Gold(I)-Mediated Thiourea Organocatalyst Activation: A Synergic Effect for Asymmetric Catalysis

Anabel Izaga, Raquel P. Herrera,* and M. Concepción Gimeno*

Introduction

In the last decade, between the two main families of catalysts, namely, metal and enzymatic catalysis, a third complementary approach has emerged, organocatalysis,[1] which has become an important tool to provide efficient and environmentally friendly access to enantiomerically pure compounds, including many drugs and bioactive natural products.[2]

Although organocatalysis has experimented great progress in the field of homogeneous catalysis, the organocatalysts still require more improvement to emulate and reach the achievements reported with metal or enzyme catalysts. With this aim, many efforts have been directed towards the synthesis of more efficient organocatalysts through the use of several strategies. One of them has been the development of bifunctional organocatalysts,[3] following the multifunctional catalytic mode exhibited by enzymes. These complex systems have inspired the design of many catalytic systems such as chiral bifunctional thioureas/ureas,[4] among others, which keep simultaneous activation of the nucleophile and the electrophile involved in the process (Figure 1).

Another strategy to improve the reactivity of organocatalysts, which has received considerable attention in the last years, has been the use of two different catalysts in a cooperative way, a metal catalyst and an organocatalyst, which is called dual catalysis (Figure 2).[5] This idea has emerged as a promising strategy for developing new and more valuable processes, and also takes advantage of simultaneous activation of the electrophile as well as the nucleophile by two different, but compatible and synergically acting catalysts.

The enormous success of chiral urea and thiourea compounds as hydrogen-bond-donor organocatalysts in asymmet-
ric synthesis has led to a continuous improvement of these organocatalysts through the use of several modes of activation, trying to improve parameters such as catalysts loading, reaction time, and substrate scope for a given reaction. All these efforts made in the last years have materialized in several upgraded catalysts. Among them, Seidel and Ganesh have reported the use of an internal Brønsted acid forming a protonated thiourea catalyst (Figure 3a),[6] although it was not the most active catalyst in this work. Later, Smith’s group and Probst et al. developed new conformationally well-defined but flexible thiourea catalysts, stabilized by intramolecular hydrogen bonds (Figure 3b).[7,8] More recently, Herrera and co-workers have described the use of an external Brønsted acid (Figure 3c)[9] to improve the efficiency of the corresponding chiral thiourea catalysts.

The use of an internal Brønsted acid produced significant rate acceleration and only a slight improvement in enantioselectivity for the Friedel–Crafts reaction.[6] In contrast, the external Brønsted acid was able to assist thiourea catalysts as very effective catalytic species for promoting the enantioselective addition of indoles to nitroalkenes.[9] The synergic effect between both species was demonstrated to be higher than the effect promoted by each one separately and better results in terms of enantioselectivity and reactivity were reached than with the corresponding thiourea alone.[9] Mattson and co-workers have also developed hybrid transition metal catalysts which act as hydrogen bond donor catalysts such as urea palladacycles,[10] inspired at the same time in boronates ureas developed by the same research group (Figure 3). However, in these examples the authors only use nonchiral ureas.[10]

In the search of new types of activation of thioureas as organocatalysts, and taking into account this novel concept together with our experience in the chemistry of group 11 metals,[13] we were encouraged to use a Lewis acidic metal atom (AH = Brønsted acid).

In the context of our research program focused on the design and synthesis of more active organocatalysts, we report here an unprecedented mode of activation of thiourea organocatalysts through the use of metallic Lewis acids. A wide range of group 11 metal-thiourea complexes have been synthesized and used as single catalysts in asymmetric catalysis, taking advantage of the best part of both species in a synergic way.

Results and Discussion

To test our hypothesis, we started our study with the synthesis of a variety of group 11 metal complexes with thioureas as potential catalysts for the Friedel–Crafts alkylation reaction as a model process.

Thioureas T1-3 were chosen as model catalytic structures because they exhibit different electronic and steric properties (Figure 5). Moreover, T3 was the best catalyst in our previously developed works.[9,15]

The exploration was started with T1 presenting less steric hindrance and without electronegative groups in the aromatic ring. The straightforward preparation of the metal complexes 1a–g is shown in Scheme 1. There are neutral or cationic CuI, AgI, AuI, or AuIII species that have been perfectly identified and characterized by NMR spectroscopy (see Supporting Information).

Subsequently, the efficiency of these species in the benchmark reaction between indole 4 and nitrostyrene 5 was ana-

The results confirmed our hypothesis about the possible activation of a potential organocatalyst, because moderate to good yields and enantioselectivities were obtained in all the cases, whereas almost lack of reactivity was found with T1 (entry 12) or the metal precursor alone (entry 13), which proved the synergic effect between both species. Moreover, the new more hindered complexes likely make the transition state of this reaction more rigid and stable and consequently, able to induce enantioselectivity contrasting the results obtained with thiourea T1 (entry 12). Excellent reactivity values were found for the silver complexes [Ag(OTf)T1] 1a (Tf = trifluoromethanesulfonyl, entry 2) and [Ag(T1)]OTf 1e (entry 8), and promising selectivities were achieved for the gold species [Au(PPh3)T1]OTf 1d (entry 5) and [Au(T1)]OTf 1f (entry 10), with ee values of 42 and 30%, respectively. We can conclude that coordination of a Lewis acid to the thiourea organocatalyst T1 greatly enhances reactivity and selectivity, compared with the values obtained with this thiourea species alone.

These initial promising results encouraged us to examine other metal(M)–thiourea complexes varying the electronic properties of the thiourea catalyst. Thiourea T2 was the center of the subsequent study. As better values were obtained in terms of enantioselectivity with Au–T1 1d and 1f complexes and in terms of reactivity the best value was obtained with Ag–T1 1a, in the ensuing screening, different Ag–T2 and Au–T2 catalysts were designed and tested (Scheme 2 and Table 2).

In this case, the better ee values were found with complexes 2a and 2e (Table 2, entries 1 and 5, respectively), although in terms of reactivity complex 2e was the most active one (88%, entry 5), followed by 2f (60%, entry 6). In summary, the silver(I) 2c, the gold(I) 2a and 2f, and the gold(III) 2e species bearing two thiourea ligands showed better results, as previously observed for T1 with complexes 1e and 1f (Table 1, entries 6–10). As previously found for T1, T2 activated with a metal Lewis acid affords better results than T2 alone (entry 7, Table 2), which again supports our main idea. Moreover, the reaction rate was increased if using 10 mol% of complex 2e (entry 5) compared with that using 20 mol% of T2 alone (entry 7), probably because of the considerable decrease in the pKa of thiourea T2. With the aim of improving the reactivity state of this reaction more rigid and stable and consequently, able to induce enantioselectivity contrasting the results obtained with thiourea T1 (entry 12). Excellent reactivity values were found for the silver complexes [Ag(OTf)T1] 1a (Tf = trifluoromethanesulfonyl, entry 2) and [Ag(T1)]OTf 1e (entry 8), and promising selectivities were achieved for the gold species [Au(PPh3)T1]OTf 1d (entry 5) and [Au(T1)]OTf 1f (entry 10), with ee values of 42 and 30%, respectively. We can conclude that coordination of a Lewis acid to the thiourea organocatalyst T1 greatly enhances reactivity and selectivity, compared with the values obtained with this thiourea species alone.

These initial promising results encouraged us to examine other metal(M)–thiourea complexes varying the electronic properties of the thiourea catalyst. Thiourea T2 was the center of the subsequent study. As better values were obtained in terms of enantioselectivity with Au–T1 1d and 1f complexes and in terms of reactivity the best value was obtained with Ag–T1 1a, in the ensuing screening, different Ag–T2 and Au–T2 catalysts were designed and tested (Scheme 2 and Table 2).

In this case, the better ee values were found with complexes 2a and 2e (Table 2, entries 1 and 5, respectively), although in terms of reactivity complex 2e was the most active one (88%, entry 5), followed by 2f (60%, entry 6). In summary, the silver(I) 2c, the gold(I) 2a and 2f, and the gold(III) 2e species bearing two thiourea ligands showed better results, as previously observed for T1 with complexes 1e and 1f (Table 1, entries 6–10). As previously found for T1, T2 activated with a metal Lewis acid affords better results than T2 alone (entry 7, Table 2), which again supports our main idea. Moreover, the reaction rate was increased if using 10 mol% of complex 2e (entry 5) compared with that using 20 mol% of T2 alone (entry 7), probably because of the considerable decrease in the pKa of thiourea T2. With the aim of improving the reactivity

and enantioselectivity of this process, we tested the efficiency of T3 synthesizing the same promising metal complexes 3a–d containing Ag or Au (Scheme 3).

All these complexes were completely characterized and the data are collected in the Supporting Information. Subsequently, the efficiency of these species in the benchmark reaction between indole and nitrostyrene was analyzed and the results are reported in Table 3. As thiourea T3 reaches the best results in this reaction, and because we aimed to avoid high catalyst loading of thioureas as organocatalysts, we decided to test the reaction with only 5 mol% compared with the reported 20 mol% for T3.\(^{[9,15]}\)

The gold(I)–bis(thiourea) complex \(3d\) was the most active, leading to the best results in terms of reactivity and enantioselectivity (Table 3, entry 4). Remarkably, we used only 5 mol% of catalyst loading compared to 20 mol% in the former works with \(T3\).\(^{9,15}\) These data exceed those obtained with the catalyst thiourea \(T3\) alone despite the lower catalyst loading (entry 5).

To finely tune the optimal reaction conditions with \(T3\), we carefully checked the variation of other parameters such as solvent, temperature, and variation in the concentration of all species (Table 4), because we realized that small variations in all these parameters could play an important role in governing the enantioselectivity and reactivity of the process. Variations in the amount of indole afforded changes in the values of enantioselectivity and reactivity. However, at low temperature we discarded the use of only 1 equivalent of indole because the rate of the reaction would be too slow. An increase in the enantioselectivity was observed by lowering the reaction temperature to \(-15^\circ\text{C}\) (Table 5, entries 5–9) although the reaction rate was lower. Increasing the concentration of the reaction accelerates the rate of the process and better yields are obtained. Unfortunately, the large differences achieved at room temperature between the reaction performed with the thiourea \(T3\) alone or with \(3d\) were not maintained at low temperature, probably because of a different mode of coordination between the thiourea catalyst and the metal at different temperatures. The best solvent was found to be \(\text{CH}_2\text{Cl}_2\).

With the optimal reaction conditions in hand, and since one of our concerns in organocatalysis is the high catalyst loading we decided to investigate the changes of reactivity and selectivity between the thioureas \(T1–T3\) and the corresponding gold complexes [Au(thiourea)]\(\text{OTf}\), depending on the catalysts loading in the benchmark reaction (Table 5). \(T1\) in a 10 mol% of catalyst loading gives very poor values (entry 1), with a yield of only 19% and a racemic mixture. However, the gold complex [Au(T1)]\(\text{OTf}\) \(1f\) in a 10% produces a 65% yield and an ee of 40% (entry 2), which means a considerable increase in both reactivity and overall selectivity. The decrease in the catalyst loading to 3 mol% affords only slightly lower values of 51% and 32% ee (entry 3). The same tendency is observed with thiourea \(T2\), with values increasing from 35% yield and 26% ee (entry 6) to 64% and 48% for the gold complex \(2f\) (entry 7).

### Table 4. Screening of the reaction promoted by \(3d\)\(^{15}\)

[a] Amount of reagents: indole \(4\) (0.15 mmol) and nitrostyrene \(5\) (0.1 mmol). [b] Isolated yields after column chromatography. [c] Determined by chiral HPLC analysis (Chiralpak Daicel IA, 90:10 Hex/iPrOH, 1 mL min\(^{-1}\)). [d] Reaction performed with 1 equivalent of indole. [e] Reaction performed with 2 equivalents of indole.
Again, these values are maintained to a lowering of the catalyst amount up to 3%. For thiourea T3, which provided the best results in previous studies, the catalyst loading was lowered to 1 mol % without a significant decrease neither in the reactivity nor the enantioselectivity (entry 18). To illustrate this, in Figure 6 the comparative study between the thiourea T3 alone and the gold complex [Au(T3)2]OTf 3d is shown for a variation in the catalyst loading.

The effect of the metal over the electronic properties of the thiourea catalysts T3 is disclosed in the NMR spectra shown in Figure 7. At the same concentration (0.005 mmol catalyst and 500 µL CD2Cl2) in two NMR tubes both compounds, T3 and 3d, were analyzed at room temperature.

Some of the most relevant resonances in the thiourea catalysts T3 are downfield shifted because of coordination to the Au center in the new catalytic complex 3d. A displacement of 0.9 ppm (signal from 8.01 ppm to 9.00 ppm) was observed for the thiourea N–H hydrogen atom, and 0.27 ppm (signal from

[a] Experimental conditions: To a mixture of catalyst (mol %) and nitroalkene 5 (0.1 mmol) in CH2Cl2 (0.25 mL), indole 4 (0.15 mmol) was further added, in a test tube at room temperature. After the reaction time, product 6 was isolated by flash chromatography. [b] Isolated yields after column chromatography. [c] Determined by chiral HPLC analysis (Chiralpak IA, 90:10 Hex/iPrOH, 1 mL min⁻¹). [d] Racemic.
6.98 ppm to 7.25 ppm) was observed for the aminoindanol N–H hydrogen atom of T3. Additionally, a downfield shifting of the OH group in the aminoindanol scaffold was observed of 0.56 ppm (signal from 2.23 ppm to 2.79 ppm). These displacements would be in agreement with our initial hypothesis and the better values of yield found with complex 3d with a more acidic thiourea skeleton. Both aliphatic CH–Het (Het = heteroatom) protons experience an upfield shifting (Figure 8).

**Mechanistic study**

Interestingly, the sense of the stereoselection in product 6 was in all cases the same as that expected if (R,R)-aminoindanol thioureas T2 and T3 were the sole catalysts. This shows that chirality is preferentially governed by the thiourea catalyst, which prompted us to conclude that the metal is only activating the thiourea moiety rather than simply driving by itself some of the reagents into the transition state. Moreover, the metal does not activate this process as above mentioned. Based on our previous works (for TSI and TSII),[9,15] we proposed TSIII as the plausible mode of activation in this reaction (Figure 9).

Assumably, the M-thiourea catalyst complex is the most reactive species, owing to the increased acidity of the NH in the thiourea after a synergetic coordination with the metal atom, thereby increasing the reaction rate and favoring the activation of the substrates. Furthermore, improvement in the enantioselectivity could be attributed to the formation of a more rigid assembly in the transition state TSIII as combination of both structures. This mode of activation TSIII (Figure 9) would agree with the fact that the observed enantiomer is given by the enantioselectivity of the thiourea organocatalyst employed as obtained in the previous works.[9,15]

As the gold atom is joined to two thiourea ligands in the best catalyst 3d, we cannot discard that the same process occurs by both thiourea organocatalysts, which was supported by the better yields and enantioselectivities observed in this really congested catalyst, in comparison with the thiourea T3 alone.

**Conclusions**

The unprecedented activation of thiourea organocatalysts through the coordination of a metallic Lewis acid was described. Coordination of the metal produces the consequent acidification of the thiourea protons achieving a better activity in terms of conversion and selectivity in the benchmark reaction of addition of indole to nitrostyrene. Three thiourea organocatalysts T1–T3 with different electronic and steric requirements were used to prepare several group 11 metal complexes 1–3. All the tested M–thiourea complexes provided better results than the thioureas alone, and the gold complexes [Au(thiourea)2]OTf were the best in terms of reactivity and selectivity. After achieving the optimum experimental conditions a comparison of the activity of the thioureas versus the [Au(thiourea)2]OTf complexes in different catalysts loading were performed. As expected the higher values were achieved with thiourea T3 and [Au(T3)2]OTf 3d showing a great improvement in the reactivity and selectivity values of the metal thiourea complex compared with the thiourea alone. It was possible to reduce the catalyst loading to 1 mol% without a significant decrease of the activity, although optimum values are afforded with 3 mol% catalyst loading. Thus, a new concept was proved demonstrating the cooperative effect between a metallic Lewis acid and thioureas providing metal complexes acting as organocatalysts.
Experimental Section

Instrumentsation

Mass spectra were recorded on a BRUKER ESQUIRE 3000 PLUS, with the electrospray (ESI) technique. The attenuated total reflection (ATR–FTIR) spectra of solid samples were recorded on a PerkinElmer FT-IR spectrometer equipped with a universal ATR sampling accessory. 1H and 13C 1H APT NMR, including 2D experiments, were recorded at room temperature on a BRUKER AVANCE 400 spectrometer (1H, 10.6 MHz; 13C, 75.5 MHz; 19F, 282.3 MHz), with chemical shifts (ppm) reported relative to the solvent peaks of the deuterated solvent.

Starting materials

All reactions were performed under air atmosphere and solvents were used as received without further purification or drying. The complexes [Ag(OTf)(PPh3)2] and [Au(OTf)(PPh3)2] were prepared following published procedures. [Au(OTf)(PPh3)2] was obtained from [AuCl(PPh3)2] with AgOTf in dichloromethane. All other reagents were commercially available.

NMR spectra of all synthesized catalysts and the characterization of all new compounds are reported in the Supporting Information.

General procedure for the catalyzed Friedel–Crafts alkylation reaction

To a mixture of catalyst M–(T1–T3) (1–10 mol%), and nitroalkene S (0.1 mmol) at the indicated temperature (n.t. or −15 °C) in a test tube with CH2Cl2 (0.25 mL), indole 4 (0.15 mmol) was further added. After the appropriate reaction time (see Tables 1–5), the residue was purified by column chromatography (SiO2; hexane/ EtOAc, 8:2) to afford final adduct 6. Yields and enantioselectivities are reported in Tables 1–5. Spectral and analytical data for compound 6 is in agreement with those previously reported in the literature [15a].
