**Abstract**

Arthropods harbor a largely undocumented diversity of RNA viruses. Some arthropods, like mosquitoes, can transmit viruses to vertebrates but are themselves parasitized by other arthropod species, such as mites. Very little is known about the viruses of these ectoparasites and how they move through the host–parasite relationship. To address this, we determined the virome of both mosquitoes and the mites that feed on them. The mosquito *Aedes communis* is an abundant and widely distributed species in Sweden, in northern Europe. These dipterans are commonly parasitized by water mite larvae (Trombidiiformes: Mideopsidae) that are hypothesized to impose negative selection pressures on the mosquito by reducing fitness. In turn, viruses are dual-host agents in the mosquito–mite interaction. We determined the RNA virus diversity of mite-free and mite-detached mosquitoes, as well as their parasitic mites, using metatranscriptomic sequencing. Our results revealed an extensive RNA virus diversity in both mites and mosquitoes, including thirty-seven putative novel RNA viruses that cover a wide taxonomic range. Notably, a high proportion of viruses (20/37) were shared between mites and mosquitoes, while a limited number of viruses were present in a single host. Comparisons of virus composition and abundance suggest potential virus transfer between mosquitoes and mites during their symbiotic interaction. These findings shed light on virome diversity and ecology in the context of arthropod host–parasite–virus relationships.

**Key words:** meta-transcriptomics; mosquito-borne viruses; arthropod-borne viruses; virus evolution; virome.

**Introduction**

Arthropods can interact in various ways to establish symbiotic relationships in nature (Kaplan and Eubanks 2005; Peng et al. 2013; Werblow et al. 2015). Among these, parasitic associations have profound effects on host populations and community ecology (Vasquez et al. 2020). This symbiotic strategy allows a parasitic arthropod to exploit the resources of an arthropod host to survive and reproduce. In freshwater ecosystems, parasitic associations can be observed between water mites and other arthropods such as crustaceans and insects (Pozojević et al. 2019; Vasquez et al. 2020). However, such biotic associations are not only confined to hosts and parasites. Relatedly, viruses are ubiquitous actors capable of permeating through arthropod symbiotic systems and interacting with either the parasite and/or the ‘base host’, resulting in a dynamic tripartite setting (i.e. host–parasite–virus system) (Di Prisco et al. 2016; Parratt and Laine 2016).

Parasitic mites can act as vectors or activators of viral diseases. For instance, RNA viruses, such as Kashmir bee virus (KBV), sacbrood virus (SBV), and deformed wing virus (DWV), are often detected in honeybee colonies infested with *Varroa* mites (Shen et al. 2005, Dainat et al. 2009). Importantly, there are major gaps in our current knowledge of the diversity and biology of viruses associated with natural mite populations that parasitize mosquitoes and their vectorial capacity. Indeed, most research on viruses infecting mites are related to pathogens of mammals and plants (Poinar and Poinar 1998; Valiente Moro, Chauve, and Zenner 2005; Yu and Tesh 2014). In the same way, the relationship between parasitism (e.g. multiparasitism) and virus ecology at the mosquito–mite–virus interface remains to be determined (Auld, Searle, and Duffy 2017).

Water mite larvae (Acari: Parasitengona: Hydrachnid) are obligate ectoparasites of culicid mosquitoes (Werblow et al. 2015). Although the exact nature of the host–parasite relationship between mosquitoes and mites is uncertain, water mites exhibit predatory and parasitic behaviors on larval and adult stage mosquitoes, respectively (Werblow et al. 2015;...
Atwa, Bilgrami, and Al-Saggaf 2017; Vasquez et al. 2020). During the biotic interaction, water mite larvae often attach to preimaginal stages or adult mosquitoes that provide the larvae with nutrients and transport to complete their life cycle (Werblow et al. 2015). Once the larval stage is complete, water mites detach from the mosquito for post-larval (nymphal stages) and adult development, feeding on insect larvae, including mosquito eggs and larvae present in aquatic habitats (Atwa, Bilgrami, and Al-Saggaf 2017; Vasquez et al. 2020). Conversely, parasitism of mosquitoes by mites is usually associated with adverse effects on mosquito fitness (i.e. reduced reproductive ability and survival) (Dos Santos et al. 2016). Among these, mite infestation might impact flight, sexual maturity, and egg production in mosquitoes.

The snow-pool mosquito species, Aedes communis (De Geer 1776), is a monogenic species with a Holartic distribution, occurring in Eurasia and North America (Becker et al. 2010). It is commonly found not only in forested areas such as coniferous and temperate forests but also on the tundra (Medvedev, Albatalov, and Panyukova 2011). Aedes communis females commonly blood feed during twilight on a variety of vertebrates, including humans, rabbits, birds, rodents, and cattle. In Sweden, A. communis is abundant and widespread in spring and early summer (Lundström et al. 2013). The virome of A. communis is largely unknown but has been shown to include insect-specific viruses (ISVs) from the families Phasmaviridae, Rhabdoviridae, and Solenomoviridiae of RNA viruses (Ohlund et al. 2019). Sporadic detections of different arboviruses have also been reported from this species (Campbell et al. 2019; Lvov et al. 2015), although it is not considered a vector species for any arbovirus (Campbell et al. 1991).

The use of metagenomic sequencing to characterize virus diversity has revolutionized our understanding of the evolutionary history, ecology, and distribution of RNA viruses in nature (Shi, Zhang, and Holmes 2018; Zhang, Shi, and Holmes 2018), transforming our ability to detect viruses in terms of scalability, speed, and accuracy. In particular, these studies have revealed an enormous number and diversity of viruses in invertebrates, including both ISVs and arboviruses, some of which fall into highly divergent lineages or RNA virus families (Li et al. 2015). During the mosquitoes, we compared our contigs against a custom database of RNA viruses (Ohlund et al. 2019). Sequence data processing

Sequence read quality assessment was performed with FastQC v0.11.8 (Andrews 2010) and summarized using the MultiQC tool (Ewels et al. 2016). Ribosomal reads of Archaea, Bacteria, and Eukarya were filtered from the meta-transcriptomic data with the SortMeRNA v2.1b software (Kopylova, Noé, and Touzet 2012). Reads were assembled into contigs using the metagenomic assembler MEGAHIT v1.2.9 with default settings (Li et al. 2015b). A meta-transcriptome assembly evaluation was conducted using QUAST v4.3 (Gurevich et al. 2013). To reduce false positives in the detection of viruses due to index-hopping, putative viruses were considered as present in a library if the total read count was ≥ 0.1% of the highest count for that virus across the libraries with at least two reads per sample. Taxonomic profiling of metagenomic data was conducted using CCMetagen v1.2.4 (Marcelino et al. 2020) (summary data available at doi: 10.6084/m9.figshare.20499726).

The sequencing reads and viral sequences identified in this study have been deposited in the SRA (Bioproject: PRJNA838788, Biosamples: SAMN28502431–SAMN28502454; SRA accession codes: SRR19268734–SRR19268757) and GenBank (ON860444–ON860480, OP555115–OP555127) databases, respectively.

Virus abundance and host association inference

Abundance was quantified as the number of reads per million mapped reads (RPM). Reads were mapped to the viral assemblies and the Cox-1 gene as host marker (JX040509.1 and MN362385.1) using the BMBMap tool v3.79 (sourceforge.net/projects/bbmap/). Contig assemblies were compared against the National Center for Biotechnology Information (NCBI) nucleotide (NCBI-nr) and non-redundant protein database (NCBI-nr) using DIAMOND v2.0.9 with e-value cutoffs ≥1E–10 and ≥1E–4, respectively. To infer likely virus–host associations, we considered available data on (i) the virus prevalence within and between arthropod groups, (ii) abundance estimates, (iii) the closest hits in the BLAST/nr search, and (iv) phylogenetic relationships. To establish a likely host association, at least three of the four criteria had to be compatible.

Methods Sample collection

Aedes communis mosquitoes were collected within a mosquito control program (https://mygg.se/) across the river Dalälven floodplains in central Sweden (60.2888° N, 16.8970° E) between weeks 25 and 35 in 2014, 2019, and 2020, using the Centers for Disease Control and Prevention miniature light traps (CDC-traps) baited with dry ice. Morphological identification of mosquitoes was conducted using a stereomicroscope and the key provided by Becker et al. (2010) on a chilled table. The mosquitoes collected were examined under a stereoscopic microscope for the presence of mites (Mideopsis sp.). Detected mites were removed and, together with the mosquitoes, were separated into groups of mites (K), mite-free mosquitoes (M), and mite-detached mosquitoes (MK) (infection load = 1–20 mites per mosquito) (Supplementary Table S1). The collected specimens were kept at −80°C until molecular processing.

Sample processing and sequencing

Samples were processed in three groups corresponding to M (n = 80), MK (n = 80), and K (n = 160). In total, twenty-four sequencing libraries were prepared, eight libraries for each group. Samples were homogenized in pools of ten mosquitoes or twenty mites, using ZR BashingRead 0.1 mm (Zymo Research, Irvine, CA) for 180 s using a TissueLyzer II (Qiagen). Total RNA was extracted from the homogenates using the ZymoBIOMICS DNA/RNA Minprep Kit (Zymo Research, Irvine, California, USA) according to the manufacturer’s instructions. Ribosomal RNA (rRNA)-depleted RNA was extracted from each sample using the Rib-Zero Gold kit (Illumina). Whole-transcriptome libraries were constructed using DNA nanoball technology (paired-end sequencing) on a DNBIseq platform. Library preparation and sequencing were performed by the Beijing Genomics Institute, Hong Kong. For taxonomic identification of the most likely genus of mites detached from the mosquitoes, we compared our contigs against a custom database, including Cox-1 amino acid sequences from mites (Trombidiformes; taxid: 83136). We also assessed the variation in Cox-1 gene abundance across libraries using different reference sequences of Mideopsis sp. (Supplementary Fig. S2).
Taxonomic assignment and protein annotation

Taxonomic information was collected from the NCBI Entrez taxonomy database using the NCBI-taxonomist tool v1.2.1 (https://pypi.org/project/ncbi-taxonomist/) (Buchmann and Holmes 2020). Open reading frame (ORF) detection and sequence translation were performed on contigs >1,000 nt with the program getORF v.6.6.0 (-minsize 600 -find 0), EMBOSS (Rice, Longden, and Bleasby 2000). Classification of proteins and domain detection on predicted ORFs were performed using the InterProScan v5.51-85.0 software (Jones et al. 2014) with default search parameters, and the HMMER v3.3 program (hmmscan search) against the Pfam and PROSITE databases (Finn, Clements, and Eddy 2011). To identify and annotate highly divergent viruses that were missed in the DIAMOND BLASTX search or that had similarities to taxonomically unassigned viruses, orphan contigs and unclassified viruses were run through the RdRp-scan resource with e-value 1E−6 in the hmmscan search (Charon et al. 2022). The completeness and quality of viral sequences were assessed by visual inspection and execution of the CheckV pipeline (Nayfach et al. 2020) and Prodigal v.2.6.3 (Hyatt et al. 2012).

Statistical analyses

To determine whether virus abundance levels differed significantly among the K, M, and MK groups, we assessed the normality of the data corresponding to RMP values (raw and log10 transformed) by visual inspection and using the Shapiro–Wilk test. Since the data did not follow a normal distribution, comparisons were made using the Kruskal–Wallis chi-squared test and Pairwise Wilcoxon Rank Sum Test. All analyses were performed using the packages rstatix (Kassambara 2021) and ggpubr (Kassambara 2020) in R (R Core Team 2021) (available at https://www.R-project.org/).

Phylogenetic analysis

Viral protein sequences for the RNA-dependent RNA polymerase (RdRp) identified in this study were aligned to a set of representative sequences publicly available at NCBI/GenBank according to the virus family, using Clustal Omega v1.2.4 with default settings. The reference Quenyavirus sequences were obtained from Obbard et al. (2020). We assigned provisional names to novel viruses based on the maximum likelihood (ML) method available in IQ-TREE v1.6.12 (-m TEST -aLRT 1000 -bb 1000 -nt 4 -bnni) (Nguyen et al. 2015; Hoang et al. 2018). Nodal support was estimated with SH-aLRT and the ultrafast bootstrap (UFBoot). A total of 1,000 replicates were run for both approaches, and we used the option bnni to avoid overestimating branch supports with UFBoot. Tree visualization was conducted using the R software packages ggtree and ggrepplot2 (Wickham 2016; Yu et al. 2017).

Results

Extensive RNA virome diversity in A. communis and their parasitic mites

A total of 160 mosquitoes and their parasitic mites were collected and pooled into twenty-four separate libraries, representing three different groups, to characterize the virome of each host and assess the virus prevalence across mites and in both mite-free and mite-detached mosquitoes. Overall, we generated between 48.5 and 74 million pair reads per library, of which ∼76 per cent corresponded to rRNA content. Meta-transcriptomic reads were de novo assembled into partial viral genomes from which we identified thirty-seven novel RNA viruses based on the presence of a viral RdRp: these represented eighteen families and fifteen orders of positive-stranded RNA (n = 8), negative-stranded RNA (n = 18), and double stranded RNA (n = 6) (Table 1). Three viruses were only classified to the level of phylum or class. One additional virus was taxonomically unclassified. The newly discovered viruses shared between 25.2 and 80.7 per cent amino acid sequence similarity to the RdRp of the closest viral hit in the NCBI-nr (Table 1).

Notably, the mite-specific viruses were highly divergent. BLASTX similarity searches revealed that the majority of the virus contigs were related to arthropod-associated viruses (29/37), although we identified three viruses to be associated with those previously identified in nematodes (Wuchang romanomermis nematode virus 2; similarity = 33.5 per cent), protozoans (Leptomonas moramongo leishbunyavirus, similarity = 80.7 per cent), and algae (diatom colony-associated dsRNA virus 11, similarity = 54.2 per cent). Likewise, we identified three viruses in the families Narnaviridae and Tymoviridae that are most often associated with fungi or plants (Table 1).

Based on the phylogenetic analysis, we identified several putative novel viruses in mosquitoes and mites that shared close relationships to known RNA viruses within the families Chuviridae, Flaviviridae, Metaviridae, Narnaviridae, Orthomyxoviridae, Partitiviridae, Iflaviridae, Qnviridae, Sedoreoviridae, Totiviridae, and Tymoviridae (Figs 1–5). Of particular note was a novel pestivirus, tentatively named Hede virus, that exhibited ∼31 per cent amino acid sequence similarity to Xinzhou spider virus 2 previously discovered in spiders (Araneae), and the novel Kvarnor virus that shared ∼51 per cent similarity to the errantivirus Aedes aegypti Tb virus 2 (Metalvirdae) (Table 1 and Figs 3B and 4C) (Shi et al. 2016b). Similarly, we identified viruses related to members of the Leishbunyaviridae and Nairoviridae within the order Bunyavirales, as well as members of the Rhadonoviridae, Lispiviridae, and Xinmoviridae in the order Mononegavirales of single-strand negative-sense RNA viruses (Fig. 1). A small number of the novel viruses identified here was grouped with unclassified RNA virus sequences in the Bunyavirales and Mononegavirales. Due to the limited similarity shared between the novel and known viruses, we only recovered partial genome/replicase sequences encoding conserved domains, such as the RdRp and MPro, as well as segments encoding uncharacterized proteins (Supplementary Table S3 and Fig. 5).

Although the newly discovered Baggbo virus, Fullsta virus, Sala virus, and Nedre virus shared limited similarity with unclassified viruses (similarity = 39.2–42.7 per cent) (Table 1), we provided a broad taxonomic assignment for these viruses within the Sobelivirales, Ellioviricetes, and Pisuviricota (Supplementary Table S2). Also of note was that the newly identified viruses for which the taxonomic status could be assigned fell into distinct clades within several families, helping to fill the gaps in the phylogenies of these groups. In other cases, the putative viruses identified here are grouped together as sister taxa to each other. For example, the Halterbos virus fell as a sister taxon to Mogongava virus (Qnviridae) as part of a clade of mosquito-associated viruses (Fig. 2D), as did Malby virus and Bro virus (Xinmoviridae) (Fig. 1B). Finally, some of the newly identified viral sequences occupied basal phylogenetic positions, such as Heby virus (Bunyavirales), which was a sister to a clade comprising the newly discovered viruses Smedsang bunya-like virus, Avesta bunya-like virus, Buska virus, and their closest known relatives in mosquitoes (Fig. 1A). Similarly, Sater
### Table 1

List of putative viruses discovered in this study and present in mite/mosquito hosts. Each viral sequence was compared with the NCBI non-redundant (nr) database using DIAMOND BLASTX. Hosts are represented with letters corresponding to mites (K), mite-free mosquitoes (M), and mite-detached mosquitoes (MK).

---

virus (a Nairo-like virus) shared common ancestry with other tick nairoviruses (Fig. 1A).

**Composition and distribution of RNA viruses reveal host connectivity**

To assess the differences in the virome composition between groups, we determined virus prevalence across all the sequencing libraries generated here. This revealed a similar number of viruses present in M (n = 29), MK (n = 25), and K (n = 26) (Fig. 6). Notably, six viruses were specific to the mite (K) libraries, eighteen viruses were shared between mosquitoes (M/MK) and mites (K), whereas five viruses were exclusively present in the mite-free (M) libraries (Table 1, Fig. 6). The shared viruses were classified within the Chuviridae, Narnaviridae, Orthomyxoviridae, Partitiviridae, and Quenyaviridae, as well as those assigned to the orders Bunyavirales and Mononegavirales (Table 1, Fig. 6). Cross-reference between some MK and K pools was concordant with these results (Supplementary Fig. S1). Within the Partitiviridae, Ormpussen galbut-like virus and Hundmyran chaq-like virus exhibited limited sequence similarity to galbut (similarity = 36 per cent) and Chaq virus (similarity = ~ 53 per cent), respectively (Table 1). Remarkably, these viruses also co-occurred in most libraries (7/10) (Fig. 7.
Supplementary Fig. S1). In general, we found at least four viruses per library, with the exception of the mite-free mosquito library M3, which harboured seventeen novel viruses (Fig. 7).

Although we expected that all viruses present in MK libraries (i.e., mosquitoes previously infested with mites) would also be found in either M or K libraries, Kagbo partiti-like virus was only recovered from a single MK library (Figs 6 and 7). In contrast, we observed common viruses among host-specific libraries, such as Hallarsbo virus (Qiniviridae) and Kvarnon virus (Metaviridae) in mosquitoes and Baggbo virus (Sobelivirales) and Hedemora virus (Mononegavirales) in mites (Table 1, Fig. 7). Only the putative Buska virus (Bunyavirales) was broadly distributed among most of the libraries (17/24).

Virus abundance levels suggest host associations and virome connectivity between mosquitoes and mites

We next assessed virus abundance for each newly discovered virus compared to host gene markers (Fig. 7). Accordingly, virus abundance varied from 1 to 47,863 RPM (Fig. 7). In contrast, the abundance of the reference mitochondrial gene marker Cox-1 was more stable across host-specific libraries, ranging between 40 and 307 RPM for Mideopsis sp. and 43–348 RPM for A. communis. Importantly, reads from the mosquito host were detected in all the libraries (Fig. 7). Comparisons of virus abundances between groups K, M, and MK revealed no significant differences (KW = 2.68, P-value = 0.2617). We considered viruses with values >1,000 RPM (>0.1 per cent of ribosomal-depleted RNA) to be highly abundant. For example, Hytton narna-like virus (Narnaviridae, RPM = 20–39,637) exhibited the highest abundance and was present across mite and mosquito libraries (Fig. 7). Nearly all viruses exclusively detected in mites showed very high abundance levels, such as Baggbo virus (Sobelivirales, RPM = 84–10,251), which was highly prevalent among K libraries (Figs 5 and 7). We were also able to identify some viruses that were abundant in mosquito libraries but were still present in mites at negligible levels, including Buska virus (Bunyavirales, RPM = 1–1,885), Osterbannback virus (Partitiviridae, RPM = 1–3771), and Fallet virus (Chuviridae, RPM = 6–11,594), supporting the idea that these viruses are likely more associated with mosquitoes (Fig. 7). Likewise, although both Kvarnon virus (Metaviridae, RPM = 6–19) and Hallarsbo virus (Qiniviridae, RPM = 2–93) were at low abundance, they were stably expressed and highly prevalent in M libraries while scarce in K libraries. It is also notable that viruses restricted to single libraries, such as Kagbo partiti-like virus (Partitiviridae, RPM = 125) and Disbo virus (Totiviridae, RPM = 135), were at low
Figure 2. Phylogenetic relationships among the viruses found in this study and reference sequences within the RNA virus families (A) Narnaviridae, (B) Partitiviridae, (C) Totiviridae, (D) Qinviridae, (E) Chuviridae, and (F) Virgaviridae. Phylogenetic trees were estimated using the VT+F+I+G4 (Narnaviridae, Partitiviridae, Virgaviridae) and Q.pfam+F+I+Γ4 (Totiviridae, Qinviridae, Chuviridae) substitution models. Novel viruses are indicated by blue tip points and hosts are represented with three-pack bars corresponding to mite (K; yellow), mite-free mosquito (M; green), and mite-detached mosquito samples (MK; purple). Trees are based on the amino acid sequences of the putative RdRp. Nodal support values ≥ 80 per cent SH-aLRT and ≥ 95 per cent UFboot are denoted with yellow triangles at nodes. Scale bars indicate the number of amino acid substitutions per site and the trees are midpoint rooted for clarity only. Host species information (animal icons) is shown for the closest relatives of the novel viruses.

abundance (Fig. 7). Overall, these results revealed differences in virus composition and abundance that might help demonstrate virus–host associations as well as connectivity (i.e. potential virus transfer) through the host–parasite system.

Discussion

Host–parasite relationships between mosquitoes and mites have impact on both arthropod and ecosystem ecology. However, aspects such as host and parasite virome diversity and composition have largely been neglected within the mite–mosquito interaction. Here, we provide an overview of the diversity of RNA viruses in these arthropods, comparing their virome profile to investigate possible transfer events between both hosts. In line with previous studies on arthropod viromes (Li et al. 2015a; Obbard et al. 2020; Pettersson et al. 2017; Shi et al. 2016a), we observed a high abundance of many viruses, suggesting that many more arthropod viruses remain to be discovered (Harvey and Holmes 2022; Junglen and Drosten 2013; Shi et al. 2016a).

Although mites are known to be vectors of some pathogens of medical and veterinary importance for vertebrate hosts (Gubler 1988; Hubálek, Rudolf, and Nowotny 2014; Mullen and O’Connor 2019; Weaver and Reisen 2010; Yu and Tesh 2014), these arthropods can also act as vectors of viral agents to other arthropods. For example, Varroa mites (Varroa destructor) appear to mediate transmission of KBV, SBV, and DWV to honey bees (Shen et al. 2005). As a consequence, the interaction between parasites and their hosts is also likely to lead to the transfer of viruses. We investigated the virome of mosquitoes and their infesting mites to reveal mosquito–mite interactions. A key result was that a number of viruses were commonly present in both mosquitoes and mite samples (Fig. 6), indicating that the transfer of viruses is likely to occur when parasitic mites feed on dipteran hosts (Dolja and Koonin 2018). Further research is needed to assess whether these viruses are able to infect, replicate, and spread in both arthropod
hosts, as opposed to being of dietary origin or infecting components of the microbiome (Supplementary Fig. S3) (Obbard 2018). In the latter case, the presence of partitiviruses, such as Ormpussen galbut-like virus and Hebron partiti-like virus, both widely distributed among mite and mosquito samples, suggest the presence of common fungal and/or protozoan microbiota (Figs 2B and 7). Nonetheless, we cannot definitively exclude possible contamination with microorganisms present on the surface of arthropods or derived from sample processing.

The repertoire of putative viruses identified in this study spanned different viral families previously reported in mites and mosquitoes (Table 1, Figs 1–4) (Chang et al. 2021; Junglen and Drosten 2013; Li et al. 2015a; Shi et al. 2016a). In particular, prior to this work, there were a relatively limited number of viruses recorded in mites that parasitize other arthropods, representing the Chuviridae, Dicistroviridae, Ibbaviridae, and Rhabdoviridae families (Shen et al. 2005; Dietzgen et al. 2014; Niu et al. 2019). Our results expand this virus diversity to include viruses within the orders Sobellivirales and Mononegavirales and the family Ibbaviridae (Figs 1B, 3B, and 7). The occurrence of flaviviruses has been previously recorded in acarid ectoparasites parasitizing natural bird populations (Santillán et al. 2015; Kovalev and Yakimenko 2021). In contrast, the highly divergent Hedv virus (likely partial RdRp) found in mites was most closely related to arthropod-specific long genome flaviviruses (Table 1, Figs 3B and 5) (Paraskevopoulos et al. 2021), with related viruses documented in ticks (Tokarz et al. 2014; Xu et al. 2022). Therefore, the presence of highly divergent viruses in mites suggests a hidden diversity in Acari.

A key outcome of this study was the presence of viruses restricted to either mosquito or mite libraries, which we hypothesized to correspond to host-specific viruses or those associated with the host microbiota. For example, the presence of the Baggvo virus at abundant levels across several K samples (Table 1, Fig. 7) suggests that these arthropods might serve as natural carriers of this virus. In contrast, Kvarnon virus, which was found at low abundance in the majority of the M and MK libraries, yet not the K libraries, is presumed to derive from symbionts in A. communis mosquitoes (Supplementary Fig. S3). However, due to the small sample size, caution is needed in the formulation of definitive virus–host associations.

Insect-specific viruses (ISVs) in mosquitoes represent the Bunyaviridae, Sedoreoviridae, Ibbaviridae, Mononegavirales, and Flaviviridae (Roundy et al. 2017). Bro virus (Xinmoviridae), Nor ifla-like virus (Ibbaviridae), and Berg reo-like virus (Sedoreoviridae) described here may also constitute ISVs as they were found in high abundance and grouped with other viruses reported in mosquitoes (Figs 1–5) (Pettersson et al. 2019). In contrast, the novel totiviruses are more likely to have a fungal or protozoan origin (Fauver et al. 2016; Wu...
Figure 4. Phylogenetic relationships among the viruses found in this study and reference sequences within the RNA virus families (A) Quenyaviridae (B) Tymoviridae, and (C) Metaviridae. Phylogenetic trees were estimated using the rtREV+F+I+Γ4 substitution model. Novel viruses are indicated by blue tip points and hosts are represented with three-pack bars corresponding to mite (K; yellow), mite-free mosquito (M; green), and mite-detached mosquito samples (MK; purple). Trees are based on the amino acid sequences of the putative RdRp or RT. Nodal support values ≥ 80 per cent SH-aLRT and ≥ 95 per cent UFboot are denoted with yellow triangles at nodes. Scale bars indicate the number of amino acid substitutions per site and the trees are mid-point rooted for clarity only. Host species information (animal icons) is shown for the closest relatives of the novel viruses.

et al. 2020, Coatsworth et al. 2021) (Supplementary Fig. S3). Finally, among the set of newly discovered viruses, the broad distribution of the Buska virus across most libraries (Fig. 7) is consistent with that reported for its closest match—Zhee mosquito virus in Coquillettia richardii and Aedes spp. (Öhlund et al. 2019). Together with the substantial variation in the abundance of Buska virus between mite and mosquito libraries, we hypothesized that this bunyavirus might infect and replicate well in A. communis mosquitoes.

Given the occurrence of Kagbo partiti-like virus in a single MK library and the lack of detection in K and M samples, its true host association is difficult to assign (Figs 2B and 7). Despite our thorough examination of the samples, it is possible that small remnants of mouthparts contaminated with fungi or protozoa were still present in the M/MK libraries, which may explain the sporadic occurrence of the novel Kagbo partiti-like virus. Conversely, the presence of contaminant viral sequences might offer an alternative explanation (Porter et al. 2021). It has previously been shown that contaminant viruses can not only be derived from multiple sources, including specimen surface contamination, reagents, controls, and cell culture, but can also be introduced at any step in sample preparation and sequencing (Batson et al. 2021; Cobbin et al. 2021; Porter et al. 2021). Interestingly, the closest relative to Kagbo partiti-like virus (Fig. 2B) has been reported in Culex modestus, Culex vishnui, Culex tritaeniorhynchus, Culex quinquefasciatus, Culex pipiens, and Culex torrentium and A. aegypti from different geographic globally (Faizah et al. 2020; Öhlund et al. 2019; Pettersson et al. 2019; Shi et al. 2019; Wang et al. 2021).

Previous work on arthropod viral transcriptomes strongly suggests that galbut and chaq virus are associated with a satellite–helper virus system or are part of the same segmented RNA virus (Batson et al. 2021; Cross et al. 2020; Shi et al. 2018; Webster et al. 2015), although key aspects of the system are still poorly understood. In this context, the co-occurrence of the novel partitiviruses Ormpussen galbut-like virus and Hundmyran chaq-like virus, distantly related to galbut virus- and chaq virus-like sequences, respectively, which further supports the notion of an existing relationship between these viruses, extending this association to more distant viral relatives. It is important to note that we detected a similar pattern of co-occurrence for Hebron partiti-like virus (Fig. 7). This observation agrees with previous studies reporting the presence of multiple partitiviruses in samples (Webster et al. 2015; Faizah et al. 2020), although, based on the available data, we were unable to determine whether Hebron partiti-like virus is specifically associated with Ormpussen galbut-like virus and Hundmyran chaq-like sequences.

It is also important to consider the co-occurrence of multiple virus taxa within libraries regardless of the arthropod host (Fig. 7). Accordingly, our analysis revealed a heterogeneous diversity (i.e. composition and abundance) of RNA viruses within libraries. These differences might reflect underlying interactions at the host–parasite–virus interface. Indeed, viral infection can shape host–parasite relationships by impacting ectoparasite virulence and imposing differential selective pressures on the hosts in question (Di Prisco et al. 2016; Parratt and Laine 2016). However, the
Figure 5. Schematic representation of protein domains found in the viral sequences identified in this study. Putative novel viruses are grouped by virus family. Diagrams represent predicted ORFs (gray), while domains are displayed as colored boxes (see legend). ORFs lacking conserved domains are annotated (text labels) based on the closest hit in the BLASTX search. The question marks (?) represent ORFs encoding hypothetical/unknown proteins. The ORFs size is shown as number of nucleotides, and each ORF is located along the contig according to the predicted coordinates. Multiple segments of a virus are indicated by asterisks (*). GP: glycoprotein; HP: hypothetical protein; CP: core protein; MTase: methyltransferase; NP: nucleoprotein; PA: polymerase acidic protein; PB2: polymerase basic protein 2; RdRp: RNA-dependent RNA polymerase; RNase H: nuclease H; RT: reverse transcriptase.

Figure 6. Comparison of the number of viruses shared between mites (K), mite-free mosquitoes (M), and mite-detached mosquito libraries (MK). The total number of viruses is indicated for each group. The size of the circle is proportional to the number of viruses identified in each host group. Color coding is the same as in Figs 1–4.
Figure 7. Overview of virus abundance quantified as reads per million (RPM). The newly discovered viruses are indicated on the y-axis. Abundance levels are color-coded as a heat map as specified in the legend. The queried libraries corresponding to mite (K), mite-free mosquito (M), and mite-detached mosquito (MK) are shown on the x-axis. Host abundance levels based on the Cox-1 gene marker are represented in the bottom panel.

the impact of these viruses on host–parasite relationships as well as the ecological and evolutionary implications for this and other tripartite systems
