Abstract. The Cellular Potts Model (CPM) successfully simulates drainage and shear in foams. Here we use the CPM to investigate instabilities due to the flow of a single large bubble in a dry, monodisperse two-dimensional flowing foam. As in experiments in a Hele–Shaw cell, above a threshold velocity the large bubble moves faster than the mean flow. Our simulations reproduce analytical and experimental predictions for the velocity threshold and the relative velocity of the large bubble, demonstrating the utility of the CPM in foam rheology studies.

Keywords: foams, rheology
1. Introduction

Foams’ unusual rheology suits them to applications as diverse as efficient fire suppression and oil extraction in the petroleum industry [1, 2]. Foams are non-Newtonian, so understanding their flow helps explain the complex behaviours of other structured fluids, which are difficult to investigate analytically. Though we know that foams behave like solids under small stress and flow like fluids under large stress, we do not understand the relationship between the macroscopic and microscopic properties of foams. We still need experiments and simulations to provide insight into foam-flow behaviour [3, 4]. Here, we show that the Cellular Potts Model (CPM) can successfully model dry, i.e. low-fluid-fraction, foam flow in a quasi-two-dimensional (2D) Hele–Shaw (HS) cell, in which a single bubble layer flows lengthwise between two closely spaced long and narrow parallel plates. HS flow is important in industry, e.g. in injection moulding [16] and display device manufacture [17].

The sizes and shapes of the bubbles in a foam may change due to gas diffusion between neighbouring bubbles, bubble coalescence, shear and drainage of the liquid in the walls between bubbles [5]. This paper considers only shear-induced topological rearrangements or T1 processes, where two bubbles come together to form a side, pushing apart two previously adjacent bubbles [6]. Since the timescale of the approach to a T1 depends on the shear rate, while the usually fast relaxation time depends on the fluid-surface effective drag, at low shear rates bubble motion appears jagged. Under certain circumstances many T1s occur together, each T1 triggering the next, forming an avalanche. Jiang et al [15] have shown that the flow becomes smoother as the strain rate increases. However, even at low strain rates, because the typical jump size is a fraction of the size of a bubble, large-aspect-ratio flows, where bubbles are very small, appear smooth. The collective phenomena of foam flow have inspired many models, including constitutive, vertex, centre, bubble and CPM models [7]–[14]. For example, Okuzano and Kawasaki used a vertex model to study the effect of low shear rates on foams [11] and found avalanche-like rearrangements. Durian’s bubble model [12] gave similar predictions, but Weaire’s centre model [13] suggested that avalanche-like rearrangements are only possible for wet foams. Jiang et al tried to reconcile the different model predictions and experiments using the CPM [15, 14]. They demonstrated hysteresis and avalanche-like rearrangements in a 2D
non-coarsening foam and found that the T1 dynamics depended sensitively on the foam’s topology. Because the CPM derives from an equilibrium model, we must establish its suitability to describe dynamic phenomena. Here we show that it correctly reproduces the rather subtle experimental behaviour of the flow of a large bubble in a background of small bubbles, further validating the use of the CPM to simulate flowing foams.

In a HS cell, a monodisperse foam (i.e., a foam of bubbles of equal size), under a uniform pressure gradient, exhibits simple plug flow. However, a polydisperse (i.e., a foam made of bubbles of different sizes) foam’s flow becomes unstable above a critical velocity. The size distribution of the bubbles then controls the velocity field, with the larger bubbles moving faster than the smaller ones, as experiments by Lordereau [18] have shown. Recently, Cantat and Delannay [19] studied the phenomenon in more detail, both experimentally and numerically. Their experiments used a dry soap froth contained in a HS cell, with newly produced bubbles maintaining a steady pressure gradient along the length of the cell. Their simulations used a vertex model with periodic boundary conditions along the direction of flow. Their analytical predictions for the critical velocity at which a single large bubble begins to move faster than the bulk flow in an otherwise monodisperse foam agree with their numerical and experimental results.

According to Cantat and Delannay [19], below the critical velocity, all the bubbles in the foam move with a velocity \( v_0 u_x \), where \( u_x \) is a unit vector in the direction of flow. The viscous force per unit surface, averaged on the scale of a bubble, is:

\[
F_{\text{visc}} = -\frac{\eta v_0}{d} u_x,
\]

(1)

where \( \eta \) is the effective viscosity and \( d \) is the diameter of the small bubbles. The large bubble induces a pressure deficit, \( \delta f = n\eta v_0 d u_x \), where \( n \) is the number of films that would be present across the large bubble in the \( x \) direction if it were filled with small bubbles. Assuming the friction deficit concentrates at \( r = r_0 \), the force equation becomes:

\[
F_{\text{visc}} = -\nabla \left( \frac{\eta v_0 x}{d} + \delta (r - r_0) \frac{\eta v_0 D^2}{d} u_x \right),
\]

(2)

where \( D \) is the diameter of the large bubble. As the large bubble moves, it distorts the small bubbles and changes their stress distribution. Combining the forces due to surface tension and viscosity, Cantat and Delannay [19] obtained the equations of motion:

\[
-\nabla \left( \frac{\eta v_0 x}{d} + P \right) + \mu \nabla^2 X = -\delta (r - r_0) \frac{\eta v_0 D^2}{d} u_x,
\]

(3)

where \( X \) is the bubble displacement from the equilibrium position,

\[
\nabla \cdot X = 0.
\]

(4)

\( P \) is the pressure field given by

\[
P = -\frac{\eta v_0 x}{d} + \frac{\eta v_0 D^2}{2\pi d} \frac{x - x_0}{(r - r_0)^2},
\]

(5)

for the small bubbles. The last term on the RHS of equation (5) gives the pressure discontinuity for the large bubble at \( r = (D/2)u_x \), which must counterbalance the stress. The force balance gives the critical velocity:

\[
v_c \sim \frac{\gamma}{\eta D}.
\]

(6)
where $\gamma$ is the surface tension. The critical velocity is directly proportional to the surface tension and inversely proportional to the diameter of the large bubble and the viscosity.

In this work we use the CPM to reproduce large-bubble migration. Our results agree with the results in [19]. While CPM simulations are computationally simple, we are not able to predict the viscosity analytically from model parameters, though we can obtain an effective viscosity and other viscoelastic information from our simulations. In this respect, CPM simulations resemble experiments, in which we also cannot predict the effective foam viscosity from the fluid component’s viscosity and surface tension [2]. The capillary number appears to relate the velocity of the foam to the fluid viscosity and surface tension, but experiments have shown it is not sufficient to describe the dynamic regime of a flowing foam [21]. New experiments have investigated the dependence of mobility on various parameters [22–24], but more experiments and analysis are still required.

2. The CPM

Jiang et al [15] provide details on the use of the CPM to study foam rheology. The CPM is lattice-based, with each lattice point having an integer spin. Like spins form bubbles while boundaries between unlike spins correspond to soap films. The CPM Hamiltonian contains a surface-energy term corresponding to film surface tension and a term constraining bubble areas corresponding to the conservation of mass within each bubble. The area constraint allows bubble compression according to the ideal gas law and transmits forces between bubbles, which is essential in a rheological simulation. We prevent coarsening, since in experiments the slow coarsening of bubbles during their brief residence in a HS cell is unmeasurable [20].

The CPM Hamiltonian thus has two terms:

$$H = \sum_{i,j} J (1 - \delta_{\sigma_i \sigma_j}) + \lambda \sum_n (a_n - A_n)^2,$$

where $J$ is the coupling strength between spins $\sigma_i$ and $\sigma_j$ at neighbouring lattice sites $\vec{i}$ and $\vec{j}$ and $\lambda$ is the inverse of the compressibility of the gas. $A_n$ is the area of a bubble with no forces (including surface tension) acting on it, which we call the target area, while $a_n$ is the current area of the same bubble as it flows. The difference between the areas $(a_n - A_n)$ gives a bubble’s pressure. The first term gives the total surface energy and the second term the pressure energy. The CPM spins evolve according to a Modified Metropolis algorithm [15]. Each time step corresponds to a complete Monte Carlo sweep (MCS) of the lattice.

Figure 1 shows a detail of a simulation with a large bubble moving through smaller bubbles. The shade denotes the pressure inside each bubble, darker shades denoting lower pressures. The bubbles move from left to right. Our lattice geometry is rectangular (usually 1000 × 200 sites) with open boundary conditions at the short sides, like a HS experiment. We nucleate bubbles at a steady rate at one short end (the head end) and remove them at the opposite short end (the tail end).

All the bubbles, except the large bubble, nucleate at a fraction of their target area (large pressure). As they enter the lattice, they gradually expand, generating an excess pressure at the head end. As the bubbles move from left to right, they expand and their pressure decreases. When a bubble contacts the tail end of the lattice, we set its
area constraint to zero so that it disappears smoothly at near-zero pressure. Pressure differences between bubbles induce boundary movement with a velocity proportional to the applied force [15]. This method of bubble creation and disappearance corresponds closely to HS experiments which generate bubbles continuously at one end of the channel and allow them to exit at near-atmospheric pressure at the opposite end. Thus, simulation and experiment both have a constant bubble-flux boundary condition at the head end and an absorbing boundary condition at the tail end. As we mentioned earlier, the absence of a simple relationship between the mobility of the bubbles and $J$ and $\lambda$ is a limitation of both the CPM and experiments.

Our simulations have $J = 5$ and $\lambda = 3$ and run at zero temperature. The small-bubble target area is usually 625 lattice sites. We create a single large bubble of diameter $D$ at the first time step at a random position along the head end. We nucleate small bubbles every 50 MCS with initial sizes between 4 and 481 pixels. Varying the nucleation size of the bubbles at the head end changes the pressure gradient, which in turn changes the velocity of the flow. We also vary the large-bubble size. If the large-bubble radius is more than four times the small-bubble radius, we use a larger lattice to avoid boundary effects. The small bubbles all have approximately the same velocity at any given time and we define the foam velocity as the average of the centre-of-mass velocities of the small bubbles at a fixed time. For each case, we run multiple replicas with different random-number-generator seeds. As in [11] and [15] we define the total stored surface energy $\phi$ to be:

$$\phi = \sum_{i,j} (1 - \delta_{i,j}).$$

The average stress tensor $\sigma$, as reference [11] points out, relates directly to $\phi$. $\phi = \text{Tr}(\sigma)$. We scale out differences due to initial conditions by using $\phi(t)/\phi(0)$, where $\phi(0)$ is the value of $\phi$ at the start of the simulation. The applied strain rate is very high initially, then falls sharply to a low constant value, after which the applied strain is proportional to time and the energy-versus-time curve becomes equivalent to the energy-versus-applied-strain curve. We call the flow quasistationary when any drift in the total energy is less than 2% of the average energy over 1000 MCS and the bubble velocity changes by less than 10%
of the average velocity over 1000 MCS. We make all measurements in the quasistationary state. Since we introduce and eliminate bubbles continuously, we never reach a static equilibrium. The finite HS cell and pressure drop along it mean that bubble velocity varies down the cell length.

3. Results

Figure 2(a) plots $\phi$ as a function of time and figure 2(b) plots the velocity of large and small bubbles as a function of time. For slow flows, the small and large bubbles flow with the same velocity as a solid. Above a critical velocity, the bubbles’ velocities depend on their sizes, e.g., in our simulations the critical velocity is 0.014 pixels/MCS when the radius of the large bubble is twice that of the small bubbles. We plot the difference in velocity between the large bubble and the foam ($v_L - v_f$) versus the velocity of the foam $v_f$ for different large-bubble sizes $D$, scaling the velocity difference by $r = D/d$, where the diameter of the small bubbles $d$ is constant. Figure 3 shows our results. We checked that $v_c$ was independent of $d$ by running simulations with a small-bubble target area, $A_n = 400$ pixels. We examined the cases $r = 2, 3, 3.5$ and 4. Since very large bubbles tend to wobble and break into smaller bubbles, we analysed only simulations in which the large bubble traversed the HS cell without breaking. We find excellent agreement between our data and the theoretical form of Cantat and Delannay [19]:

$$\frac{(v_L - v_f)}{v_f(D/d)} = -\frac{A}{v_f} \frac{1}{B \ln(1 - A/v_f)}.$$
Cellular Potts Model approach

Figure 3. Difference between large-bubble velocity $v_L$ and average foam velocity, rescaled by $rv_f$, versus $v_f$ for different large-bubble sizes, on a semilog scale. The symbols on the graph correspond to different values of $r$.

where $(v_L - v_f)$ is the difference between the large bubble velocity and the foam velocity and $A$ and $B$ are fitting parameters. The fitting value for the critical velocity $A = 0.013$ pixels/MCS and $B = 8.66$ is a dimensionless parameter which scales the velocity. The asymptotic standard error for both parameters is less than 5%.

The theoretical critical velocity is \[ v_c = \frac{h}{\eta D}, \] (10)

where $h$ is the thickness of the HS cell. Taking $h$ to be the small-bubble size, we obtain $v_c$ from the values of $\gamma$ and $\eta$ obtained from our simulations. We obtain $\eta$ by measuring the relation between the effective pressure along the channel and the foam velocity and $\gamma$ from the size and pressure of the small bubbles. We find $v_c = 0.014$ pixels/MCS, agreeing with the value which we obtained in the previous paragraph.

We can also calculate an analogue of the Deborah Number ($N_D$) for our simulated bubble motion, the product of the shear strain rate and the event timescale \[ N_D = \frac{(v_L - v_f)\tau}{d}. \] (11)

Our small bubble size is usually 25 pixels, while $\tau$ is approximately 20 MCS so $N_D$ is between $10^{-2}$ and $10^{-1}$ for most of our simulations. Our maximum $N_D$ is 0.08.

4. Conclusions

We have shown that we can use the CPM to study the flow of a large bubble embedded in a monodisperse foam. For small velocities, all the bubbles in the foam flow at the same velocity. Above a critical velocity, the velocities of the bubbles vary with their sizes. The critical velocity in our detailed simulations of a large bubble twice the size of the small bubbles matches very well with the critical velocity we obtain by fitting our simulation results for bubbles of various sizes to the analytical equation of Cantat and Delannay [19], and with the critical velocity we deduce theoretically from the effective viscosity and surface tension of the simulated foam.

We have also checked that in a polydisperse foam, above a critical velocity different-size bubbles travel at different velocities, the large bubbles travelling faster. The dimensional form of the definition of the critical velocity suggests that bubbles of different sizes should have different critical velocities, however, we have not been able to verify this dependence in a simulated polydisperse foam because the very large scatter in the velocity difference prevents us from identifying the critical velocities. Experiments by Park and Durian revealed fingering instabilities in radial HS cells [25] which may relate to the viscous instability in rectangular HS cells. However, the aspect ratios of these experiments are very different from those in our simulations, so direct comparison is difficult.

Acknowledgments

We acknowledge the use of AVIDDD, the distributed computing facility at Indiana University Bloomington to run our simulations. We thank Debasis Dan, Ariel Balter, Lenhilson Coutinho, Roeland Merks and Julio Espinoza Ortiz for discussions, suggestions and comments. We also thank Isabelle Cantat for supplying the preprints which we cite in this paper and discussing the details of her experiments and simulations. We also acknowledge support from NSF grant IBN-0083653, NASA grant NAG2-1619, an IBM Innovation Institute award, an Indiana University Pervasive Technologies Laboratory Fellowship and the Biocomplexity Institute of Indiana University.
