $L_k(\tilde{y}) \geq d'_k c_{i_1(k)k}$.

Lemma 3.7. We have $H(y') \leq T(\tilde{y})$.

Proof. Define $B_j(\tilde{y}) := d'_j (2 \sum_{i \in G_j} c_{ij} \tilde{y}_i + 4 \gamma_j (1 - \tilde{y}(G_j)))$. So $T(\tilde{y}) = \sum f_i \tilde{y}_i + \sum_{j \in D} B_j(\tilde{y})$. Clearly $\sum_i f_i \tilde{y}_i \leq \sum_i f_i \hat{y}_i$. We show that $L_j(\tilde{y}) \leq B_j(\tilde{y})$ for every $j \in D$, which will complete the proof.

We first argue that $d'_j C'_j \leq B_j(\tilde{y})$ for every $j \in D$. If $\tilde{y}(G_j) = 1$, then $d'_j C'_j = \sum_{i \in G_j} d'_j c_{ij} \tilde{y}_i \leq B_j(\tilde{y})$. Otherwise, $\tilde{y}(G_j) = \frac{1}{2}$, and $c_{1\sigma(j)} + c_{i_2(\sigma(j))\sigma(j)} \leq 3 \gamma_j$; so $d'_j C'_j \leq d'_j \left( \sum_{i \in G_j} c_{ij} \tilde{y}_i + 3 \gamma_j (1 - \tilde{y}(G_j)) \right) \leq B_j(\tilde{y})$.

For a client $j \in D'$, we have $L_j(\tilde{y}) = d'_j (c_{i_1(j)j} + c_{i_2(j)j})/2 \leq d'_j C'_j \leq B_j(\tilde{y})$. Now consider a client $k \in D \setminus D'$. Let $j = \text{ctr}(k)$, and $i' = i_1(j), i'' = i_2(j)$. Note that $C'_j \leq C_k'$. We consider two cases.

1. $i_1(k) \in S_j$. This means that $i_1(k) = i'' \neq i'$ and $k = \sigma(j)$. So

\[ L_k(\tilde{y}) = \frac{d'_k}{2} \cdot (c_{i''k} + c_{i'k}) \leq \frac{d'_k}{2} \cdot (c_{i'j} + c_{jk} + c_{i''k}) = d'_k C'_j \leq d'_k C'_k \leq B_k(\tilde{y}). \]

2. $i_1(k) \notin S_j$. This implies that $\tilde{y}(G_k) = \tilde{y}_{i_1(k)} = 1$. Let $\ell = \sigma(k)$ (which is the same as $j$ if $i_2(k) = i_1(j)$). We have $L_k(\tilde{y}) = \frac{d'_k}{2} \cdot (2c_{k\ell} + c_{i'\ell} + c_{i''\ell} + c_{i_1(k)k} - c_{kk} - c_{i_1(\ell)\ell})$. If $\ell = j$, then $L_k(\tilde{y}) = \frac{d'_k}{2} \cdot (c_{i_1(k)k} + c_{jk} + c_{i''k})$. Notice that $c_{i''j} \leq 2 C'_j - c_{i''j}$. So we obtain that

\[ L_k(\tilde{y}) \leq \frac{d'_k}{2} \cdot (c_{i_1(k)k} + c_{jk} + 2 C'_j - c_{i''j}) \leq \frac{d'_k}{2} \cdot (c_{i_1(k)k} + c_{jk} + 2C'_k - c_{i''j}) = d'_k (c_{i_1(k)k} + c_{jk}). \]

If $\ell \neq j$, then $i'' = i_2(k) = i_1(\ell)$, so $\ell = \sigma(j)$, and $c_{i''j} + c_{jk} + c_{i''\ell} = 2 C'_j \leq 2 C_k' = c_{i_1(k)k} + c_{jk} + c_{i''\ell}$. So $L_k(\tilde{y}) \leq \frac{d'_k}{2} \cdot (c_{i_1(k)k} + c_{jk} + c_{i''\ell}) \leq d'_k (c_{i_1(k)k} + c_{jk})$. In both cases,

\[ L_k(\tilde{y}) \leq d'_k (c_{i_1(k)k} + c_{k\sigma(k)}) \leq d'_k \left( 2 \sum_{i \in G_k} c_{ik} \tilde{y}_i + 4 \gamma_k (1 - \tilde{y}(G_k)) \right) = B_k(\tilde{y}). \]

\[ \square \]

Theorem 3.8. The integer solution $(\tilde{x}, \tilde{y})$ translates to an integer solution to the original instance of cost at most $8 \cdot OPT$.

Remark 3.9. It is easy to modify the above algorithm to obtain a so-called Lagrangian-multiplier preserving (LMP) 8-approximation algorithm, that is, where the solution $(\tilde{x}, \tilde{y})$ returned satisfies $\sum_i f_i \tilde{y}_i + \sum_{j \in D} d_j c_{ij} \tilde{x}_{ij} \leq 8 \cdot OPT$. To obtain
We now have $T(y) \leq T(y') \leq 8 \sum_i f_i y_i + 4 \sum_{j \in D} d_j' C_j$, and $8 \sum_i f_i y_i + \sum_{j \in D,i} d_j' c_{ij}^x i j \leq H(y) \leq H(y')$. Also, as before, we have $H(y') \leq T(y)$. Thus, we have

$$8 \sum_i f_i y_i + \sum_{j \in D,i} d_j c_{ij} x i j \leq 8 \sum_i f_i y_i + \sum_{j \in D,i} d_j' c_{ij} x i j + \sum_{j \in D \setminus D} 4d_j C_j$$

$$\leq 8 \sum_i f_i y_i + 4 \sum_{j \in D} d_j C_j + 8 \sum_{j \in D \setminus D} d_j C_j \leq 8 \cdot \text{OPT}.$$
satisfies (i) and (ii) above, and (iii) $F \cap F_2 \in \mathcal{I}_2$. We may modify the matroids $M$ and $M_2$ to incorporate the upper bounds $ub$ and $ub^2$ respectively in their definition; we assume that this has been done in the sequel. The LP-relaxation for 2MMed is quite similar to (P). We augment (P) with the constraints:

$$y(S) \leq r_2(S) \forall S \subseteq F_2, \quad lb \leq y(F_1) \leq ub^1, \quad lb \leq y(F_2), \quad lb \leq y(F).$$

Let $(x, y)$ denote an optimal solution to this LP, and $OPT$ denote its cost. The rounding procedure dovetails the one in Section 3. The first step is again Step I in Section 3.2. Let $D$ be the new client-set with demands $(d'_j)_{j \in D}$, $OPT'$ be the new cost of $(x, y)$, and for each $j \in D$, we define $F_j, F'_j, \gamma_j$, and $G_j$ as before. Note that $F_j \subseteq F_1$ for all $j \in D$.

A slight technicality arises in mimicking Step A1 in Section 3.4: setting $y'_j = x_{ij}$ for some facility $i \in G_j$ need not satisfy the lower-bound constraints. To deal with this, for every $j \in D$ and $i \in G_j$ with $0 < x_{ij} < y_i$, we replace facility $i$ with two co-located “clones” $i_1$ and $i_2$. We set $f_{i_1} = f_{i_2} = f_i, y_{i_1} = x_{ij}, y_{i_2} = y_i - y_{i_1}, x_{i_2j} = 0$, and for every client $k \in D, k \neq j$, we arbitrarily split $x_{ik}$ into $x_{i_1k} \leq y_{i_1}$ and $x_{i_2k} \leq y_{i_2}$ so that $x_{i_1k} + x_{i_2k} = x_{ik}$.

We define a new set $G'_j$ consisting of the new facilities $i$ for which $c_{i_1} = \min_{k \in D} c_{ik}, c_{i_2} \leq \gamma_j$ and $x_{ij} = y_i > 0$ (that is, $G'_j$ consists of the new $i_1$-clones and the old facilities $i \in G_j$ with $x_{ij} = y_i > 0$). We continue to let $F'_j$ denote the facilities $i$ with $c_{i_1} = \min_{k \in D} c_{ik}$ and $c_{i_2} \leq 2\gamma_j$. Let $F'_j$ denote the new $F_1$-set after these changes, and $F' = F'_1 \cup F_2$; the bounds $lb, ub^1, lb, ub$ are unchanged. Set $h(i) = \{i_1, i_2\}$ if $i$ is cloned into $i_1, i_2$, and $h(i) = \{i\}$ otherwise. We update the rank function $r$ to $r'$ (over $2F'$) in the obvious way: $r'(S) = r(\{i \in F : h(i) \cap S = \emptyset\})$. Note that $r'$ defines a matroid on $F'$. Clearly, a solution to the modified translates to a solution to the original instance and vice versa.

We continue with steps A1, A2 in Section 3.4, replacing $G_j$ with $G'_j$, and using suitable polytopes in place of $P$ and $R$ to obtain the half-integral and integral solutions. To obtain a half-integral solution, we define

$$P' := \left\{ v \in \mathbb{R}_{+}^{F'} : v(S) \leq r'(S) \forall S \subseteq F', \quad v(S) \leq r_2(S) \forall S \subseteq F_2, \quad lb \leq v(F') \right\} \quad \text{(6)}$$

Clearly (the new vector) $y$ lies in $P'$. The key observation is that an extreme point of $P'$ is again defined by a linearly independent system of tight constraints coming from two laminar systems: one consisting of some tight $v(S) \leq r'(S)$ and $lb \leq v(F') \leq ub$ constraints; the other consisting of some tight $v(S) \leq r_2(S)$ and $lb \leq v(F'_1) \leq ub^1, lb \leq v(F_2) \leq ub^2$ constraints, and some tight $v(F'_j) \leq \frac{1}{2}$ and $v(G'_j) \geq 1$ constraints. Thus, $P'$ has half-integral extreme points, and so we can find a half-integral $\hat{y}$ such that $T(\hat{y}) \leq T(y)$ (where $T(.)$ is as defined in Section 3.4), and a corresponding solution $(\hat{x}, \hat{y})$ as in step A1.

We round $(\hat{x}, \hat{y})$ to an integral solution as in step A2. Recall that $S_j = \{i : \hat{x}_{ij} > 0\}$. We define $C'_j$ and cluster clients in $D$ as in step A2 (again using $G'_j$, instead of $G_j$) to obtain the set $D'$ of cluster centers. A useful observation is that if $|S_j| = 1$ then we may assume that $j \in D'$. This is because for any $k \in D$ with $S_k \cap S_j \neq \emptyset$, we have $\sigma(k) = j$ and therefore $C'_k \geq (c_{jk} + c_{i(j)j})/2 \geq c_{i(j)j} = C'_j$. Thus, if $j \in D'$, then $\hat{x}_{ij} = \hat{y}_i$ for all $i \in S_j$; this is clearly true if $|S_j| = 1$; otherwise, we have that $|S_{\sigma(j)}| = 2$ (since...
\[ \sigma(j) \notin D' \] and so \( \hat{y}_{\sigma(j)} = \frac{1}{2} \). The polytope used to round \( \hat{y} \) is

\[
\mathcal{R}' := \left\{ z \in \mathbb{R}_{+}^{F'} : z(S) \leq r'(S) \quad \forall S \subseteq F', \quad z(S) \leq r_2(S) \quad \forall S \subseteq F_2, \right. \\
\left. lb_1 \leq z(F_1') \leq ub_1, \quad lb_2 \leq z(F_2), \quad lb \leq z(F'), \quad z(S_j) = 1 \quad \forall j \in D' \right\}
\]

which has integral extreme points. So we obtain an integral vector \( \tilde{y} \) such that \( H(\tilde{y}) \leq H(\hat{y}) \) (were \( H(\cdot) \) is as defined in in Section 3.4), and hence an integer solution \((x, \tilde{y})\).

Mimicking the analysis in Section 3.4, we obtain that \( T(\tilde{y}) \leq T(\hat{y}) \leq 4 \cdot OPT' \), and the cost of \((x, \tilde{y})\) is at most \( H(\tilde{y}) \leq H(\hat{y}) \leq T(\hat{y}) \). Thus, we obtain the following theorem.

**Theorem 4.1.** The integer solution \((\tilde{x}, \tilde{y})\) yields an integer solution to 2MMed of cost at most \( 8 \cdot OPT \).

**Laminarity-constrained matroid median (LCMMed).** In LCMMed, in addition to the common setup, we have a laminar family \( L \) on \( F_2 \) and bounds \( 0 \leq \ell_S \leq u_S \) for every set \( S \in L \); a set \( F \) of facilities is feasible if it satisfies (i) and (ii) above, and (iii) \( \ell_S \leq |F \cap S| \leq u_S \) for all \( S \in L \).

The approach used for 2MMed also works for LCMMed. The only (obvious) changes are that the LP-relaxation, as well as the definition of the polytopes \( \mathcal{R}' \) and \( \mathcal{R} \) (in (6) and (7)) now also include the laminarity constraints in place of the rank constraints for the second matroid. All other steps and arguments proceed *identically*, and so we obtain an 8-approximation algorithm for laminarity-constrained matroid median.

### 4.2. Matroid median with penalties

This is the generalization of matroid median where are allowed to leave some clients unassigned at the expense of incurring a penalty \( d_j \pi_j \) for each unassigned client \( j \). This changes the LP-relaxation (P) as follows. We use a variable \( z_j \) for each client \( j \in D \) to denote if we incur the penalty for client \( j \), and modify the assignment constraint for client \( j \) to \( \sum_i c_{ij} x_{ij} + z_j \geq 1 \); also the objective is now to minimize \( \sum_i f_i y_i + \sum_j d_j (\sum_i c_{ij} x_{ij} + \pi_j z_j) \). Let \((x, y, z)\) denote an optimal solution to this LP and \( OPT \) be its value.

Krishnaswamy et al. [Krishnaswamy et al. 2011] showed that \((x, y, z)\) can be rounded to an integer solution losing a factor of 360. We show that our rounding approach for matroid median can be adapted to yield a substantially improved 24-approximation algorithm. The rounding procedure is similar to the one described in Section 3 for matroid median, except that we now need to deal with the complication that a client need be assigned fractionally to an extent of 1.

Let \( X_j = \sum_i x_{ij} \), \( C_j = \sum_i c_{ij} x_{ij} / X_j \), and \( \text{LP}_j = \sum_i c_{ij} x_{ij} + \pi_j z_j = C_j X_j + \pi_j z_j \). We may assume that \( X_j + z_j = 1 \) for every client \( j \) and that if \( x_{ij} > 0 \) then \( c_{ij} \leq \pi_j \), so we have \( C_j \leq \text{LP}_j \leq \pi_j \).

**Step 0.** First, we set \( z_j = 1 \) and incur the penalty for each client \( j \) for which \( \pi_j \leq 2 \text{LP}_j \). In the sequel, we work with the remaining set \( D' = \{ j \in D : 2 \text{LP}_j < \pi_j \} \) of clients. Note that \( X_j \geq \frac{1}{2} \) for every \( j \in D' \). Let \( OPT'' = \sum_i f_i y_i + \sum_{j \in D'} d_j (\sum_i c_{ij} x_{ij} + \pi_j z_j) \).

**Step I: Consolidating demands.** We consolidate demands around centers in a manner similar to Step I of the rounding procedure in Section 3. The difference is that if \( k \) is consolidated with client \( j \), then we cannot simply add \( d_k \) to \( j \)'s demand and replicate \( j \)'s assignment for \( k \) (since \( \pi_k \) could be much larger than \( \pi_j \) so that \( C_j X_j + \pi_k (1 - X_j) \) need not be bounded in terms of \( \text{LP}_k \)). Instead, we treat \( k \) as being co-located with \( j \) and recompute \( k \)'s assignment.
Let $L$ be a list of clients in $D'$ arranged in increasing order of $LP_j$. We compute a new assignment $(x',z')$ for the clients as follows. Set $x'_{ij} = z'_{ij} = 0$ for all $i,j$. Remove the first client $j \in L$ and add it to $D$. Set $x'_{ij} = x_{ij}$ for all facilities $i$ and $z'_{ij} = z_{ij}$; also set $\text{nbr}(j) = j$. For every client $k$ in $L$ with $c_{jk} \leq 4Lp_k$, we remove $k$ from $L$, and set $\text{nbr}(k) = j$. We consider $k$ to be co-located with $j$ and re-optimize $k$'s assignment. So we set $x'_{ik} = y_i$, starting from the facility nearest to $j$ and continuing until $k$ is completely assigned or until the last facility $i$ such that $c_{ij} \leq \pi_k$, in which case we set $z'_{ik} = 1 - \sum_i x'_{ik}$. Note that $\sum_i c_{ij} x'_{ik} + \pi_k z'_{ik} \leq \sum_i c_{ij} x_{ik} + \pi_k z_k \leq 4Lp_k + Lp_k$.

We call each client in $D$ a cluster center. Let $\{c'_{ij}\}$ denote the assignment costs of the clients with respect to their new locations. Let $OPT' = \sum_i f_i y_i + \sum_{j \in D'} d_j \left(\sum_i c'_{ij} x_{ij} + \pi_j z'_{ij}\right)$ denote the cost of the modified solution for the modified instance. The following lemma is immediate.

**Lemma 4.2.** The following hold: (i) if $j,k \in D'$ are not co-located, then $c_{jk} \geq 4 \max(\{LP_j, Lp_k\})$, (ii) $OPT' \leq 5 \cdot OPT''$, and (iii) any solution to the modified instance can be converted to a solution to the original instance involving client-set $D'$ incurring an additional cost of at most $4 \cdot OPT''$.

**Step II:** Obtaining a half-integral solution. As in Step II of Section 3, we define a suitable vector $y'$ that lies in a polytope with half-integral extreme points and construct a linear function $T(\cdot)$ with $T(y') = O(OPT')$ bounding the cost of a fractional solution. We can then obtain a “better” half-integral vector $\hat{y}$, which yields a half-integral solution. In Step III, we round $\hat{y}$ to an integral solution whose cost we argue is at most $T(\hat{y}) \leq T(y')$.

Consider a client $j \in D$. Let $F_j = \{i : c_{ij} = \min_{k \in D} c_{ik}\}$, $F'_j = \{i \in F_j : c_{ij} \leq 2Lp_j\}$, $\gamma_j = \min_{i \in F'_j} c_{ij}$, and $G_j = \{i \in F_j : c_{ij} \leq \gamma_j\}$. Note that $\sum_{i \in F'_j} x'_{ij} = \sum_{i : c_{ij} \leq 2Lp} x'_{ij} > \frac{1}{2}$ since $Lp_j \geq \sum_{i : c_{ij} > 2Lp_j} c_{ij} x'_{ij} + \gamma_j z'_{ij}$ and $\pi_j > 2Lp_j$ implies that $\sum_{i : c_{ij} > 2Lp_j} x'_{ij} + z'_{ij} < \frac{1}{2}$.

Consider the facilities in $G_j$ in increasing order of their distance from $j$. For every facility $i \in G_j$, we set $y'_i = \min\{y_i, 1 - \sum_{i' \in G_j, i' \text{ comes before } i} y'_{i'}\}$. We set $y'_i = 0$ for all other $i \in F_j$. Note that $y'(F'_j) = \min\{1, y(F'_j)\} \geq \frac{1}{2}$. Clearly, $y'(F_j) = y'(G_j) \leq 1$ and if $y(G_j) \leq 1$, then $y'_i = y_i$ for all $i \in G_j$.

Given $v \in \mathbb{R}^D_+$, for a client $k \in D'$ with $\text{nbr}(k) = j$, we define $B_k(v) = d_k \left(\sum_{i \in G_j, c_{ik} \leq \pi_k} 2c_{ik} v_i + \min(2\pi_k, 4\gamma_j) \left(1 - \sum_{i \in G_j, c_{ik} \leq \pi_k} v_i\right)\right)$. Now set $T(v) = \sum_i f_i y_i + \sum_{j \in D'} B_j(v)$. Clearly $y' \leq y$, so $y'$ lies in the polytope $P$ (see (4)), which has half-integral extreme points. So we can obtain a half-integral point $\hat{y} \in P'$ such that $T(\hat{y}) \leq T(y')$.

We now obtain a half-integral assignment for the clients in $D'$ as follows. Consider a client $k$ and let $j = \text{nbr}(k)$. (Note that we could have $k = j$.) Set $\sigma(j)$ to be $j$ if $\hat{y}(G_j) = 1$, and $\arg \min_{i \in D : i \neq j} c_{ij}$ otherwise (as in Section 3.4). Call the facility $i$ in $F'_j$ nearest to $j$ the primary facility of $k$, and set $\hat{x}_{ik} = \hat{y}_i$. If $\hat{y}_i < 1$, then define $i'$ to be the facility nearest to $j$ other than $i$ with $\hat{y}_{i'} > 0$ if $\hat{y}(G_j) = 1$, and the primary facility of $\sigma(j)$ otherwise. If $\hat{y}(\{i'' : i'' \in G_j : c_{i''j} \leq \pi_k\}) = \frac{1}{2}$ and $\pi_k \leq 2\gamma_j$, we set $\hat{z}_k = \frac{1}{2} = 1 - \hat{x}_{ik}$.

Otherwise, we set $\hat{x}_{ik} = \frac{1}{2} = 1 - \hat{x}_{ik}$ and call $i'$ the secondary facility of $k$.

**Step III:** Rounding $(\hat{x}, \hat{y})$ to an integer solution. This step is quite straightforward. We incur the penalty for all clients $j \in D'$ with $\hat{z}_j = \frac{1}{2}$. Note that all the remaining clients $k$ with $\text{nbr}(k) = j$ are (co-located and) assigned identically and completely in $(\hat{x}, \hat{y}, \hat{z})$. Viewing this as an instance with demand consolidated at the cluster centers, we use the rounding procedure in step A2 of Section 3.4 to convert the half-integral solution of these remaining clients into an integral one. Let $(\tilde{x}, \tilde{y}, \tilde{z})$ denote the resulting integer solution.
LEMMA 4.3. We have $T(\hat{y}) \leq T(y') \leq 4 \cdot OPT'$.

PROOF. It suffices to show that for every client $k$, we have $B_k(y') \leq 4d_k(\sum_i c_{ik}'x_{ik}' + \pi_k z_k')$. Let $j = \text{nbr}(k)$. Consider the facilities in $G_j$ in increasing order of their distance from $j$. If $\pi_k < \gamma_j$, then (we may assume that) $k$ uses the facilities in $G_j$ with $c_{ik}' = c_{ij}$ fully (i.e., $x_{ik}' = y_i$) until either it is completely assigned (and the last facility used by $k$ may be partially used) or we exhaust the facilities in $G_j$ with $c_{ij} \leq \pi_k$. In both cases, we have $x_{ik}' = y_i$ for all $i \in G_j$ with $c_{ik}' \leq \pi_k$ and $z_k' = 1 - \sum_{i \in G_j} c_{ik}' y_i$, and so $\sum_i c_{ik}'x_{ik}' + \pi_k z_k' = \sum_{i \in G_j} c_{ik}' y_i + \pi_k (1 - \sum_{i \in G_j} c_{ij}y_i)$. If $\pi_k \geq \gamma_j$, then $\sum_i c_{ik}'x_{ik}' + \pi_k z_k' \geq \sum_{i \in G_j} c_{ik}'y_i + \gamma_j (1 - \sum_{i \in G_j} x_{ik}')$; also, $x_{ik}' = y_i$ for all $i \in G_j$ since $\pi_k \geq c_{ik}'$. So in every case, we have $B_k(y') \leq 4d_k(\sum_i c_{ik}'x_{ik}' + \pi_k z_k')$. \hfill $\square$

LEMMA 4.4. The cost of $(\hat{x}, \hat{y}, \hat{z})$ for the modified instance is at most $T(\hat{y})$.

PROOF. Consider a client $k$ and let $j = \text{nbr}(k)$. If $\hat{z}_k = 1$ then $B_k(\hat{y}) \geq \pi_k$, since $\hat{z}_k = \frac{1}{2}$ implies that $\hat{y}(N_k) = \frac{1}{2}$, where $N_k = \{i \in G_j : c_{ij} \leq \pi_k\}$, and $\pi_k < 2\gamma_j$. If $\hat{z}_k = 0$ then we claim that $B_k(\hat{y}) = d_k(2\sum_{i \in G_j} c_{ij} y_i + 4\gamma_j (1 - \hat{y}(G_j)))$. If $\hat{y}(N_k) = \frac{1}{2}$, then this follows since we must have $\pi_k > 2\gamma_j$ for $\hat{z}_k$ to be 0; otherwise, $\hat{y}(N_k) = 1 = \hat{y}(G_j)$ and again the equality holds.

The proof of Lemma 3.6 now shows that $\sum_i f_i\hat{y}_i + \sum_{k: \hat{z}_k = 0} c_{ik}\hat{x}_{ik} \leq H(\hat{y}) \leq \sum_i f_i\hat{y}_i + \sum_{k: \hat{z}_k = 0} B_k(\hat{y})$, where $H(\cdot)$ is the function defined in step A2 of Section 3.4 for the instance where each cluster center $j$ has demand $d'_j := \sum_{k: \text{nbr}(k) = j} d_k$. Hence, the total cost of $(\hat{x}, \hat{y}, \hat{z})$ for the modified instance is at most $T(\hat{y})$. \hfill $\square$

Combined with parts (ii) and (iii) of Lemma 4.2, we obtain a solution to the original instance involving client-set $D'$ of cost at most $24 \cdot OPT''$. Adding in the penalties of the clients in $D \setminus D'$ (recall that $\pi_j \leq 2LP_j$ for each $j \in D \setminus D'$), we obtain that the total cost is at most $24 \cdot OPT$.

THEOREM 4.5. One can round $(x, y, z)$ to an integer solution of cost at most $24 \cdot OPT$.

5. APPLICATIONS

We now show that the various facility location problems listed below can be cast as special cases of matroid median or the extensions considered in Section 4.1. Thus, our 8-approximation algorithms for matroid median and these extensions immediately yield improved approximation guarantees for all these problems.
The data placement problem. We have a set of caches \( F \), a set of data objects \( O \), and a set of clients \( D \). Each cache \( i \in F \) has a capacity \( u_i \). Each client \( j \in D \) has demand \( d_j \), for a specific data object \( o(j) \in O \) and has to be assigned to a cache that stores \( o(j) \). Storing an object \( o \) in cache \( i \) incurs a storage cost of \( f_i \), and assigning client \( j \) to cache \( i \) incurs an access cost of \( d_j c_{ij} \), where the \( c_{ij} \)s form a metric. We want to determine a set of objects \( O(i) \subseteq O \) to place in each cache \( i \in F \) satisfying \( |O(i)| \leq u_i \), and assign each client \( j \) to a cache \( i(j) \) that stores object \( o(j) \), (i.e., \( o(j) \in O(i(j)) \)) so as to minimize \( \sum_{i \in F} \sum_{o \in O(i)} f_i o + \sum_{j \in D} d_j c_{i(j)j} \). 

Reduction to matroid median. The facility-set in the matroid-median instance is \( F \times O \). Facility \((i, o)\) denotes that we store object \( o \) in cache \( i \), and has cost \( f_i \). The client set is \( D \). We set the distance \( c_{(i,o)j} \) to be \( c_{ij} \) if \( o(j) = o \) and \( \infty \) otherwise, thus enforcing that each facility \( j \) is only assigned to a facility containing object \( o(j) \). The new distances form a metric if the \( c_{ij} \)s form a metric. The cache-capacity constraints are incorporated via the matroid where a set \( S \subseteq F \times O \) is independent if \( |\{(i', o) \in S : i' = i\}| \leq u_i \) for every \( i \in F \).

Mobile facility location. In the version with general movement costs, the input is a metric space \( (V, \{c_{ij}\}) \). We have a set \( D \subseteq V \) of clients, with each client \( j \) having demand \( d_j \), and a set \( F \subseteq V \) of initial facility locations. A solution moves each facility \( i \in F \) to a final location \( s_i \in V \) incurring a movement cost of \( w_{is} \geq 0 \), and assigns each client \( j \) to the final location \( s \) of some facility incurring an assignment cost of \( d_j c_{sj} \). The goal is to minimize the sum of all the movement and assignment costs.

Reduction to matroid median. We define the facility-set in the matroid-median instance to be \( F \times V \). Facility \((i, s_i)\) denotes that \( i \in F \) is moved to location \( s \in V \), and has cost \( w_{is} \) (note that \( s \) could be \( i \)). The client-set is unchanged, and we set \( c_{(i,s)j} \) to be \( c_s \) for every facility \((i, s) \in F \times V \) and client \( j \in D \). These new distances form a metric: we have \( c_{(i,s)j} \leq c_{(i,s)k} + c_{(i',s')k} + c_{(i',s')j} \) since \( c_{sj} \leq c_{sk} + c_{s'k} + c_{s'j} \). The constraint that a facility in \( F \) can only be moved to one final location can be encoded by defining a matroid where a set \( S \subseteq F \times V \) is said to be independent if \( |\{(i', s) \in S : i' = i\}| \leq 1 \) for all \( i \in F \).

---

We are assuming here that \( w_{is} = 0 \) for every \( i \in F \), so that not opening any facility in \((i) \times V \) correctly encodes that \( i \) is not moved and no clients are assigned to it in the mobile-facility-location instance. This condition is without loss of generality. If \( w_{is} \neq 0 \) then if \( r \in V \) is such that \( w_{ir} = \min_{s \in V} w_{is} \), we can “move” \( i \) to \( r \) (i.e., set \( F \leftarrow F \setminus \{i\} \cup \{r\} \) making a copy of \( r \) if \( r \) was previously in \( F \)), and define the movement cost...
Improved Approximation Algorithms for Matroid and Knapsack Median Problems

$k$-median forest. In the non-uniform version, we have two metric spaces $(V, \{c_{uv}\})$ and $(V, \{d_{uv}\})$. The goal is to find $S \subseteq V$ with $|S| \leq k$ and assign every node $j \in V$ to $i(j) \in S$ so as to minimize $\sum_j c_{ij(j)} + d(MST(V/S))$, where MST($V/S$) is a minimum spanning forest where each component contains a node of $S$.

Reduction to $2MMed$ (or LCMMed). We actually reduce a generalization, where there is an “opening cost” $f_i \geq 0$ incurred for including $i$ in $S$; the resulting instance is also an LCMMed instance. We add a root $r$ to $V$. The facility-set $F$ is the edge-set of the complete graph on $V \cup \{r\}$. The client-set is $D := V$. Selecting a facility $(r, i)$ denotes that $i \in S$, and selecting a facility $(u, v)$, where $u, v \neq r$, denotes that $(u, v)$ is part of MST($V/S$). We let $F_1$ be the edges incident to $r$, and $F_2$ be the remaining edges. The cost of a facility $(r, i) \in F_1$ is $f_i$; the cost of a facility $(u, v) \in F_2$ is $d_{uv}$. The client-facility distances are given by $c_{(r,i)} = c_{ij}$ and $c_{(u,v)} = \infty$ for every $e \in F_2$. Note that these $\{c_{ij}\}$ distances form a metric. We let $M$ be the graphic matroid of the complete graph on $V \cup \{r\}$. We impose a lower bound of $|V|$ on the number of facilities opened from $F$, and an upper bound of $k$ on the number of facilities opened from $F_1$. The matroid $M_2$ on $F_2$ is the vacuous one where every set is independent.

A feasible solution to the $2MMed$ instance corresponds to a spanning tree on $V \cup \{r\}$ where $r$ has degree at most $k$. This yields a solution to $k$-median forest of no-greater cost, where the set $S$ is the set of nodes adjacent to $r$ in this edge-set. Conversely, it is easy to see that a solution $S$ to the $k$-median forest instance yields a $2MMed$ solution of no-greater cost.

Metric uniform MLUFL. We have a set $F$ of facilities with opening costs $\{f_i\}_{i \in F}$, and a set $D$ of clients with assignment costs $\{c_{ij}\}_{j \in D, i \in F}$, where the $c_{ij}$s form a metric. Also, we have a monotone latency-cost function $\lambda: \mathbb{Z}_+ \mapsto \mathbb{R}_+$. The goal is to choose a set $F \subseteq F$ of facilities to open, assign each open facility $i \in F$ a distinct time-index $t_i \in \{1, \ldots, |F|\}$, and assign each client $j$ to an open facility $i(j) \in F$ so as to minimize $\sum_{i \in F} f_i + \sum_{j \in D} (c_{ij(j)} + \lambda(t_{i(j)}))$.

Reduction to matroid median. We define the facility-set to be $F \times \{1, \ldots, |F|\}$ and the matroid on this set to encode that a set $S$ is independent if $|\{(i, t') \in S : t' = t\}| \leq 1$ for all $t \in \{1, \ldots, |F|\}$. We set $f_{(i,t)} = f_i$ and $c_{(i,t),j} = c_{ij} + \lambda(t)$; note that these distances form a metric. It is easy to see that we can convert any matroid-median solution to one where we open at most one $(i, t)$ facility for any given $i$ without increasing the cost, and hence, the matroid-median instance correctly encodes metric uniform MLUFL.

6. KNAPSACK MEDIAN

We now consider the knapsack median problem [Krishnaswamy et al. 2011; Kumar 2012], wherein instead of a matroid on the facility-set, we have a knapsack constraint on the facility-set. Kumar [Kumar 2012] obtained the first constant-factor approximation algorithm for this problem, and [Charikar and Li 2012] obtained an improved 34-approximation algorithm. We consider a somewhat more general version of knapsack median, wherein each facility $i$ has a facility-opening cost $f_i$ and a weight $w_i$, and we have a knapsack constraint $\sum_{i \in F} w_i \leq B$ constraining the total weight of open facilities. We leverage the ideas from our simpler improved rounding procedure for matroid median to obtain an improved 32-approximation algorithm for this (generalized) knapsack-median problem. We show that one can obtain a nearly half-integral solution whose cost is within a constant-factor of the optimum. It then turns out to be easy

of $r$ to be $w'_{ij} = w_{ij} - w_{ir}$ for all $s \in V$. It is easy to see that a $\rho$-approximate solution to the new instance translates to a $\rho$-approximate solution to the original instance.
to round this to an integral solution. The resulting algorithm and analysis is simpler than that in [Kumar 2012; Charikar and Li 2012]. We defer the details to Appendix C.

APPENDIX

A. ALTERNATE PROOF OF HALF-INTEGRALITY OF THE POLYTOPE $\mathcal{P}$ DEFINED BY (4)

We give an alternate proof of half-integrality of $\mathcal{P}$ based on the integrality of the intersection of two submodular polyhedra. Observe that by setting $z_i = 2v_i$ for $i \in \mathcal{F}$, and introducing slack variables $s_j$ for every $j \in D$, the system defining $\mathcal{P}$ is equivalent to

$$0 \leq z(S) \leq 2r(S) \quad \forall S \subseteq \mathcal{F}, \quad z(G_j) + s_j = 2, \quad z(G_j \setminus F_j') + s_j \leq 1, \quad s_j \geq 0 \quad \forall j \in D. \quad (8)$$

This in turn is equivalent to

$$z(S) + s(A) \leq h_1(S \cup A) \quad \forall S \subseteq \mathcal{F}, \quad A \subseteq D \quad (9)$$
$$z(S) + s(A) \leq h_2(S \cup A) \quad \forall S \subseteq \mathcal{F}, \quad A \subseteq D \quad (10)$$
$$z_s, s \geq 0 \quad \forall j \in D \quad (11)$$
$$z(G_j) + s_j = 2 \quad \forall j \in D \quad (12)$$

where $h_1$ and $h_2$ are submodular functions defined over $\mathcal{F} \cup D$ given by $h_1(S \cup A) := 2r(S) + |A|$ and $h_2(S \cup A) := 2(|\{j : F_j' \cap S \neq \emptyset\}| + |\{j : F_j' \cap S = \emptyset \text{ and } (j \in A \text{ or } G_j \cap S \neq \emptyset)\}|)$. (To see the equivalence, it is clear that constraints (9)–(12) include (8). Conversely, (9) follows by adding the constraints $z(S) \leq 2r(S)$ and $s_j \leq 1$ for all $j \in A$; (10) is implied by the sum of constraints $z(G_j) + s_j = 2$ for all $j$ such that $F_j' \cap S \neq \emptyset$, and $z(G_j) + s_j \leq 1$ for all other $j$ such that $j \in A$ or $G_j \cap S \neq \emptyset$.) Let $\mathcal{Q}$ be the polytope defined by (9)–(11). Since $h_1$ and $h_2$ are integer submodular functions, $\mathcal{Q}$ is the intersection of the submodular polyhedra for $h_1$ and $h_2$, which is known to be integral. Also, constraints (9)–(12) define a face of $\mathcal{Q}$. Now it is easy to see that an extreme point $v$ of $\mathcal{P}$, maps to an extreme point $(2v, s)$, for a suitably defined $s$, of this face (which must be integral). Hence, $\mathcal{P}$ has half-integral extreme points.

B. INAPPROXIMABILITY OF MATROID-INTERSECTION MEDIAN

We show that the problem of deciding if an instance of matroid-intersection median has a zero-cost solution is $\text{NP}$-complete. This implies that no multiplicative approximation factor is achievable in polytime for this problem unless $\text{P} = \text{NP}$. The reduction is from the $\text{NP}$-complete directed Hamiltonian path problem, wherein we are given a directed graph $D = (N, A)$, and two nodes $s, t$, and we need to determine if there is a simple (directed) $s \sim t$ path spanning all the nodes. The facility-set in the matroid-intersection median problem is the arc-set $A$, and every node except $t$ is a client. One of the matroids $M$ is the graphic matroid on the undirected version of $D$, that is, an arc-set is independent if it is acyclic when we ignore the edge directions. The second matroid $M_2$ is a partition matroid that enforces that every node other than $s$ has at most one incoming arc. All facility-costs are 0. We set $c_{ij} = 0$ if $i$ is an outgoing arc of $j$, and $\infty$ otherwise. Notice that this forms a metric since the sets $\{i : c_{ij} = 0\}$ are disjoint for different clients.

It is easy to see that an $s \sim t$ Hamiltonian path translates to a zero-cost solution to the matroid-intersection median problem. Conversely, if we have a zero-cost solution to matroid-intersection median, then it must open $|N| - 1$ facilities, one for each client. Hence, the resulting edges must form a (spanning) arborescence rooted at $s$, and moreover, every node other than $t$ must have an outgoing arc. Thus, the resulting edges yield an $s \sim t$ Hamiltonian path.
C. KNAPSACK MEDIAN: ALGORITHM DETAILS AND ANALYSIS

Recall that we consider a more general version of knapsack median than that considered in [Krishnaswamy et al. 2011; Kumar 2012; Charikar and Li 2012]. Each facility \( i \) has a facility-opening cost \( f_i \) and a weight \( w_i \), and we have a knapsack constraint \( \sum_{i \in F} w_i \leq B \) constraining the total weight of open facilities. The goal is to minimize the sum of the facility-opening and client-connection costs while satisfying the knapsack constraint on the set of open facilities. We may assume that we know the maximum facility-opening cost \( f^{opt} \) of a facility opened by an optimal solution, so in the sequel we assume that \( f_i \leq f^{opt} \), \( w_i \leq B \) for all facilities \( i \in F \).

Krishnaswamy et al. [Krishnaswamy et al. 2011] showed that the natural LP-relaxation has a bad integrality gap; this holds even after augmenting the natural LP with knapsack-cover inequalities. To circumvent this difficulty, Kumar [Kumar 2012] proposed the following lower bound, which we also use. Suppose that we have an estimate \( C^{opt} \) within a \((1 + \epsilon)\)-factor of the connection cost of an optimal solution (which we can obtain by enumerating all powers of \((1 + \epsilon)\)). Then, defining \( U_j := \arg \max \{ z : \sum_k d_k \max \{0, z - c_{jk}\} \leq C^{opt}\} \), Kumar argued that the constraint \( x_{ij} = 0 \) if \( c_{ij} > U_j \) is valid for the knapsack median instance. We augment the natural LP-relaxation with these constraints to obtain the following LP (K-P).

\[
\begin{align*}
\min & \quad \sum_i f_i y_i + \sum_j \sum_i d_{ij} c_{ij} x_{ij} \\
\text{s.t.} & \quad \sum_j x_{ij} \geq 1 \quad \forall j \\
& \quad x_{ij} \leq y_i \quad \forall i, j \\
& \quad \sum_i w_i y_i \leq B \\
& \quad x_{ij}, y_i \geq 0 \quad \forall i, j; \quad x_{ij} = 0 \quad \text{if } c_{ij} > U_j.
\end{align*}
\]

Let \((x, y)\) be an optimal solution to (K-P) and \(OPT\) be its value. Let \( \tilde{C}_j = \sum_i c_{ij} x_{ij} \). Note that if our estimate \( C^{opt} \) is correct, then \( OPT \) is at most the optimal value \( opt \) for the knapsack median instance. We show that \((x, y)\) can be rounded to an integer solution of cost \( f^{opt} + 4C^{opt} + 28 \cdot OPT \). Thus, if consider all possible choices for \( C^{opt} \) in powers of \((1 + \epsilon)\) and pick the solution returned with least cost, we obtain a solution of cost at most \((32 + \epsilon)\) times the optimum. The rounding procedure is as follows.

K1. Consolidating demands. We start by consolidating demands as in Step I in Section 3.2. We now work with the client set \( D \) and the demands \( \{d_{ij}'\}_{i \in D} \). For \( j \in D \), we use \( M_j \subseteq D \) to denote the set of clients (including \( j \)) whose demands were moved to \( j \). Note that the \( M_j \)'s partition \( D \). Let \( OPT' \) denote the cost of \((x, y)\) for this modified instance. As before, for each \( j \in D \) we define \( F_j = \{ i : c_{ij} = \min_{k \in D} c_{ik}\}, F'_j = \{ i \in F_j : c_{ij} \leq 2\tilde{C}_j \}, \gamma_j = \min_{i \in F_j} c_{ij}, \) and \( G_j = \{ i \in F_j : c_{ij} \leq \gamma_j\} \).

K2. Obtaining a nearly half-integral solution. Set \( y'_i = x_{ij} \leq y_i \) if \( i \in G_j \), and \( y'_i = 0 \) otherwise. Let \( F' = \bigcup_{j \in D} G_j \). In the sequel, we will only consider facilities in \( F' \). Consider the following polytope:

\[
\mathcal{K} := \left\{ v \in \mathbb{R}^F_+ : v(F'_j) \geq \frac{1}{2}, \quad v(G_j) \leq 1 \quad \forall j \in D, \quad \sum_i w_i v_i \leq B \right\}. \tag{13}
\]

Define \( K(v) = \sum_i 2f_i v_i + \sum_j d_{ij}' (2 \sum_{i \in G_j} c_{ij} v_i + 8\gamma_j (1 - v(G_j))) \) for \( v \in \mathbb{R}^F_+ \). Since \( y'_i \in \mathcal{K} \), we can efficiently obtain an extreme point \( \hat{y} \) of \( \mathcal{K} \) such that \( K(\hat{y}) \leq K(y'_i) \), the support of \( \hat{y} \) is a subset of the support of \( y'_i \), and all constraints that are tight
under $y'$ remain tight under $\hat{y}$. Thus, if $i \in G_j$ and $\hat{y}_i > 0$, then $y'_i > 0$ and so $c_{ij} \leq U_j$. Also, if $\hat{y}(G_j) < 1$ then $y'(G_j) < 1$, and so $\gamma_j \leq U_j$. We show in Lemma C.1 that there is at most one client, which we call the special client and denote by $s$, such that $G_s$ contains a facility $i$ with $\hat{y}_i \notin \{0, 1/2, 1\}$.

As in Section 3.4, for each client $j \in D$, define $\sigma(j) = j$ if $\hat{y}(G_j) = 1$, and $\sigma(j) = \arg\min_{k \in D: k \neq j} c_{jk}$ otherwise (breaking ties arbitrarily). Note that $c_{j\sigma(j)} \leq 2\gamma_j$. We now define the primary and secondary facilities of each client $j \in D$, which we denote by $i_1(j)$ and $i_2(j)$ respectively. If $j$ is not the special client $s$, then $i_1(j)$ is the facility $i$ nearest to $j$ with $\hat{y}_i > 0$; otherwise, $i_1(j) = \arg\min_{i \in F_j: \hat{y}_i > 0} w_i$ (breaking ties arbitrarily). If $\hat{y}_i(j) = 1$, then we set $i_2(j) = i_1(j)$. If $\hat{y}(G_j) < 1$, we set $i_2(j) = i_1(\sigma(j))$. If $\hat{y}_i(j) < \hat{y}(G_j) = 1$, we set $i_2(j)$ to: the half-integral facility in $G_j$ other than $i_1(j)$ that is nearest to $j$ if $j \neq s$; and the facility with smallest weight among the facilities $i \in G_j$ with $\hat{y}_i > 0$ (which could be the same as $i_1(j)$ if $j = s$. Define $S_j = \{i_1(j), i_2(j)\}$.

To gain some intuition, observe that the facilities $i_1(j)$ and $i_2(j)$ naturally yield a half-integral solution, where these facilities are open to an extent of $1/2$ and $j$ is assigned to them to an extent of $1/2$; as before, if $i_1(j) = i_2(j)$, then this means that $i_1(j)$ is open to an extent of $1$ and $j$ is assigned completely to $i_1(j)$. The choice of the primary and secondary facilities ensures that this solution is feasible. (We do not however modify $\hat{y}$ as indicated above.)

**K3. Clustering and rounding to an integral solution.** This step is quite straightforward. We define $C'_j$ for $j \in D$, and cluster clients in $D$ exactly as in step A2 in Section 3.4, and we open the facility with smallest weight within each cluster. Finally, we assign each client to the nearest open facility. Let $(\hat{x}, \hat{y})$ denote the resulting solution. Recall that $D'$ is the set of cluster centers, and for $k \in D$, $\text{ctr}(k)$ denotes the client in $D$ due to which $k$ was removed in the clustering process (so $\text{ctr}(j) = j$ for $j \in D'$).

**Analysis.** We call a facility $i$ half-integral (with respect to the vector $\hat{y}$ obtained in step K2) if $\hat{y}_i \in \{0, 1/2, 1\}$ and fractional otherwise.

**Lemma C.1.** The extreme point $\hat{y}$ of $K$ obtained in step K2 is such that there is at most one client, called the special client and denoted by $s$, such that $G_s$ contains fractional facilities. Moreover, if $1/2 < \hat{y}(G_s) < 1$, then there is exactly one facility $i \in F'_s$ such that $\hat{y}_i > 0$.

**Proof.** Since $\hat{y}$ is an extreme point, it is well known that the submatrix $A'$ of the constraint matrix whose columns correspond to the non-zero $\hat{y}_i$'s and rows correspond to the tight constraints under $\hat{y}$ has full column-rank. The rows and columns of $A'$ may be accounted for as follows. Each client $j \in D$ contributes: (i) a non-empty disjoint set of columns corresponding to the positive $\hat{y}_i$'s in $G_j$; and (ii) a possibly-empty disjoint set of at most two rows corresponding to the tight constraints $\hat{y}(F'_j) = 1/2$ and $\hat{y}(G_j) = 1$. This accounts for all columns of $A'$. There is at most one remaining row of $A'$, which corresponds to the tight constraint $\sum_i w_i \hat{y}_i = B$.

---

3We can obtain $\hat{y}$ as follows. Let $A v \leq b, v \geq 0$ denote the constraints of $K$. Recall that $z$ is an extreme point of $K$ iff the submatrix $A'$ of $A$ corresponding to the non-zero variables and the tight constraints has full column rank. So if $y'$ is not an extreme point, then letting $F' = \{i : y'_i > 0\}$, we can find some $d' \in \mathbb{R}^{F'}$ such that $A'd = 0$. So letting $d_i = d'_i$ if $i \in F'$ and 0 otherwise, we can find some $\epsilon > 0$ such that both $y' + \epsilon d$ and $y' - \epsilon d$ are feasible and all constraints that were tight under $y'$ remain tight. So moving in the direction that does not increase the $K(.)$-value until some non-zero $y'_i$ drops down to 0 or some new constraint goes tight, and repeating, we obtain the desired extreme point $\hat{y}$.
Let \( p_j \) and \( q_j \) denote respectively the number of columns and rows contributed by \( j \in D \). First, note that \( p_j \geq q_j \) for all \( j \in D \). This is clearly true if \( q_j \leq 1 \); if \( q_j = 2 \), then \( \hat{y}(F'_j) = \frac{1}{2} \). \( \hat{y}(G_j) = 1 \), so both \( F'_j \) and \( G_j \) must have at least one positive \( \hat{y}_i \). Also, note that if \( p_j = q_j \), then \( G_j \) contains only half-integral facilities. Since \( \sum_j p_j \leq \sum_j q_j + 1 \), there can be at most one client such that \( p_j > q_j \); we let this be our special client \( s \). Note that we must have \( p_s = q_s + 1 \).

If \( \frac{1}{2} < \hat{y}(G_s) < 1 \) then: (i) \( q_s = 0 \), so \( p_s = 1 \); or (ii) \( q_s = 1 \), so \( p_s = 2 \), and since \( \hat{y}(F'_s) = \frac{1}{2} < \hat{y}(G_s) \), both \( F'_s \) and \( G_s \) contain exactly one positive \( \hat{y}_i \). \( \square \)

It is easy to adapt the proof of Lemma 3.2, and obtain that \( K(\hat{y}) \leq K(y') \leq 8 \cdot OPT' \leq 8 \cdot OPT \). Next, we prove our main result: the integer solution \((\hat{x}, \hat{y})\) computed is feasible and its cost for the modified instance is at most \( K(\hat{y}) + f^{opt} + 4C^{opt} + 16 \cdot OPT \). Thus, “moving” the consolidated demands back to their original locations yields a solution of cost at most \((32 + \epsilon) \cdot opt\) for the correct guess of \( f^{opt} \) and \( C^{opt} \). The following claims will be useful.

**Claim C.2.** If \( \hat{y}(G_j) = 1 \) for some \( j \in D \), then \( (we \ may \ assume \ that) \ j \) is a cluster center.

**Proof.** Let \( i' = i_1(j), \ i'' = i_2(j) \). Let \( k \in D \) be such that \( S_k \cap S_j \neq \emptyset \). Then \( \sigma(k) = j \).

So \( 2(C'_k - C'_j) = c_{i_1(k)} + c_{i_2(j)} - c_{i_2(k)} \geq c_{i_1(k)} - c_{i_2(k)} \geq 0 \) since \( i_2(k) \notin G_j \). \( \square \)

**Claim C.3.** For any client \( j \in D \), we have \( \sum d_j U_j \leq C^{opt} + 4 \cdot OPT \).

**Proof.** By definition, \( \sum k d_k \max\{0, U_j - c_{jk}\} \leq C^{opt} \). So \( \sum d_j U_j = \sum_{k \in M_j} d_k U_j \), which equals

\[
\sum_{k \in M_j} d_k (U_j - c_{jk}) + \sum_{k \in M_j} d_k c_{jk} \leq C^{opt} + \sum_{k \in M_j} 4d_k C_{jk} \leq C^{opt} + 4 \cdot OPT.
\]

\( \square \)

**Theorem C.4.** The solution \((\hat{x}, \hat{y})\) computed in step K3 for the modified instance is feasible and has cost at most \( K(\hat{y}) + f^{opt} + 4C^{opt} + 16 \cdot OPT \).

**Proof.** Let \( B_j(v) = d'_j \left( 2 \sum_{i \in G_j} c_{ij} v_i + 8 \gamma_j(1 - v(G_j)) \right) \) for \( v \in \mathbb{R}^D_+ \). So \( K(\hat{y}) = 2 \sum_{i} f_i \hat{y}_i + \sum_j B_j(\hat{y}) \).

Recall that \( S_j = \{ i_1(j), i_2(j) \} \) for every \( j \in D \).

We first prove feasibility and bound the total facility-opening cost. Consider a cluster centered at \( j \). Let \( i' = i_1(j), \ i'' = i_2(j) \). Let \( \hat{i} \) be the facility opened from \( S_j \). If \( \hat{y}(S_j) = 1 \), then \( w_{\hat{i}} \leq \sum_{i \in S_j} w_i \hat{y}_i \). Otherwise, either \( j = s \) or \( \sigma(j) = s \). If \( j = \sigma(j) = s \), then \( \hat{i} \) is the least-weight facility in \( G_j \). Otherwise, if \( j = s \) then \( \hat{i} \) is the least-weight facility in \( F'_j \) and \( \hat{y}(F'_j) + \hat{y}(G_j) \geq 1 \); finally, if \( j = \sigma(j) = s \) then \( \hat{i} \) is the least-weight facility in \( \{ i_1(j) \} \cup F'_{\sigma(j)} \) and \( \hat{y}(i_1(j)) + \hat{y}(F'_{\sigma(j)}) \geq 1 \). Since \( S_j \subseteq G_j \cup G_{\sigma(j)} \), in every case, we have \( w_{\hat{i}} \leq \sum_{i \in G_j \cup G_{\sigma(j)}} w_i \hat{y}_i \).

If all facilities in \( S_j \) are half-integral, then \( \hat{f}_i \leq 2 \sum_{i \in S_j} \hat{f}_i \hat{y}_i \leq 2 \sum_{i \in G_j \cup G_{\sigma(j)}} \hat{f}_i \hat{y}_i \). Otherwise, we have \( \hat{f}_i = s \) or \( \sigma(j) = s \), and we bound \( \hat{f}_i \) by \( f^{opt} \).

Note that if \( k \in D' \) is some other cluster center, then \( G_j \cup G_{\sigma(j)} \) is disjoint from \( G_k \cup G_{\sigma(k)} \). If not, then we must have \( \sigma(j) = k \) or \( \sigma(k) = j \) or \( \sigma(j) = \sigma(k) \), which yields the contradiction that \( S_j \cap S_k \neq \emptyset \). So summing over all clusters, we obtain that the total weight of open facilities is at most \( \sum_{j \in D'} \sum_{i \in G_j \cup G_{\sigma(j)}} w_i \hat{y}_i \leq \sum_i w_i \hat{y}_i \leq B \), and the facility opening cost is at most \( 2 \sum_{i} \hat{f}_i \hat{y}_i + f^{opt} \)
We now bound the total client-assignment cost. Fix a client \( j \in D' \). The assignment cost of \( j \) is at most \( d'_kJ_{ij}(j) \). Note that \( c_{ij}(j) \leq 3U_j \). If \( j \neq s \), then \( B_j(\hat{y}) \geq d'_kJ_{ij}(j) \); this holds if \( \hat{y}(G_j) = 1 \) since \( \hat{y}(G_j) \geq \frac{1}{2} \); otherwise, \( B_j(\hat{y}) \geq d'_kJ_{ij}(j) \). If \( j = s \), then its assignment cost is at most \( 3d'_kU_j \leq 3C' + 12 \cdot OPT \) (Claim C.3).

Now consider \( k \in D \setminus D' \). Let \( j = \text{ctr}(k) \), and \( i' = i_1(j) \), \( i'' = i_2(j) \). We consider two cases.

1. \( i_1(k) \in S_j \). Then \( k = \sigma(j) \) and \( k \)'s assignment cost is at most \( d'_k(c_{ij}(k) + 4\gamma_k) \). To see this, first suppose \( \ell \neq j \), and so \( \ell = \sigma(j) \). Then, \( k \)'s assignment cost is at most \( d'_k(c_{jk} + c_{ij} + c_{j\ell}) \leq d'_k(2c_{jk} + c_{ij}(k)) \leq d'_k(c_{ij}(k) + 4\gamma_k) \), where the first inequality follows since \( C_j \leq C'_j \). If \( \ell = j \), then \( i_2(k) = i_1(j) = i' \) and \( k \)'s assignment cost is at most \( d'_k(c_{jk} + c_{ij}(j) + c_{ij}(j)) \leq d'_k(c_{ij}(k) + 2c_{jk}) \leq d'_k(c_{ij}(k) + 4\gamma_k) \), where the first inequality again follows from \( C_j \leq C'_j \).

Since \( k \notin D' \), we have \( \hat{y}(G_k) < 1 \) (by Claim C.2). So \( y'(G_k) < 1 \) and \( \gamma_k \leq U_k \). If \( k \neq s \), then \( B_k(\hat{y}) \geq d'_k(c_{ij}(k) + 4\gamma_k) \). If \( k = s \) and \( \hat{y}(G_k) = \frac{1}{2} \), then \( B_k(\hat{y}) \geq 4d'_k\gamma_k \) and \( d'_k(c_{ij}(k) + 4\gamma_k) \). Otherwise, by Lemma C.1, we have \( \hat{y}(i_1(k)) > \frac{1}{2} \), and so \( B_k(\hat{y}) \geq d'_k(c_{ij}(k)) \) and \( d'_k\gamma_k \leq 4d'_kU_k \).

Putting everything together, the total cost of \( (\tilde{x}, \hat{y}) \) is at most \( 2 \sum_i f_i \hat{y}_i + \sum_j B_j(\hat{y}) + f^* + 4C' + 16 \cdot OPT = K(\hat{y}) + f^* + 4C' + 16 \cdot OPT \). \( \square \)

**Corollary C.5.** There is a \((32 + \epsilon)\)-approximation algorithm for the knapsack median problem.
