Abstract

Very strong El Niño events occur sporadically every 10-20 years. The origin of this bursting behavior still remains elusive. Using a simplified 3-dimensional dynamical model of the tropical Pacific climate system, which captures the El Niño-Southern Oscillation (ENSO) combined with recently developed mathematical tools for fast-slow systems we show that decadal ENSO bursting behavior can be explained as a Mixed Mode Oscillation (MMO), which also predicts a critical threshold for rapid amplitude growth. It is hypothesized that the MMO dynamics of the low-dimensional climate model can be linked to a saddle-focus equilibrium point, which mimics a tropical Pacific Ocean state without ocean circulation.

1 Introduction

The ENSO phenomenon is the dominant source of interannual climate variability. El Niño events are characterized by positive sea surface temperature anomalies (SSTA) in the eastern equatorial Pacific which cause anomalous diabatic heating of the atmosphere. This in turn drives global atmospheric planetary wave adjustments impacting weather in regions far away from the tropical Pacific (Bjerknes, 1969; Deser and Wallace, 1990; Karoly, 1989).

ENSO can be regarded as a coupled atmosphere/ocean instability, subject to atmospheric noise, external periodic forcing through the annual cycle and atmosphere and ocean nonlinearities. From a dynamical systems perspective the oscillatory ENSO mode emerges from a Hopf bifurcation. To capture the irregular nature of ENSO, its occasional amplitude bursting (Timmermann et al., 2003) (Figure 1) and the presence of extreme El Niño events, nonlinear extensions to the standard ENSO recharge oscillator theory (Jin, 1997, 1998) have been suggested, including noise-induced instabilities (Levine and Jin, 2010), frequency entrainment, chaotic dynamics originating from annual cycle/ENSO interactions (Chang et al., 1995, 1994; Jin et al., 1994; Lin, 2002; Stein et al., 2014; Timmermann and Jin, 2002; Timmermann, 2003; Tziperman et al., 1994) and homoclinic/heteroclinic dynamics (Timmermann et al., 2003).

In view of the socio-economic impacts of very extreme El Niño events, it is paramount to further refine existing theories for the decadal-scale emergence of these large events. Here we hypothesize that ENSO’s bursting behavior can be interpreted in terms of Mixed-Mode Oscillations.
Figure 1: Upper panel: Observed sea surface temperature anomalies averaged over Niño 3 region. High temperatures correspond to strong El Niño events; Red lines indicate a repeated El Niño bursting pattern. Lower panel: Simulated eastern tropical Pacific SSTA in build-up phase and termination phase of strong El Niño events using equations [1] and the parameters in Table 1.

To demonstrate the applicability of this powerful mathematical framework for ENSO, we adopt the same 3-dimensional nonlinear ENSO recharge oscillator equations used by Timmermann et al. (2003).

Mixed-Mode Oscillations (MMOs) are comprised of $L_1$ large amplitude oscillations (LAOs) followed by $s_1$ small amplitude oscillations (SAOs), then $L_2$ large oscillations, $s_2$ small ones, and so on. The sequence $L_1^{s_1} L_2^{s_2} L_3^{s_3} \ldots$ is called the MMO signature (Desroches et al., 2012). There are a number of geometric explanations for MMOs, and the Shilnikov mechanism mentioned by Timmermann et al. (2003) is the poster-child for MMOs in a system with a single time-scale. In systems with multiple time scales, MMO mechanisms can be more robust, and these mechanisms are surveyed by Desroches et al. (2012). The bursting behavior observed in Figure 1 is often an indicator that the underlying model has a multiple time-scale structure.

Here we set out to analyze a dimensionless version of the model from Timmermann et al. (2003) to show that there is a parameter regime in which the model exhibits MMOs. We isolate two distinct types of MMO: one has an SAO which is monotonically increasing in amplitude while the other has SAOs that first decrease in amplitude and then increase again. They are each formed
by a distinct mathematical mechanism that will be explained in the analysis below. We shall refer to them as monotone and non-monotone SAOs respectively. We also relate the observed MMOs to the Shilnikov mechanism discussed by Timmermann et al. (2003).

We stress that the model under consideration is idealized and omits many processes certainly relevant to the dynamics of ENSO. The goal of the paper is to show that the basic mechanisms captured by the recharge oscillator can account for the bursting seen in ENSO.

The outline of the paper is as follows: In Section 2 we describe the physical model. Then we prepare the model for MMO analysis through a coordinate transformation and nondimensionalization. In particular, we identify the dimensionless model as a multiple time-scale problem and identify the time-scale parameters. In Section 3 we analyze the model with a focus on demonstrating the existence of MMOs. This analysis includes an in-depth discussion of the mathematical theory behind both mechanisms leading to MMOs in the ENSO model. Finally, we conclude with a discussion of the physical implications in Section 4.

2 A Nonlinear Model for ENSO

2.1 The Physical Model

The fundamental dynamics of ENSO can be described in terms of the recharge oscillator paradigm (Jin, 1997). The key regions for ENSO physics are the western and eastern equatorial Pacific. The important dynamical variables are the temperatures in these regions \( T_1, T_2 \), eastern tropical Pacific subsurface temperature \( T_{sub} \) and its linkage to western tropical Pacific thermocline changes \( h_1 \). Following the original model (Jin, 1998; Timmermann et al., 2003) the underlying ordinary differential equations describing ENSO and its linkage to the mean steady state can be written as

\[
\begin{align*}
\frac{dT_1}{dt} &= -\alpha(T_1 - T_r) - \epsilon \mu (T_2 - T_1)^2 \\
\frac{dT_2}{dt} &= -\alpha(T_2 - T_r) + \zeta \mu (T_2 - T_1)(T_2 - T_{sub}(T_1, T_2, h_1)) \\
\frac{dh_1}{dt} &= r \left( -h_1 - \frac{bL\mu(T_2 - T_1)}{2\beta} \right),
\end{align*}
\]

where \( T_1, T_2, \) and \( h_1 \) represent the equatorial temperature of the Western Pacific, equatorial temperature of the Eastern Pacific, and thermocline depth of the Western Pacific, respectively. The first terms of the temperature equations represent a relaxation of the system back towards a climatological mean state \( T_r \), which represents the radiative-convective equilibrium state (the temperature which the tropical Pacific would attain in the absence of ocean dynamics). The second quadratic term in the \( T_1 \) equation captures the anomaly wind-driven zonal advection of temperature. The wind anomalies themselves are determined by the east/west temperature gradient \( T_2 - T_1 \), thus leading to a quadratic dependence in temperature.

The eastern tropical Pacific temperature tendency is determined by relaxation towards \( T_r \) and the vertical temperature advection term, which depends on \( T_2 \) and the subsurface temperature \( T_{sub} \). The prognostic equation for the western tropical Pacific thermocline variation, \( h_1 \), captures a relaxation back to mean climatological conditions with a damping timescale \( r \) and the effect of wind-stress curl changes on the Sverdrup transport. The latter describes the corresponding discharging (recharging) process for El Niño (La Niña) events, which is assumed to be proportional to the east/west temperature gradient. The system of ordinary differential equations is closed by a nonlinear parameterization of eastern tropical Pacific subsurface temperature variations and
eastern thermocline depth $h_2 = h_1 + bL\mu(T_2 - T_1)/\beta$:

$$T_{\text{sub}}(T_1, T_2, h_1) = \frac{T_r + T_{r_0}}{2} - \frac{T_r - T_{r_0}}{2} \tanh \left( \frac{H - z_0 + h_1 + bL\mu(T_2 - T_1)/\beta}{h^*} \right).$$

The difference $T_r - T_{r_0}$ controls the nonlinear scaling between thermocline anomalies and subsurface temperature anomalies relative to a mean subsurface temperature of $(T_r + T_{r_0})/2$. $T_{r_0}$ corresponds to a mean eastern equatorial temperature attained at a depth of about 75m, $H$ denotes an eastern thermocline reference depth, and $h^*$ indicates the sharpness of the thermocline.

| Parameter | Value | Unit | Parameter | Value | Unit |
|-----------|-------|------|-----------|-------|------|
| $T_{r_0}$ | 16    | °C   | $T_r$     | 29.5  | °C   |
| $\alpha$ | 1/180 | day$^{-1}$ | $\epsilon$ | 0.11  |  |
| $H$      | 100   | meter (m) | $z_0$     | 75    | m    |
| $h^*$    | 62    | m    | $\mu$     | 0.0026| K$^{-1}$ day$^{-1}$ |
| $\epsilon$ | 0.11 | 1 | $\zeta$ | 1.3  | 1 |
| $L$      | $15 \times 10^6$ | m | $\frac{abL}{\beta}$ | 22    | mK$^{-1}$ |

Table 1: Parameters used by Timmermann et al. (2003).

The parameters used by Timmermann et al. (2003) are listed in Table 1. To illustrate the dynamical behaviour of this simplified ENSO system we conduct a numerical simulation of the system (1). The results are shown in the lower panel of Figure 1. The large simulated amplitude modulation of eastern tropical Pacific temperatures $T_2$ provides evidence for a separation of timescales. In the paper by Timmermann et al. (2003), the simulated El Niño bursting behavior is attributed to a Shilnikov saddle-focus mechanism. In this paper we seek a more robust mechanism for MMOs, and the analysis relies on a global time-scale separation. Such a global separation can only be seen in a dimensionless model, because nondimensionalizing the system gives insights into the relative sizes of the time-scale parameters that are relevant to the MMO analysis.

### 2.2 The Mathematical Model

Before taking on the scaling, we introduce a change of variables as follows:

$$S = T_2 - T_1 \quad T = T_1 - T_r \quad h = h_1 + H - z_0 = h_1 + K$$

With this change of variables, system (1) takes the form

\[
\begin{align*}
\frac{dS}{dt} &= -\alpha S + \epsilon \mu S^2 + \zeta \mu S \left( S + T + C - C \tanh \left( \frac{h}{h^*} + bL\mu \frac{S}{h^*\beta} \right) \right) \\
\frac{dT}{dt} &= -\alpha T - \epsilon \mu S^2 \\
\frac{dh}{dt} &= -r \left( h - K + \frac{bL\mu}{2\beta} S \right)
\end{align*}
\]

In system (2), $S$ is the temperature difference between the eastern and western Pacific surface water, $T$ is the departure of the western Pacific surface ocean temperature from some reference temperature, and $h$ represents the western Pacific thermocline depth anomaly.
Remark 1. Despite the change of coordinates, the new system (2) captures the same dynamics as the original system (1) because the two systems are equivalent. Indeed, they exhibit the same behavior as the dimensionless system (3) that we are preparing to introduce. For example, Kim and An (2011) show that the original system (1) is sensitive to the radiative-convective equilibrium temperature, $T_r$. By translating $T_1$ and $T_2$, the value $T_r$ is no longer explicitly present in the new equations (2), however it appears implicitly in the new parameter $C$ (see Table 2). We make this relationship explicit when we introduce the dimensionless parameter $c$ (4) that corresponds to $C$.

As the analysis will show, the parameter $c$ determines the relative strength of the super El Niño. Here we see a benefit of the nondimensionalization: it is not $T_r$ alone that is important, but rather the difference $T_r - T_{r_0}$, which characterizes the maximum possible temperature range in the model. Neither $T_r$ nor $T_{r_0}$ alone appear in any of the other dimensionless parameters, implying that their effect on the system is entirely dependent on each other.

| Parameter | Value | Unit |
|-----------|-------|------|
| $T_0=S_0$ | 2.8182 | °C   |
| $h_0$     | 62    | m    |
| $t_0$     | 104.9819 | days |
| $\delta$  | 0.2625 | 1    |
| $\rho$    | 0.3224 | 1    |
| $a$       | 6.8927 | 1    |
| $k$       | 0.4032 | 1    |
| $c$       | 2.3952 | 1    |

Table 2: Rescaled parameters of the system from Timmermann et al. (2003).

Now seek the dimensionless version of the system. We define the following dimensionless variables:

$$
x = \frac{S}{S_0} \quad y = \frac{T}{T_0} \quad z = \frac{h}{h_0} \quad \tau = \frac{t}{t_0}.
$$

If we indicate the new time derivative by a prime, i.e. $' = \frac{d}{d\tau}$, the dimensionless system then takes the form:

$$
\begin{align*}
x' &= \rho \delta (x^2 - ax) + x (x + y + c - c \tanh(x + z)) \\
y' &= -\rho \delta (ay + x^2) \\
z' &= \delta (k - z - \frac{z}{2})
\end{align*}
$$

(3)

where the key parameters can be expressed as

$$
\begin{align*}
\delta &= \frac{rbL}{\zeta h^* \beta} \\
\rho &= \frac{ch^* \beta}{rbL} \\
a &= \frac{\alpha bL}{\epsilon \beta h^*} \\
c &= \frac{T_r - T_{r_0}}{2S_0} \\
k &= \frac{H - z_0}{h^*} \\
S_0 &= T_0 = \frac{h^* \beta}{bL \mu} \\
h_0 &= h^* \\
t_0 &= \frac{bL}{\beta \zeta h^*}
\end{align*}
$$

(4)

The zonal advection feedback is represented by the term $\delta x^2$ and the vertical advection and thermocline feedback are captured through $x (x + y + c - c \tanh(x + z))$. The term $-\delta x/2$ is a representation of the recharging mechanism of the thermocline through wind-stress curl-induced
Figure 2: Examples of MMO patterns in (3) when (upper left panel) $\delta = 0.01$, $\rho = 0.5$, $a = 2.75$, $c = 3.75$, $k = 0.34$, (bottom left panel) $\delta = 0.1$, $\rho = 0.35$, $a = 2.75$, $c = 3.75$, $k = 0.35$, and (bottom right panel) $\delta = 0.2$, $\rho = 0.25$, $a = 2.75$, $c = 3.75$, $k = 0.34$. Upper right panel: a closer look at the small oscillations in the upper left panel. Notice that the size of the small amplitude oscillations scale with $\delta$, making them difficult to see in the upper left panel. El Niño events occur when $x > -2$, whereas strong La Niña events are characterized by $x < -4$.

Sverdrup transport. Thermal relaxation of sea surface temperatures in this system is expressed in terms of $-\rho \delta a x$, $-\rho \delta a y$. The bursting corresponds to the development of extreme El Niño events with eastern sea surface temperatures approximating those in the western Pacific ($x > -2$), similar to the bursting in equation (2). The model simulates a rapid termination of these events into a La Niña state ($x < -4$) and a slow recharge of the system through growing small amplitude ENSO oscillations. Upon reaching a threshold state, the system rapidly develops into an extreme El Niño event and the cycle repeats itself.

The system (3) has two global time-scale parameters $\varepsilon_1 = \delta$ and $\varepsilon_2 = \rho \delta$. The parameter $\rho \delta = \varepsilon / \zeta$ relates the efficiency of the advective process to the efficiency of the upwelling term, and $\delta$ is the relative timescale associated with the thermocline adjustment. Motivated by the bursting behavior seen in Figure 1, we will assume $\delta \ll 1$ so that the system has one fast variable ($x$) and two slow variables ($y, z$). Note that the value of the standard model set-up (Table 2) is $\delta = 0.26$, but smaller values can be physically justified, if for instance the recharging timescale increases beyond 400 days, or if the upwelling efficiency $\zeta$ increases. In the case where both $\delta \ll 1$ and $\rho \ll 1$, then (3) will be a three time-scale system with $x$ fast, $z$ slow, $y$ super-slow.

The foundation of the approach we use for analyzing systems with multiple time scales is called Geometric Singular Perturbation Theory (GSPT) (Fenichel, 1979; Jones, 1995). The combination of GSPT with blow-up techniques provides results on global behavior, including complicated patterns.
such as mixed-mode oscillations (Brøns et al., 2006; Desroches et al., 2012; Krupa and Szmolyan, 2001a,b). Figure 2 depicts mixed mode oscillations observed in equations (3). Similar bursting behavior has been observed in neurophysiological experiments (Amir et al., 2002; Del Negro et al., 2002; Dickson et al., 1998; Gutfreund et al., 1995; Khosrovani et al., 2007). Recent mathematical developments have enhanced our ability to explain such phenomena by exploiting a time-scale separation of the underlying model. The method combines the theory of canards (Benoît, 1983; Benoît et al., 1981; Szmolyan and Wechselberger, 2001; Wechselberger, 2007) with a suitable global return mechanism (Brøns et al., 2006; Guckenheimer, 2008; Kuehn, 2011; Milik et al., 1998; Roberts et al., 2015; Wechselberger, 2005, 2012), and it is now widely accepted as a robust explanation for dynamical behavior that is qualitatively similar to that observed in Figure 2 (Brøns et al., 2008; De Maesschalck et al., 2009; Desroches et al., 2012).

3 Model Analysis

We approach the problem as a singular perturbation problem with respect to the parameter δ, and then relate the dynamics for physically relevant parameters to the geometry of the singular limit. Thus, we treat the system as a problem with 1 fast variable and 2 slow variables.

3.1 GSPT

Recall that τ is the dimensionless time variable in (3). We can rescale time by the small parameter δ by setting $s = \delta \tau$ to obtain the system

$$\begin{align*}
\dot{x} &= \rho \delta (x^2 - ax) + x (x + y + c - c \tanh(x + z)) \\
\dot{y} &= -\rho (ay + x^2) \\
\dot{z} &= (k - z - \frac{x}{2}).
\end{align*}$$

where the dot indicates differentiation with respect to the new variable $s$ (i.e., $\dot{\;} = d/ds$). This scaling does not change the trajectories of the system—that is, they have identical phase portraits. It does reparametrize the trajectories, changing the speed at which the curves are traced. In that sense, the two systems are equivalent as long as $\delta > 0$. The initial formulation (3) is referred to as the ‘fast system’ and (5) as the ‘slow system.’ However, in the limit as $\delta \to 0$, the systems are different and the case where $\delta = 0$ is referred to as the singular limit.

When $\delta = 0$, the fast system (3) becomes the layer problem:

$$\begin{align*}
x' &= x (x + y + c - c \tanh(x + z)) \\
y' &= 0 \\
z' &= 0.
\end{align*}$$

(6)

Physically, this corresponds to a state of constant $T_1$ and $h$, but varying $T_2$. The dynamical evolution of $T_2$ is governed by vertical advective processes in the eastern tropical Pacific. Notice that the dynamics in the $y$ and $z$ directions are trivial in the layer problem, while the $x$ dynamics are not. The $y, z$ dynamics are described in the reduced problem obtained by taking the limit as $\delta \to 0$ of the slow system (5):

$$\begin{align*}
0 &= x (x + y + c - c \tanh(x + z)) \\
\dot{y} &= -\rho (ay + x^2) \\
\dot{z} &= (k - z - \frac{x}{2}).
\end{align*}$$

(7)
This set of equations characterizes a balance between advection and thermocline processes for some value of \((S, T_2, h)\). Physically this corresponds to a situation in which the western tropical Pacific SST \(T_1\) and thermocline depth \(h\) essentially decay towards \(T_r\) and 0, respectively.

### 3.2 The Layer Problem: The Critical Manifold and its Stability

The set

\[
M = \{ x \mid x + y + c - c \tanh(x + z) = 0 \} = \{ F(x, y, z) = 0 \}
\]

is important in both components of the singular limit. In the layer problem (equations \(\ref{eq:layer_problem} \)), \(M\) is the set of equilibrium points. As such, the stability of these points for fixed \((y, z)\) values can be computed by the linearization of the layer equation. We view \(y\) and \(z\) as parameters that affect both the location and stability of the equilibria. In the reduced problem (equations \(\ref{eq:reduced_problem} \)), we observe that \(M\) defines the set on which the slow \((y, z)\) dynamics are defined. In contrast to a “standard” parameter drift approach where \(y\) and/or \(z\) vary based on an explicit function of time, here \(y\) and \(z\) vary depending on the fast variable \(x\), and hence implicitly as a function of time. In the singular limit, the fast system equilibrates to a point in \(M\) and then the slow system evolves along \(M\). The importance of \(M\) cannot be overstated—it forms the backbone of complicated dynamical behavior—and it is referred to as the critical manifold.

Since the \(x'\) equation in \(\ref{eq:layer_problem} \) contains a product, the critical manifold has two components:

\[
M_0 = \{ x = 0 \}
\]

\[
M_s = \{ x + y + c - c \tanh(x + z) = 0 \} = \{ y = -x - c + c \tanh(x + z) \}. \tag{9}
\]

The first condition characterizes an extreme El Niño event \((x = 0, T_2 = T_1)\), depicted e.g. in Figure \ref{fig:critical_mantle}.

GSPT guarantees that for \(\delta\) small enough, our intuitive approach will work unless the Jacobian of the layer problem is 0. Computing the Jacobian, we get

\[
F_x = x[1 - \sech^2(x + z)] + [x + y + c - c \tanh(x + z)].
\]

\(M\) is attracting wherever \(F_x|_M < 0\) and repelling wherever \(F_x|_M > 0\). First, looking at the stability of \(M_0\), we see that

\[
F_x|_{M_0} = y + c - c \tanh(z).
\]

Therefore \(M_0\) is attracting where \(y < c \tanh(z) - c\) and repelling when \(y > c \tanh(z) - c\). This condition is crucial in determining the dynamical behavior near an extreme El Niño state \((x = 0)\).

\(F_x = 0\) along the curve \(y = c \tanh(z) - c\), and geometrically, this curve represents the intersection of \(M_0\) with \(M_s\). Thus, \(M_0\) is attracting below \(M_s\) and repelling above \(M_s\).

Turning to the stability of \(M_s\), we see

\[
F_x|_{M_s} = x[1 - c \sech^2(x + z_0)], \tag{10}
\]

which has three zeroes for fixed \(z_0\). There exist \(x_-(z_0) < x_+(z_0)\) such that \(c \sech^2(x_\pm + z_0) = 1\). Generically, there are three possible orders of these zeros: (1) \(x_- < x_+ < 0\), (2) \(x_- < 0 < x_+\), and (3) \(0 < x_- < x_+\). In each of these cases, let \(X_1 < X_2 < X_3\) be the roots of \(x[1 - c \sech^2(x + z_0)]\).

Then the left-most branch of \(M_s\), i.e. \(M_s \cap \{ x < X_1 \}\), is attracting, with stability alternating at each subsequent root. Thus \(M_s\) is attracting for \(X_1 < x < X_2\) as well as for \(x > X_3\). The lines

\[
L^\pm = \{ x = x_{\pm}(z) \} \cap M_s
\]
are called fold curves. As seen in Figure 3, fold curves separate the stable and unstable regions of $M_s$. Along the folds, the standard GSPT approach for normally hyperbolic critical manifolds breaks down. However, it is this degeneracy that allows for more complicated interaction between the fast and slow dynamics that lie at the heart of the interesting mathematical and dynamical behavior of the conceptual ENSO model.

### 3.3 The Reduced Problem: Dynamics on the Critical Manifold

Next, we consider the slow dynamics of the reduced problem (7). In general, a reduced problem describes a flow of reduced dimension restricted to a manifold given by an algebraic condition. Since $M$ is the union of the manifolds $M_0$ and $M_s$, we need to solve two separate reduced problems—one on each of the two manifolds.

The reduced problem on $M_0$, described by

\[
\begin{align*}
0 &= x \\
\dot{y} &= -\rho ay \\
\dot{z} &= k - z.
\end{align*}
\]

is simple because the global coordinate chart $x = h^0(y, z) = 0$ describes the manifold $M_0$. Moreover, the dynamics are already formulated in terms of the coordinate variables $y$ and $z$. Since (11) is a linear system, it is easy to see that $(y, z) = (0, k)$ is the unique globally attracting fixed point on $M_0$ (extreme El Niño case). It is worth noting that, while trajectories on $M_0$ will be drawn to this fixed point, it lies in the region where $M_0$ itself is unstable. This observation will play a major role in the global dynamics of (3) when $\delta > 0$.

Next we turn to the reduced problem on $M_s$, given by

\[
\begin{align*}
0 &= x + y + c - c\tanh(x + z) \\
\dot{y} &= -\rho(ay + x^2) \\
\dot{z} &= (k - z - \frac{y}{2}).
\end{align*}
\]
In this case we are not as lucky as we were for the problem on $M_0$; the fold lines $L^\pm$ indicate that we will be unable to formulate a global coordinate chart as $x = h^s(y, z)$. However, using the algebraic condition

$$y + x + c - c\tanh(x + z) = 0$$

we obtain a single coordinate chart, namely

$$y = h(x, z) = -x - c + c\tanh(x + z), \quad (13)$$

where we can study the whole reduced flow on $M_s$. This is done by differentiating the algebraic condition (13) and substituting it for the $\dot{y}$ equation in (12) to obtain

$$0 = \dot{y} - h_x \dot{x} - h_z \dot{z}$$
$$\dot{z} = (k - z - \frac{x}{2}).$$

Substitution and some minor rearranging yields

$$[1 - c \sech^2(x + z)] \dot{x} = \rho ah(x, z) + x^2 + c \left(k - z - \frac{x}{2}\right) \sech^2(x + z)$$
$$\dot{z} = \left(k - z - \frac{x}{2}\right), \quad (14)$$

Note that the system (14) is singular along the fold curves $L^\pm$ (denoted by green lines in Figure 4) since it is precisely the set $\{1 - c \sech^2(x + z) = 0\}$.

The system (14) can be desingularized by rescaling the time variable $s$ by a factor of $1 - c \sech^2(x + z)$. The new system, called the desingularized system, is

$$\text{Desingularized problem on } M_s \begin{cases} 
\dot{x} = \rho ah(x, z) + x^2 + c \left(k - z - \frac{x}{2}\right) \sech^2(x + z) \\
\dot{z} = [1 - c \sech^2(x + z)] \left(k - z - \frac{x}{2}\right). 
\end{cases} \quad (15)$$

The rescaling is quite powerful in that we are now able to define dynamics on the entirety of $M_s$, including the folds. Recalling condition (10), we see that the scaling factor changes signs across the fold curves $L^\pm$. The time orientation of trajectories is reversed in the region where $[1 - c \sech^2(x + z)] < 0$. As indicated in Figure 4, we are primarily interested in the region of phase space where $x < 0$. In fact, $x = 0$ is invariant, even for $\delta > 0$ in the full system (3). Therefore, trajectories starting in the region $x < 0$ will remain there for all time. Physically this means that no El Niño event can grow beyond the warm pool temperature $T_1$. When $x < 0$, $M_s$ is attracting wherever $[1 - c \sech^2(x + z)] > 0$. Thus, the rescaling reverses trajectories on the repelling branch of $M_s$ where the time variable is scaled by a negative factor.

In the desingularized system (15), it is easy to classify three types of special points of the reduced problem:

- Equilibria occur where $\dot{x} = 0$ and $k - z - x/2 = 0$. At these points, the scaling factor $[1 - c \sech^2(x + z)] \neq 0$.

- Regular fold points are fold points that are not equilibria of (15). That is, $[1 - c \sech^2(x + z)] = 0$ but $x \neq 0$.

- Folded singularities are equilibria of (15) where $\dot{z} = 0$ due to the rescaling. That is, folded singularities occur where $\dot{x} = 0$ and $[1 - c \sech^2(x + z)] = 0$, but $k - z - x/2 \neq 0$. The point labeled ‘FN’ in Figure 4 is an example of a folded singularity.
Some folded singularities lead to the formation of the small amplitude oscillations in an MMO. Similar to equilibria, folded singularities are classified by the eigenvalues of the linearization of the flow at the equilibrium. A folded singularity with real, negative eigenvalues, for example, is a stable folded node, while a folded singularity with complex conjugate eigenvalues with positive real part is an unstable folded focus. The ‘FN’ in Figure 4 labels a stable folded node.

3.4 Geometry of MMOs

3.4.1 Non-monotone SAOs

Folded nodes can produce MMOs with a suitable global return mechanism (Brøns et al., 2006; Desroches et al., 2012; Guckenheimer, 2008; Krupa and Wechselberger, 2010; Kuehn, 2011). In a 2D system such as (15), a node is an equilibrium point with two real eigenvalues of the same sign: a weak eigenvalue \( \mu_w \) and a strong eigenvalue \( \mu_s \) such that \( |\mu_w| < |\mu_s| \). For the folded node denoted ‘FN’ in Figure 4, we have

\[
\text{Eigenvalues at FN} \begin{cases} 
\mu_s & \approx -3.48, \\
\mu_w & \approx -0.13,
\end{cases}
\tag{16}
\]

so ‘FN’ is a stable node. Trajectories approach the node tangent to one of the eigenvectors. The strong stable manifold, corresponding to \( \mu_s \), is a single trajectory denoted by \( \gamma_s \), while all other trajectories approach the folded node in the direction of the eigenvector of \( \mu_w \). Trajectories that
approach the folded node from the left without hitting the fold line $L^-$ fill a region called the \textit{funnel} of the folded node. The strong stable manifold $\gamma_s$, denoted ‘SC’ in the left panel of Figure 4, bounds one side of the funnel.

The folded node is key to one mechanism for generating SAOs in the ENSO system when $\delta > 0$. As $\delta$ is increased from 0, the attracting and repelling sheets of the critical manifold perturb to invariant slow manifolds that no longer share the same boundaries along the fold lines. The slow manifolds twist in a region surrounding the vanished folded node point so that they continue to intersect along a finite set of trajectories. The number of intersections is related to the eigenvalues of the folded node [Benoît 1990, Wechselberger 2005]. The intersections of the slow manifolds partition the attracting slow manifold into rotational sectors consisting of trajectories that make different numbers of rotations as they pass through the folded node region. A key characteristic of these monotone SAOs is that the number of small amplitude oscillations has an upper bound determined by the geometry of the intersecting slow manifolds. Figure 5 depicts a few trajectories lying in different rotational sectors. Note that as the number of rotations grows, their amplitude becomes very small and the oscillations can hardly be seen in the figure [Desroches et al. 2012].

3.4.2 Monotone SAOs

The reduced system (14) has an equilibrium point that lies close to the folded node. As parameters are varied in the system, this equilibrium crosses the fold curve $L^-$ in a bifurcation that is called a \textit{folded saddle-node type II}. Figure 6 shows the relative location of the equilibrium of the singular limit.
Figure 6: Bifurcation diagram showing how close the system is to a folded saddle-node type II when $\rho = 0.5$, $k = 0.34$, and $c = 3.75$. A folded saddle-node type II occurs when (3) in its singular limit undergoes a transcritical bifurcation where one equilibrium is an ordinary singularity and the other is a folded singularity.

to the folded node as the parameter $a$ varies. The folded saddle-node type II bifurcation is located at the intersection of these two curves. The equilibrium itself changes from a sink to a saddle as it crosses $L^-$. In the full system with $\delta > 0$, the equilibrium undergoes a singular Hopf bifurcation at parameter values that are $O(\delta)$ close to where the equilibrium crosses $L^-$. The adjective singular here refers to the fact that the slow and fast time scales both play a role in the bifurcation: the imaginary eigenvalues of the equilibrium have magnitude $O(1/\sqrt{\delta})$ intermediate between the two time scales. For parameters to one side of this Hopf bifurcation, the equilibrium point is a saddle-focus with a real negative eigenvalue and a pair of complex eigenvalues with positive real parts. Due to the large relative magnitude of the imaginary parts of these eigenvalues, trajectories in the unstable manifold of the equilibrium spiral away with a large number of oscillations as the amplitude of the oscillations grows slowly. These growing oscillations constitute a second mechanism for generating SAOs. All trajectories that come close to the equilibrium, leave along its unstable manifold and acquire SAOs as they do so.

This behavior connects the multiple time scale analysis presented here to the Shilnikov analysis of chaotic behavior associated with homoclinic orbits to saddle-focus equilibria in three dimensional vector fields (Guckenheimer and Holmes, 1983). Shilnikov bifurcation was a mechanism proposed earlier to occur in ENSO models of the type studied here (Timmermann et al., 2003).

Folded nodes and singular Hopf bifurcation are two mechanisms for producing small amplitude oscillations in systems with two slow and one fast variable. For these SAOs to be embedded in MMOs, there must be a global return of trajectories that leave the SAOs. These global returns may have a singular limit as $\delta \to 0$ consisting of a singular cycle $\Gamma$ that concatenates trajectories of the reduced system with trajectories of the layer system. Below we find a singular cycle that approximates MMO orbits of the ENSO model.
3.4.3 MMOs in ENSO

Figure 7a shows a three dimensional phase portrait of an MMO in the ENSO model represented by both systems (3) and (5). Setting $\delta = 0$ produces the singular limit in which trajectories are concatenations of solutions to the reduced and layer equations (7) and (6). Here, we construct a singular cycle that approximates this MMO orbit and suggests its decomposition into slow and fast segments.

The singular cycle projected onto the $(x,z)$ plane is shown in the left panel of Figure 4. The cycle is composed of five segments. Beginning at the lower left corner which represents the La Niña state ($T_2 < T_1$) of the system following discharge of a large El Niño event, the first segment S1 is a trajectory of the reduced system on $M_s$ that lies in the funnel flowing to the folded node FN. The system recharges during this event; as the western thermocline depth increases, the temperature in the western Pacific $T_1$ increases and the zonal temperature gradient ($T_2 - T_1$) decreases. We anticipate that there may be SAOs with decreasing amplitude in this region when $\delta > 0$. From the folded node, there are a continuum of possible choices for the second segment of the singular cycle. (Recall that the desingularization process reversed the orientation of the reduced flow on $M_s$ between $L^+$ and $L^-$, so that trajectories flow away from the folded node in this strip.) We choose the second segment S2 to be the stable manifold of the equilibrium point EQ in the desingularized system. This segment is short, and not much appears to happen in the phase space except that the trajectory approaches the equilibrium, which is a saddle in the reduced system. In the full system, the equilibrium is a saddle-focus and SAOs of growing amplitude begin in this region.

Upon reaching the saddle EQ, the third segment F1 of the singular cycle is selected to be a jump along a trajectory of the layer equation to the sheet $M_0$ of the critical manifold. This represents a strong El Niño event. Trajectories do not cross $M_0$ since it is invariant in both the full and reduced ENSO models. The fourth segment S3 of the singular cycle is then a trajectory of the reduced system for $M_0$. Here the thermocline and eastern Pacific temperatures evolve on the slow time scale while the zonal temperature gradient remains small throughout the strong El Niño event. Where the singular cycle departs from $M_0$ is not clear: theoretical analysis of what happens when two sheets of a slow manifold intersect along a curve is incomplete and a subject for future work (Cortez, 2011). The choice we make is to continue the trajectory along $M_0$ until the value of $z$ attains the minimum observed on the MMO trajectory. From this point, the fifth segment F2 of the singular cycle is a fast jump back to the left hand sheet of $M_s$, discharging the strong El Niño event and completing a return to the initial point of the cycle.
The right panel of Figure 4 superimposes the MMO computed for parameter values $\delta = 0.1$, $\rho = 0.5$, $a = 2.55$, $c = 3.75$, and $k = 0.34$. on the singular cycle displayed in the left panel of Figure 1. The resemblance of the two is evident. Using the singular cycle, we can decompose the MMO into slow and fast segments. The small amplitude oscillations occur in the region of the reduced model phase plane close to the folded node FN and the equilibrium point EQ. The non-monotone SAOs related to the folded node mechanism are associated with oscillations in the folded node region, whereas the monotone SAOs due to the singular Hopf mechanism are associated with oscillations that grow along the unstable manifold of the equilibrium. The two mechanisms are not mutually exclusive, and determining which is prevalent in ENSO will involve comparison with signals in either real-world observation or output from coupled ocean-atmosphere general circulation models.

4 Summary and Discussion

Even though the decadal-scale bursting of strong El Niño events has been the focus of several recent studies [Kim and An (2011); Timmermann and Jin (2002); Timmermann (2003)], the underlying dynamics still remain elusive. Our paper provides the first insight into possible connections between MMO dynamics and El Niño bursting. We study the dynamical behavior of a conceptual model of the tropical Pacific climate system, which is based on three nonlinear ordinary differential equations. For realistic physical parameters the system exhibits small amplitude oscillations (SAO), which occasionally burst into large events. More specifically, the amplitude of the El Niño/La Niña events slowly increases, until reaching a threshold in phase space where a large El Niño event emerges. The event terminates rapidly as a result of the discharging process (Fig. 1, lower panel). The discharge is so strong, that the system overshoots into a maximum amplitude La Niña event. Its subsequent evolution follows again the growth of SAOs, until the threshold is reached and the cycle repeats itself.

The underlying equations can be written as a 1 fast, 2 slow system. The fast variable is associated with the east-west temperature gradient and its rapid adjustment to changes in vertical advection in the eastern tropical Pacific. The slow system captures the adjustment of the western tropical Pacific temperature via thermal relaxation and zonal advection and of the western tropical Pacific thermocline by changes in Sverdrup transport. To better understand the complex dynamical behavior we apply geometric singular perturbation theory to the set of conceptual ENSO equations.

In the specific limit of $\delta \to 0$, which represents either a very slow thermocline discharging process or a very efficient vertical advection, we find that the dynamics of a typical periodic orbit can be spliced together by concatenating trajectories of the decoupled fast and slow dynamics. It is shown that the existence of a folded node, which is characterized by a small El Niño amplitude ($y = -3.095$) plays a key role in organizing the dynamics. This point essentially becomes a point of no return for the rapid development into a strong El Niño event which follows the fast dynamics. The system can remain on the extreme El Niño manifold ($M_0$) for quite some time (Figs. 2, 5) during which the western tropical Pacific temperature slowly decreases as well as the western tropical thermocline depth. Upon reaching another threshold jump point at western tropical Pacific temperature $y \approx -1$ the system quickly discharges which leads to a rapid transition from $M_0$ onto $M_s$. From there it moves back slowly towards the folded node to resume its trajectory.

We have shown that a global return mechanism is present in this ENSO Recharge Oscillator model. Associated with this mechanism are two types of MMOs: those with monotone SAOs and those with non-monotone SAOs. The distinction between them can be seen clearly in Figure 5. Both are potential explanations of the interspersion of El Niño bursting with small amplitude oscillations. The key characteristic of the former is the bound on the number of small amplitude
oscillations, and for the latter it is the monotonically increasing amplitude of the small oscillations. Whether these can be distinguished in an ENSO signal from observations or large-scale computation is an exciting challenge.
