Abstract

We consider the Item Pricing problem for revenue maximization in the limited supply setting, where a single seller with \( n \) items caters to \( m \) buyers with unknown subadditive valuation functions who arrive in a sequence. The seller sets the prices on individual items, and the price of a bundle of items is the sum of the prices of the individual items in the bundle. Each buyer buys a subset of yet unsold items so as to maximize her utility, defined as her valuation of the subset minus the price of the subset. Our goal is to design pricing strategies, possibly randomized, that guarantee an expected revenue that is within a small factor \( \alpha \) of the maximum possible social welfare – an upper bound on the maximum revenue that can be generated by any pricing mechanism.

Much of the earlier work has focused on the unlimited supply setting, where selling items to some buyer does not affect their availability to the future buyers. Recently, Balcan et. al. [4] studied the limited supply setting, giving a simple randomized algorithm that assigns a single randomly chosen price to all items (uniform pricing strategy) in the beginning, and never changes it (static pricing strategy). They showed that this strategy guarantees an \( 2^{O(\sqrt{\log n \log \log n})} \) approximation, and moreover, no static uniform pricing strategy can give better than \( 2^{\Omega(\log^{1/4} n)} \) approximation.

We relax the space of strategies considered in two directions: we consider dynamic uniform strategies, which can change the price upon the arrival of each buyer but the price on all unsold items is the same at all times, and static non-uniform strategies, which can assign different prices to different items but can never change it after setting it initially. Dynamic strategies can be especially useful in online stores, where it is easy to show different prices to different buyers. We design dynamic and non-uniform pricing strategies that give a poly-logarithmic approximation to maximum revenue, significantly improving upon the previous \( 2^{O(\sqrt{\log n \log \log n})} \) approximation. We also give a strengthened lower bound of \( 2^{\Omega(\sqrt{\log n})} \) for approximation factor achieved by any static uniform pricing strategy. Thus in the limited supply setting, our results highlight a strong separation between the power of dynamic and non-uniform pricing versus static uniform pricing. To our knowledge, this is the first non-trivial analysis of dynamic and non-uniform pricing schemes for revenue maximization.
1 Introduction

We consider the following Item Pricing problem. Consider a finite set of items owned by a single seller, who wishes to sell them to multiple prospective buyers. The seller can price each item individually, and the price of a set of items is simply the sum of the prices of the individual items in the set. The buyers arrive in a sequence, and each buyer has her own valuation function $v(S)$, defined on every subset $S$ of items. We assume that the valuation functions to be subadditive, which means that $v(S) + v(T) \geq v(S \cup T)$ for any pair of subsets $S, T$ of items. For some results, we shall assume the valuations to be XOS, that is, they can be expressed as the maximum of several additive functions.

If a buyer buys a subset $S$ of items, her utility is defined as her valuation $v(S)$ of the set minus the price of the set $S$. Moreover, we assume the limited supply setting where a buyer can buy only yet unsold items. We assume that every buyer is selfish and rational, and thus always buy a subset of items that maximizes her utility. The strategy used by the seller in choosing the prices of the items is allowed to be randomized, and is referred to as a pricing strategy. The revenue obtained by the seller is the sum of the amounts paid by each buyer, and our goal is to design pricing strategies that maximize the expected revenue of the seller. This problem is made difficult by the fact that the seller has no knowledge of the valuation functions of the buyers, apart from the promise that they are subadditive. This is, for instance, in contrast to the Bayesian mechanism designs for revenue maximization, which assume that the valuation functions come from a known prior distribution. Optimal mechanisms, such as that given by Myerson [18], exist under this knowledge.

Pricing Strategies: A uniform pricing strategy is one where at any point of time, all unsold items are assigned the same price. The seller may set prices on the items initially and never change them, so that cost of an (unsold) item is the same for every buyer. We call such a strategy to be a static pricing strategy. Static pricing is the most widely applied pricing scheme till date. Alternatively, a seller may set fresh prices on the arrival of each buyer (without knowing the buyer’s valuation function) – we shall call this a dynamic pricing strategy. Dynamic strategies have become more widely applicable with the introduction of online stores, since it is quite easy for online stores to show different prices to different customers. However, a dynamic strategy in which the price of an item fluctuates a lot may not be desirable in some applications. So we introduce an interesting subclass of dynamic strategies, called dynamic monotone pricing strategies, where the price of an item can only decrease with time.

Social Welfare: An allocation of items involves distributing the items among the buyers, and the social welfare of an allocation the sum of the buyers’ valuations for the items received by each of them. We denote the maximum social welfare, achieved by any allocation, by OPT. We measure the performance of a pricing strategy as the ratio of the maximum social welfare against the smallest expected revenue of the strategy, for any adversarially chosen ordering of the buyers. (Some of our results, where it will be explicitly stated, shall consider expected revenue under the assumption that the order in which buyers arrive is uniformly random.) If this ratio is at most $\alpha$ on any instance (where $\alpha$ can depend on the size of the instance), we say that the strategy achieves an $\alpha$-approximation. Note that the maximum social welfare is an upper bound on the revenue the seller can obtain under any circumstance. In fact, there exists simple instances with $n$ items and a single buyer where the maximum social welfare is $\log n$, but the revenue can never exceed 1 for any pricing function [4]. Thus we are comparing the performance of our strategies against a bar that is significantly higher than the optimal strategy, and we can never hope to achieve anything better
than a logarithmic approximation. Our general goal is to design pricing strategies that achieve polylogarithmic approximation.

**Related Work:** The Item Pricing problem is closely related to the extensive body of literature in combinatorial auctions [7], which is the setting as described above, except that the buyers need not be arriving in a sequence but instead may place simultaneous bids on the items. A lot of recent literature has focused on social welfare maximization. This includes efficient approximation algorithms for computing maximum social welfare given oracle access to the valuation functions (eg. [11]), as well as on efficiently computable mechanisms that maximize social welfare and are truthful (eg. [17, 16, 10, 9]). For the first problem, Feige [11] gave a constant approximation for subadditive buyers, while for the second problem, Dobzinski et. al. [10, 9] gave logarithmic approximation when buyers have XOS valuations and subadditive valuations respectively. The mechanism achieving this approximation is in fact a static uniform pricing strategy.

A fair amount of research has focused on algorithms and truthful mechanisms for revenue maximization as well, but it has mostly considered the unlimited supply setting [15], where unlimited number of copies of each item is available to the seller. So one buyer receiving an item does not stop another buyer receiving the same item. Thus, the order in which buyers arrive has no effect on the performance of the mechanism, and in fact, the buyers can be handled independently. Some research has been directed towards developing new truthful mechanisms that maximize revenue [3, 12, 13], while others have focused on designing strategies for item pricing that maximizes revenue. The item pricing problem has received special attention because it is and has been the most widely applied mechanism for a seller wishing to sell items to potential buyers. All the research has focused only on designing static strategies (eg. [14, 2, 1, 6, 8]), and moreover, some of them have restricted their attention to finding envy-free pricing, which implies that the buyers come simultaneously, and the pricing must ensure that two buyers does not seek the same item. Moreover, most of these works assume severely restricted classes of valuation functions. For example, [14, 2] assume that all buyers are single-minded bidders. Their strategies were not only static but also uniform. Unsurprisingly, finding envy-free pricing is hard [8], and their results do not extend to more general buyer valuations such as XOS or subadditive. In all this work, the performance of a strategy has been measured as the ratio of the maximum social welfare to the expected revenue obtained.

More recently, Balcan, Blum and Mansour [4] considered static pricing strategies with the objective of revenue maximization, in the limited supply setting, with subadditive buyer valuations. In the unlimited supply setting, they designed a pricing strategy that achieve revenue which is logarithmic approximation to the maximum social welfare even for general valuations. The strategy, again, was a uniform strategy. This result was also proved independently in [5]. However, in the limited supply setting, they could only get a $2^{O(\sqrt{\log n \log \log n})}$ factor approximation using a static uniform strategy. Crucially, they ruled out the existence of static uniform strategies that achieve anything better than a $2^{\Omega((\log n)^{1/4})}$ approximation, even if the buyer valuations are XOS, and the ordering of buyers is assumed to be chosen uniformly at random. Thus their result distinguished the limited and unlimited supply settings. This impossibility of getting a good (polylogarithmic) approximation is a consequence of being restricted to static uniform strategies, and it remains impossible even if the seller knew the buyer valuations, and had unlimited computational power. Further, almost all mechanisms in these related problems have only used a single price for all items. It is, therefore, natural to consider dropping one of these restrictions, namely, look at dynamic uniform strategies and static non-uniform strategies, both of which use multiple prices, and attempt to find better guarantees on the revenue.
### Our Results and Techniques

The table below summarizes our results on the Item Pricing problem in the limited supply setting, along with relevant earlier work. Our contributions are labeled with the relevant theorem numbers.

We strengthen the hardness result of Balcan et. al. [4] by constructing instances with XOS valuations where uniform pricing functions cannot achieve any better than a $2^{O(\sqrt{\log n})}$ approximation, even if the seller knew the buyer valuations, and had unlimited computational power. Our basic construction is essentially similar to one given in [4]. We further extend our construction so that all buyers have the same XOS valuation function, so that the revenue is small for any order of buyers. Alternatively, we can extend it so that every buyer has an XOS buyer valuation (possibly different from the other buyers) that can be expressed as the maximum of three additive functions.

In contrast, we design a simple randomized dynamic uniform pricing strategy such that its expected revenue is $O(\log^2 n)$ approximation of the optimal social welfare, when the valuation functions are subadditive. The strategy randomly chooses a threshold at the beginning, and then in each round, randomly chooses a price above the threshold (but less than $OPT$) and puts this price on each unsold item. By using a fresh random price (from a suitable set of prices) in each round, we guarantee, in expectation, to collect a large fraction of the revenue that can be obtained in that round from the remaining items.

The dynamic uniform pricing strategy described above achieves a high revenue, but requires random fluctuation in the price of an unsold item. This may not be a desirable property in some applications. We design a dynamic monotone uniform pricing strategy where the price of any unsold items only decreases over time. We show that if the ordering of buyers is assumed to be
uniformly random, that is, all permutations of buyers are equally likely, then the expected revenue is an $O(\log^2 n)$ approximation of the optimal social welfare. The strategy is in fact deterministic provided the seller knows estimates of $OPT$ and $m$ up to a constant factor. Deterministic strategies giving good approximation in such limited information settings are rare. We emphasize here that our lower bound for static uniform pricing holds for any ordering of buyers.

We show that the performance of our dynamic uniform pricing strategies are almost optimal among all dynamic uniform strategies, by showing that even if the seller knew the buyer valuations, had unlimited computational power, and could even force a particular ordering of the buyers, there exists instances with XOS valuations where the seller can achieve a revenue of at most $OPT(\log \log n)^2 / \log^2 n$ if she is restricted to choosing a uniform dynamic pricing.

All our algorithms as well as the algorithms in [4] assume that $OPT$ is known to the seller up to a constant factor. Moreover, our dynamic monotone strategy assumes that the number of buyers $m$ is known to the seller up to a constant factor. As Balcan et. al. [4] pointed out, for any parameter that is assumed to be known up to a constant factor, if the seller instead knows an upper bound of $H$ and a lower bound of $L$ on the optimum, then this assumption can be removed by guessing $OPT$ with a suitable distribution, worsening the approximation ratio by a factor of $\Theta(H/L)$. If the seller instead knows that $OPT \geq 1$, but knows no upper bound, then the assumption can be removed by worsening the approximation ratio by a factor of $\Theta(\log x(\log \log x)^2)$ in the approximation, where $x$ is the said parameter.

Finally, we give a static non-uniform strategy that gives an $O(m \log \ell \log^3 n)$-approximation if the buyers’ valuations are XOS valuations that can be expressed as the maximum of $\ell$ additive components. Note that when the order of buyers is adversarial, the hard instance for static uniform pricing has only two buyers, and their valuation functions are the maximum of $o(\log n)$ additive functions components. In particular, our strategy gives polylogarithmic (in $n$) approximation when the number of buyers are small (polylogarithmic in $n$), and has XOS valuations which are the maximum of quasi-polynomial (in $n$) additive components. It is worth noting that our lower bound for dynamic uniform strategies also satisfies these properties.

## 2 Preliminaries

In the Item Pricing problem, we are given a single seller with a set $I$ of $n$ items that she wishes to sell. There are $m$ buyers, each with their own valuation function defined on all subsets of $I$. A buyer with valuation function $v$ values a subset of items $S \subseteq I$ at $v(S)$. The buyers arrive in a sequence, and each buyer visits the seller exactly once. The seller is allowed to set a price on each item, and the price of a subset of items is the sum of the prices of items in that subset. For every item sold to the buyers, the seller receives the price of that item. Note that an item can be sold at most once. So a seller can only offer those items to a buyer that has not been sold to any previous buyer. The revenue obtained by the seller is the sum of the prices of all the sold items.

Each buyer buys a subset of the items shown to her that maximizes her utility, which is defined as the value of the subset minus the price of the subset. This is clearly the behavior that is most beneficial to the buyer. The Item Pricing problem is to design (possibly randomized) pricing strategies for the seller that maximizes the expected revenue of the seller.

Unless noted otherwise, all our algorithmic results will assume that the seller has no knowledge of the order of arrival of the buyers, total number of buyers, or the valuation functions of buyers. We refer to a setting as the full-information setting if all these parameters are known to the seller.
Valuation Functions: Throughout this paper, we will assume that the buyer valuation function \( v \) is subadditive, which means that \( v(S) + v(T) \geq v(S \cup T) \) \( \forall S \subseteq I, T \subseteq I \). Unless explicitly stated otherwise, this will be the only assumption on the buyer valuation functions. For some results, we shall assume the buyer valuations to be more restrictive than subadditive.

**Definition 2.1** A subadditive valuation function \( v \) is called an XOS valuation if it can be expressed as \( v(S) = \max \{ a_1(S), a_2(S), \ldots, a_\ell(S) \} \) \( \forall S \subseteq I \) on all subsets of items \( S \), where \( a_1, a_2, \ldots, a_\ell \) are non-negative additive functions. The functions \( a_1, a_2, \ldots, a_\ell \) are referred to as the additive valuation components of the XOS valuation \( v \). We say that \( v \) is an \( \ell \)-XOS function if it can be expressed using at most \( \ell \) additive valuation components.

We note that a 1-XOS function is simply an additive function, that all XOS valuations are subadditive, and that not all subadditive valuations can be expressed as XOS valuations.

Pricing Strategies: We will study the power of some natural classes of pricing strategies.

**Definition 2.2** A pricing strategy is said to be static if the seller initially sets prices on all items, and never changes the prices in the future. A pricing strategy is said to be dynamic if the seller is allowed to change prices at any point in time. A dynamic pricing strategy is also said to be monotone if the price of every item is non-increasing over time.

**Definition 2.3** A pricing strategy is said to be uniform if at all points in time, all unsold items are assigned the same price.

2.1 Notation

For a buyer \( B \) with a valuation function \( v \), we use \( \Phi(B, I, p) \) to denote a set of items that the buyer \( B \) may buy when presented with set \( I \) of items, each of which are priced at \( p \). Since \( v(S) - p|S| \) is the utility if the buyer buys the set \( S \), so \( \Phi(B, I, p) = \arg\max_{S \subseteq I} v(S) - p|S| \) maximizes the utility. Note that there may be multiple possible sets that maximize the utility. In this paper, when we make a statement involving \( \Phi(B, I, p) \), the statement shall hold for any choice of these sets. We shall denote the maximum utility as \( U(B, I, p) \); note that in contrast to \( \Phi(B, I, p) \), the value \( U(B, I, p) \) is uniquely defined. When the underlying buyer \( B \) is clear from the context, we shall denote these two values as \( \Phi(I, p) \) and \( U(I, p) \) respectively. Moreover, if the set of available items \( I \) is also clear from the context, then we shall denote these two values as \( \Phi(p) \) and \( U(p) \) respectively. For any set \( S \) and a buyer with valuation function \( v \), we define \( H_v(S) = \max_{S' \subseteq S} v(S') \) as the maximum utility the buyer can get if all items in \( S \) are offered to her at zero price.

**Definition 2.4** We say that a set of items \( S \) is supported at a price \( p \) with respect to some buyer \( B \) with valuation function \( v \), if \( B \) buys the entire set \( S \) when the set \( S \) is presented to \( B \) at a uniform pricing of \( p \) on each item.

The following lemma follows easily from the fact that the valuation functions are subadditive, and was proved by Balcan et. al. [4].

**Lemma 2.1** Let \( S \) be a set of items that is supported at price \( p \) with respect to a buyer \( B \) with valuation function \( v \). Then \( v(S') \geq p|S'| \) for all \( S' \subseteq S \).
A pricing strategy is said to achieve an $\alpha$-approximation if the expected revenue of the strategy $E[R]$ is at least $\OPT/\alpha$.

Unless stated otherwise, the expected revenue is computed with adversarial ordering of the buyers, that is, the ordering that minimizes the expected revenue of the strategy. In other words, we require a strategy to work well irrespective of the order of buyers in which they arrive.

Note that $\OPT$ is not a tight upper bound on the maximum revenue that can be achieved by any pricing strategy, even with full knowledge of buyer valuations and unbounded computational power. In fact, the following example was given in Balcan et. al. [4]: if there is a single buyer with valuation function $v(S) = \sum_{i=1}^{\lfloor S \rfloor} 1/i$, then for any pricing of the $n$ items, the revenue is at most 1, while $\OPT = \Theta(\log n)$. This shows that nothing better than a logarithmic approximation can be achieved in the absence of any other assumption on the buyer valuations.

2.3 The Single Buyer Setting with Uniform Pricing Strategies

Balcan et. al. [1] considered the setting where there is an unlimited supply of each item, so that no buyer is affected by items bought before her arrival. In particular, if there is only a single buyer, then there is no distinction between limited and unlimited supply, as long as the buyer never wants more than one copy of the same item. For the single buyer case, Balcan et. al. [4] gave an $O(\log n)$ approximation, and in the process proved some lemmas that will be useful for our algorithmic results in the limited supply setting as well.

Suppose a set $S$ is being shown to a buyer $B$ with valuation function $v$. The optimal social welfare in this single buyer instance is $H_v(S)$. We consider setting a uniform price, that is, the same price on all items. The following lemma states that the number of items bought monotonically decreases as the price on the items is increased. It was proved by Balcan et. al. [4],
Thus we get that \( \sum \Phi(p) \leq |\Phi(p)| \). Thus there exist prices \( \infty = q_0 > q_1 > \ldots > q_l = q_{l+1} = 0 \) and integers \( 0 = n_0 < n_1 < \ldots < n_t \leq |S| \) such that when items in \( S \) are uniformly priced at \( p \in [q_{l+1}, q_l) \) there is a subset \( S' \subseteq S \) of size \( n_t \) that is supported at price \( p \), and the utility \( U(p) \) of the buyer \( B \) satisfies

\[
U(p) = U(q_t) + n_t(q_t - p)
\]

(1)

Since the empty set maximizes utility when the price is \( q_1 \), we get that \( U(q_1) = 0 \). Moreover, the utility at price \( q_{l+1} = 0 \) is \( U(q_{l+1}) = H_v(S) \). Thus we get that \( H_v(S) = \sum_{t=1}^l n_t(q_t - q_{t+1}) \).

The following lemma is a slight variation of Lemma 8 of [4].

**Lemma 2.2** (Lemma 6 of [4]) Suppose a buyer \( B \) is offered a set \( S \) of items using a uniform pricing. Then for any \( p > p' \geq 0 \), if \( B \) buys \( \Phi(p) \) if all items are priced at \( p \), and \( \Phi(p') \) if all items are priced at \( p' \), then \( |\Phi(p)| \leq |\Phi(p')| \).

Suppose a set \( H \) uniformly priced. Let \( f \) be any number such that \( \Phi(p) \geq |S|p \). Let \( U \) be any function. Since the empty set maximizes utility when the price is \( 0 \), \( U \) is being shown to a buyer \( B \) if all items are priced at \( p \).

Almost all our algorithms use the following lemma, which was implicitly mentioned in the Appendix of [4]. It tells us that strategies can be allowed to assume that it approximately knows the value of some parameters, as long as the parameters are not too large, since these assumptions can be removed by guessing the value of these parameters and getting it correct with inverse-polylogarithmic

**Lemma 2.3** Suppose a set \( S \) is being shown to a buyer \( B \), with valuation function \( v \), using a uniform price. Let \( H' \) be any number such that \( H' \geq H_v(S) \). Let \( \gamma > 1 \), and let \( \int f \mathbb{d}x = H' / \gamma^k \).

Then, for any \( k \geq 0 \), we have \( \sum_{t=1}^k \int f \mathbb{d}x \geq H_v(S) - |S|H'/\gamma^k \).

**Proof:** Since \( H_v(S) = \sum_{t=1}^l n_t(q_t - q_{t+1}) \), it can be seen as an integral of the following step function \( f \) from \( q_{l+1} = 0 \) to \( q_1 \): in the range \([q_{l+1}, q_l)\), \( f \) takes the value \( n_t \). So we can upper bound \( H_v(S) \) by an upper integral of \( f \). Note that \( |f(p) - \Phi(p)| \leq |S| \), and also that \( f \) is a decreasing function. Since \( p[0] = H' \geq H \geq q_1 \), we get

\[
H_v(S) = \sum_{t=1}^l n_t(q_t - q_{t+1}) = \int_0^{q_1} f(x)dx
\]

\[
\leq \int_0^{p[k]} f(x)dx + \sum_{t=0}^{k-1} (p[t] - p[t+1])f(p[t+1])
\]

\[
\leq \int_0^{p[k]} f(x)dx + \sum_{t=0}^{k-1} (\gamma - 1)p[t]f(p[t+1])
\]

\[
= (\gamma - 1) \int_0^{p[k]} f(x)dx + |S|p[k]
\]

Thus we get that \( \sum_{t=1}^k \int f \mathbb{d}x \geq H_v(S) - |S|H'/\gamma^k \). □

Briefly, Lemma 2.3 will be used as follows: if one of \( \{H', H'/2, H'/4 \ldots H'/2^k \} \) is chosen uniformly at random and set as the uniform price for all items in \( S \), then for a sufficiently large choice of \( k \), the revenue obtained is \( \Omega(H_v(S)/k) \). This will happen when the right-hand-side of the equation in the lemma evaluates to \( \Omega(H_v(S)) \). We shall frequently use this lemma, and with \( H' = \Theta(H) \), our choice of \( k \) will be logarithmic in the number of items.

**2.4 Optimizing with Unknown Parameters**

Almost all our algorithms use the following lemma, which was implicitly mentioned in the Appendix of [4]. It tells us that strategies can be allowed to assume that it approximately knows the value of some parameters, as long as the parameters are not too large, since these assumptions can be removed by guessing the value of these parameters and getting it correct with inverse-polylogarithmic
probability. The lemma below is applicable to the Item Pricing problem with multiple buyers, and to both static and dynamic pricing strategies.

**Lemma 2.4** Consider a pricing strategy $S$ that gives an $\alpha$-approximation in expected revenue, provided the seller knows the value of some parameter $x$ to within a factor of 2. Then if the seller instead only knows that $L \leq x < H$, there exists a pricing strategy $S'$ that gives an $O(\alpha \log(H/L))$ approximation in expected revenue, where $L$ and $H$ are powers of 2. If the seller instead only knows that $x \geq 1$ but no upper bound, then for any constant $\epsilon > 0$, there exists a pricing strategy $S''$ that gives an $O(\alpha \log x (\log \log x)^{1+\epsilon})$ approximation in expected revenue.

**Proof:** We construct a pricing strategy by approximately guessing the value of $x$, up to the nearest power of 2, using a suitable distribution, at the beginning, and using this estimate in the given pricing strategy. Our revenue is assured only when our guess is correct, and we count only that revenue in our analysis.

In the case where $L$ and $H$ are given, we guess $x$ from the set $\{L, 2L, 4L \ldots H\}$, so that our guess of $x$ is correct within a factor of 2, with probability at least $\Omega(1/\log(H/L))$. Since the given pricing strategy gives an expected revenue of $\Omega(\text{OPT}/\alpha)$ when the guess is correct within a factor of 2, we get an expected revenue of at least $\Omega(\text{OPT}/\alpha \log(H/L))$.

In the second case, where the seller only knows that $x \geq 1$, then we guess that $x = 2^i$ with probability $\frac{1}{c(1+\epsilon)i}$, where $c = \sum_{i=1}^{\infty} 1/i\log^{1+\epsilon}i$, which is finite. If $x$ is between $2^i$ and $2^{i+1}$, then the probability of guessing $x$ correctly within a factor of 2 is at least $\Omega(1/\log x (\log \log x)^{1+\epsilon})$, so the expected revenue is at least $\Omega(\text{OPT}/(\alpha \log x (\log \log x)^{1+\epsilon}))$. $\Box$

### 3 Improved Lower Bounds for Static Uniform Pricing

We show some lower bounds for static uniform pricing. The core of our construction is the same as the lower bound construction in Balcan et. al. [4], but with improved parameters, and our lower bound almost matches the upper bound in [4]. We are also able to strengthen our construction to the case of identical buyers as well as to the case where each buyer uses simple XOS functions with only 3 additive components. The following theorem summarizes our lower bound results about static uniform pricing.

**Theorem 3.1** There exists a set of buyers with XOS valuations, such that if the seller is restricted to a static uniform pricing strategy, then even in the full information setting, for any choice of price, the revenue produced is at most $\text{OPT}/2^{\Omega(\sqrt{\log n})}$, where $n$ is the number of items. Additionally, one of the following (but not both) can also be ensured, with the revenue still being at most $\text{OPT}/2^{\Omega(\sqrt{\log n})}$:

- The valuations of all the buyers can be expressed as 3-XOS functions.
- All buyers have identical valuation function.

We now present the proof of Theorem 3.1. We first construct an instance with two buyers whose valuations consist of only three additive components each, such that if buyer 1 arrives before buyer 2, then the revenue obtained will satisfy the required upper bound. This part of our construction is very similar to that given in [4], with some changes in the parameter that allows us to improve the lower bound result from $2^{\log^{1/4}n}$ to $2^{\Omega(\sqrt{\log n})}$. We shall then extend this construction to instances
where no ordering of buyers gives a high revenue, where all buyers have identical valuations and finally where all buyers have 3-XOS valuations.

**A hard two-player instance:** Let \( X > 1 \) and \( Y < 1 \) be two parameters that shall be fixed later. Consider an instance of the problem as described below. Let \( n_0 \) be a positive parameter, and as we shall see, the number of items will be between \( n_0 \) and \( 2n_0 \). There are two buyers with buyer valuations \( v_1 \) and \( v_2 \). Let \( S_0, S_1, \ldots, S_{6k+2} \) be a partition of items, where \( k = \lfloor \sqrt{\log n_0}/3 \rfloor \). There is a subset \( S_i' \subseteq S_i \) of items of high valuation for each \( i \). \( |S_i| = n_0/X^i \) and \( |S_i'| = n_0/X^{i+1} \). Buyer 1 does not value the items in \( S_i \setminus S_i' \), that is, \( v_1(S_i \setminus S_i') = 0 \). Buyer 1 values the items in \( S_i' \) equally, such that \( v_1(S_i') = cY^i \). Similarly, buyer 2 values the items in \( S_i' \) equally, such that \( v_2(S_i') = Y^i - Y^{i+1} \) and values the items in \( S_i \setminus S_i' \) equally such that \( v_2(S_i \setminus S_i') = Y^{i+1} \). Finally, the valuation function of each buyer consists of three additive components which are additive inside the set \( S_0 \cup S_3 \cup \cdots \cup S_{6k} \), \( S_1 \cup S_4 \cup \cdots \cup S_{6k+1} \), and \( S_2 \cup S_5 \cup \cdots \cup S_{6k+2} \) respectively. Here \( Y \) is a constant \( 1/2 \), \( X \) equals \((1/Y)^k = 2^{\theta(\sqrt{\log 2})} \), so \( X^{6k} = (1/Y)^{6k^2} > 2^{-\log n_0} = 1/n_0 \). And \( c \) is a parameter to be determined later. We shall show that in this instance, if buyer 1 comes before buyer 2, we achieve the required lower bound on the revenue, with an appropriate choice of \( c \).

Below, \( u_i(S) \) denotes the utility of buyer \( i \) at price \( p \) when she buys the set \( S \). For convenience, we let \( T_i \) denote \( \cup_{j \in \zeta_i} S_j \), where \( \zeta_i = \{j | 6k + 2 \geq j \geq i, (j - i) \text{ is divisible by } 3 \} \). Similarly we define \( T_i' \) as \( \cup_{j \in \zeta_i} S_j' \). We have the following when \( j \in \{1,2\} \) and \( i \leq 3k \):

\[
v_j(T_i) \geq \sum_{\ell=0}^{k} v_j(S_{i+3\ell})
\]

\[
= v_j(S_i)(1 + Y^3 + \cdots + Y^{3k})
\]

\[
= \left( 1 - o\left( \frac{1}{X^2} \right) \right) \frac{v_j(S_i)}{1 - Y^3}
\]

\[
p |T_i| \leq p \sum_{\ell=0}^{\infty} \frac{n_0}{X^{i+3\ell}}
\]

\[
= p |S_i| \sum_{\ell=0}^{\infty} \left( \frac{1}{X^{3\ell}} \right)
\]

\[
= \left( 1 + o\left( \frac{1}{X^2} \right) \right) p |S_i|
\]

It is also clear that \( v_j(T_i) \leq \sum_{\ell=0}^{\infty} v_j(S_i) Y^{3\ell} = v_j(S_i)/(1 - Y^3) \) and \( p |T_i| > p |S_i| \). So we have \( v_j(T_i) = (1 + o(1/X^2))v_j(S_i)/(1 - Y^3) \) and \( p |T_i| = (1 + o(1/X^2))p |S_i| \). Similarly, we also have \( v_j(T_i') = (1 + o(1/X^2))v_j(S_i')/(1 - Y^3) \) and \( p |T_i'| = (1 + o(1/X^2))p |S_i'| \). Use these facts we get that

\[
v_2(T_{i+1}) = (1 + o(1/X^2))v_2(S_{i+1})/(1 - Y^3)
\]

\[
= (1 + o(1/X^2))(v_2(S_i) - v_2(S_i'))/(1 - Y^3)
\]

\[
= (1 + o(1/X^2))(v_2(T_i) - v_2(T_i'))
\]

\[
= (1 + o(1/X^2))v_2(T_i \setminus T_i')
\]

Therefore, when the price \( p \) is non-trivially large, that is, \( p |T_i \setminus T_i'| > 1/X^2 \geq v_2(T_i \setminus T_i')/X^2 \), we have \( u_2(T_{i+1}) > u_2(T_i \setminus T_i') \) since both sets have essentially the same valuation, and the former has
significantly fewer items and hence costs less. The following facts will be useful for the rest of the proof. There exists \( a_i, b_i, \) and \( c_i \) such that:

\[
\begin{align*}
    u_1(T'_i + 1) > u_1(T'_i) & \iff p > a_i = \frac{(1 \pm O(1/X))cX^{i+1}Y^i}{n_0(1 + Y + Y^2)} \\
    u_2(T_{i+1} \setminus T'_i + 1) > u_2(T_i) & \iff p > b_i = \frac{(1 \pm O(1/X))X^iY^i(1 + Y)}{n_0(1 + Y + Y^2)} \\
    p|T_i| > 1/X & \iff p > c_i = \frac{X^{i-1}}{n_0}
\end{align*}
\]

We shall ensure the following constraints:

\[
\begin{align*}
    u_1(T'_i + 1) > u_1(T'_i) & \Rightarrow u_2(T_{i+1} \setminus T'_i + 1) > u_2(T_i) \\
    p|T_{i+1}| > 1/X & \Rightarrow u_1(T'_{i+1}) > u_1(T'_i) \quad (2) \\
    p|T_{i+1}| > 1/X & \Rightarrow u_1(T'_{i+1}) > u_1(T'_i) \quad (3)
\end{align*}
\]

Equation (2) implies that the first buyer prefers \( T'_{i+1} \) than \( T'_i \) only if she can ensure that the second buyer will not buy the set \( T_i \) even if \( T'_{i+1} \) is taken away. Equation (3) indicates that when the price is non-trivially high such that the set \( T'_{i+1} \) will give high revenue, the first buyer will buy \( T'_{i+1} \) and prevent the second buyer from buying \( T_i \). Therefore, we shall have \( c_{i+1} > a_i > b_i > c_i \) and thus the parameter \( c \) satisfies that:

\[
\frac{1 + Y + Y^2}{X} > c > \frac{Y}{X}
\]

Recall that \( Y = 1/2 \), we have \( 1 + Y + Y^2 = 1.75 \). So we let \( c = 1/X \) and Equation (2) and (3) are guaranteed and we have \( c_{i+1} > a_i > b_i > c_i \). We now consider various possibilities for the choice of \( p \):

- If the single price \( p \) is in the range \([c_i, a_i]\), then buyer 1 will buy all items in \( T'_i \), and buyer 2 will buy all items in \( T_{i+1} \) since \( u_2(T_{i+1}) > u_2(T'_i \setminus T'_i) > u_2(T_{i-1}) \). Therefore, the profit is \( p|T_{i+1}| + p|T'_i| < 2/X < \text{OPT}/(X/2) \). This is true for all \( i < k \).

- If the single price \( p \) is in the range \([a_i, c_{i+1}]\), then buyer 1 will buy all items in \( T'_{i+1} \), and buyer 2 will buy all items in \( T_{i+2} \) since \( u_2(T_{i+2}) > u_2(T_{i+1} \setminus T'_{i+1}) > u_2(T_i) \). So the profit is \( p|T_{i+2}| + p|T'_{i+1}| < 2/X < \text{OPT}/(X/2) \). This is true for all \( i < k - 1 \).

- For \( p > c_k \), the only items that can be sold is \( T_k \cup T_{k+1} \cup T_{k+2} \), and the revenue is at most \( v_1(T_k) + v_2(T_k) \leq 2(Y^k) = 2/X < \text{OPT}/(X/2) \).

Thus we get an \( \Omega(X) = 2^{\Omega(\sqrt{\log n})} \) gap between revenue and the optimal social welfare. Since the total number of items \( n = \bigcup_{1 \leq i \leq k} S_i \) is between \( n_0 \) and \( 2n_0 \), the construction and proof of lower bound for the 2 player instance is complete.

**Extensions of the two-player instance:** We now complete the proof of Theorem 3.1 by extending the above two-player instance. We present three hard instances such that

1. **Instance 1:** The \( 2^{\Omega(\sqrt{\log n})} \) lower bound holds even if the buyers come in random order;

2. **Instance 2:** The lower bound holds even if the seller can choose the order of the buyers;
3. **Instance 3:** The lower bound still holds if all the buyers have identical valuation functions.

The construction of each of the latter instances is based on the previous instance. Instance 1 is almost identical to one of the scenarios used in Balcan et al. [4].

**Instance 1:** Consider a setting where there are \( m \) buyers. One of them has the same valuation function as buyer 2. The other \( m - 1 \) of them share the same valuation function as buyer 1. Each of the other \( m - 1 \) buyers has its own shadow copy of \( T' \). Then the profit is at most \( 1 + (m - 1)/X \) if the special buyer comes first and at most \( m/X \) otherwise. So the expected revenue is \( \text{OPT} > 1 \). Let \( m = \sqrt{X} \) and we have the \( 2\sqrt{X} = 2^{\Omega(\sqrt{\log n})} \) lower bound.

**Instance 2:** Now consider another instance in which we replicate (items only, not the buyers) \( m \) copies of this setting such that each buyer is the buyer 2 in exactly 1 replicate. For each buyer, there is an additive component for each combination of the additive components in all \( m \) copies. Suppose the first buyer buys \( T_i \) in the replicate in which she is the buyer 2 and buys \( T_j \) in all other replicates. We say the buyer occupies the replicate which contains \( T_i \) in this case.

- If \( j \neq i \), then each of the other \( m - 1 \) buyers will buy \( S_i \) in the replicate in which she is the buyer 2 and her own shadow copies of \( T' \). It follows from our choice of parameters that \( j \neq i \) implies each copy of the \( T_i \) and \( T_j \) provides at most \( 1/X \) revenue. So the total revenue is at most \( m^2/X \).

- If \( j = i \), then each of the other \( m - 1 \) buyers will buy \( T_{i+1} \) in the replicate in which she is the buyer 2 and her own shadow copies of \( T' \). In this case, the revenue obtained from \( T_i \) is at most 1 and each copy of \( T' \) and \( T_j \) provides at most \( 1/X \). So the total revenue is at most \( 1 + (m^2 - 1)/X \).

It is clear that the optimal social welfare is \( \text{OPT} > m \), thus giving a gap of \( 1/m + m/X = 2\sqrt{X} = 2^{\Omega(\sqrt{\log n})} \).

**Instance 3:** Finally, consider a setting where all buyers are identical and share the same valuation function \( v(S) = \max_{1 \leq i \leq m} v_i(S) \), where \( \{v_i|1 \leq i \leq m\} \) are the buyer valuation functions as defined in Instance 2. Each of the buyer comes and buys some \( S_i \) in one of the replicate and \( S'_j \) in the all other replicates. We say the buyer occupies the replicate which contains \( S_i \) in this case. Note that a copy of \( S_i \) is also available in some unoccupied replicate, and buying the copy in the unoccupied replicate does not effect the behavior of the buyers who come after her. So for each of the possible scenario, there is equivalent scenario in which each buyer occupies an unoccupied replicate. Therefore, we have the same \( 2^{\Omega(\sqrt{\log n})} \) lower bound as in the previous setting.

This completes the proof of Theorem 3.1.

4 **Dynamic Uniform Pricing Strategies**

We now present a dynamic uniform pricing strategy that achieves an \( O(\log^2 n) \)-approximation to the revenue when buyer valuations are subadditive. This improves upon the previous best known approximation factor of \( 2^{O(\sqrt{\log n \log \log n})} \) [4] for the Item Pricing problem. Our strategy makes the assumption that the seller knows \( \text{OPT} \), the maximum social welfare, to within a constant
factor. However, this assumption can easily be eliminated by using Lemma 2.4 worsening the approximation ratio of the strategy by a poly-logarithmic factor.

We will also establish an almost matching lower bound result which shows that no dynamic uniform pricing strategy can achieve $o(\log^2 n/\log \log^2 n)$-approximation even when buyers are restricted to XOS valuations, the seller knows the value of $\text{OPT}$, buyer valuation functions, and is allowed to specify the order of arrival of the buyers!

### 4.1 A Dynamic Uniform Pricing Algorithm

The algorithm follows a simple strategy. Let $k = \lceil \log n \rceil + 1$, and let $p_i = \text{OPT}/2^i$ (recall that $\text{OPT}$ denotes the maximum social welfare). The algorithm starts at time 0 by choosing a threshold value $p^*$ from the set $\{p_1, p_2, \ldots, p_{k+1}\}$, uniformly at random. Upon arrival of any buyer, the algorithm chooses a price $\hat{p}$ uniformly at random from the set $\{p_1, p_2, \ldots, p^n\}$, and assigns the price $\hat{p}$ to all items that are yet unsold.

**Theorem 4.1** If the buyer valuations are subadditive, then the expected revenue obtained by the dynamic strategy above is $\Omega(\text{OPT}/\log^2 n)$.

The following lemma is key to the proof of Theorem 4.1. It says that if the threshold is “correctly” chosen, then our dynamically reset prices give a large fraction of the maximum possible revenue.

**Lemma 4.1** Suppose when the $i^{th}$ buyer $B_i$ arrives, there remains a set $L_i^j$ of unsold items such that $v_i(L_i^j) \geq p_j|L_i^j|$, where $v_i$ is the valuation function of $B_i$. Then if the seller picks a price from $\{p_1, p_2, \ldots, p_{j+1}\}$ uniformly at random, and prices all items at this single price, it receives an expected revenue of at least $p_j|L_i^j|/2(j+1)$ from this buyer.

**Proof of Lemma 4.1** Let $L'$ be the set of unsold items when the buyer $B_i$ arrives. Since this is a single buyer setting with uniform pricing, Lemma 2.2 applies. Thus the number of items sold is a non-increasing function of the price set on all items, and equation (1) is applicable.

Now if the uniform price chosen by the seller is $p_{j+1}$, then buying the set $L_i^j$ would give $B_i$ a utility of at least $v_i(L_i^j) - p_{j+1}|L_i^j| \geq p_j|L_i^j| - p_{j+1}|L_i^j|$ since $v_i(L_i^j) \geq p_j|L_i^j|$ by the assumption of the lemma. Thus

\[
\mathcal{U}(B_i, L', p_{j+1}) \geq p_j|L_i^j| - p_{j+1}|L_i^j| = \frac{p_j|L_i^j|}{2}
\]  

(4)

Suppose $q_s > p_{j+1} \geq q_{s+1}$, for some $s \leq l$. Then, since $\mathcal{U}(B_i, L', q_0) = \mathcal{U}(B_i, L', q_1) = 0$, and also that $q_1 \leq \text{OPT}$, so

\[
\mathcal{U}(B_i, L', p_{j+1}) = \sum_{t=1}^{s-1} (\mathcal{U}(B_i, L', q_t) - \mathcal{U}(B_i, L', q_t)) + n_s(q_s - p_{j+1})
\]

\[
= \sum_{t=1}^{s-1} n_t(q_t - q_{t+1}) + n_s(q_s - p_{j+1})
\]

12
The above sum can be seen as an integral of the following step function \( f \) from \( p_{j+1} \) to \( q_1 \): in the range \([q_1, q_2)\), \( f \) takes the value \( n_t \). So we can upper bound it by an upper integral of \( f \). Note that \(|f(p) \leq \Phi(B_i, I', p)| \leq |S|\), and also that \( f \) is a decreasing function. Thus we get

\[
\mathcal{U}(B_i, I', p_{j+1}) \leq \sum_{t=0}^{j} \Phi(B_i, I', p_{t+1})|(p_t - p_{t+1})
\]

\[
= \sum_{t=0}^{j} \Phi(B_i, I', p_{t+1})|p_t
\]

\[
= \sum_{t=1}^{j+1} \Phi(B_i, I, p_t)|p_t
\]

Combining with equation 4, we get

\[
\sum_{t=1}^{j+1} \Phi(B_i, I, p_t)|p_t \geq \frac{p_j|L_i^j|}{2}
\]

(5)

Thus the expected revenue obtained from \( B_i \) is

\[
\sum_{t=1}^{j+1} \Phi(B_i, I, p_t)|p_t \geq \frac{p_j|L_i^j|}{2(j+1)}
\]

completing the proof of the lemma.

**Proof of Theorem 4.1.** Let \((T_1, T_2, \ldots T_m)\) be an optimal allocation of items to buyers \( B_1, B_2 \ldots B_m \), who has valuation functions \( v_1, v_2 \ldots v_m \) respectively, such that \( \sum_{i=1}^{m} v_i(T_i) = \text{OPT} \) is the maximum social welfare. Also, let \( T_i^j \) be the subset of \( T_i \) that would be bought by \( B_i \) if it were shown only the items in \( T_i \), and all items were uniformly priced at \( p_j \). Now consider the case when \( p^* = p_{j+1} \). Let \( R^j \) be the revenue in this case. Let \( Z_i^j \subseteq T_i^j \) be a random variable that denotes the subset of items in \( T_i^j \) that are sold before buyer \( B_i \) comes. Then \( R^j \geq \sum_{i=1}^{m} p^*|Z_i^j| = \sum_{i=1}^{m} p_j|Z_i^j|/2 \)

Note that \( v_i(T_i^j \setminus Z_i^j) \geq p_j|T_i^j \setminus Z_i^j| \) by Lemma 2.1. So, by Lemma 4.1, conditioned on the set \( Z_i^j \), the expected revenue received from \( B_i \) is at least \( \left( p_j|T_i^j \setminus Z_i^j| \right)/2(j+1) \). Thus, conditioned on the sets \( Z_i^j \) for all \( i \), we have

\[
\mathbb{E}[R^j|Z_i^j \forall 1 \leq i \leq m] \geq \Omega \left( \sum_{i=1}^{m} \left( p_j|Z_i^j| + \frac{p_j|T_i^j \setminus Z_i^j|}{j} \right) \right)
\]

Since the value on the right-hand side above is independent of the variables \( Z_i^j \) on which the expectation of \( R^j \) is conditioned on, we get

\[
\mathbb{E}[R^j] = \Omega \left( \sum_{i=1}^{m} \frac{p_j|T_i^j|}{j} \right)
\]

Thus the expected revenue \( R = \sum_{j=0}^{k} R^j \) of our dynamic strategy is given by
\[ E[R] = \frac{1}{k+1} \sum_{j=0}^{k} E[R^j] = \Omega \left( \sum_{j=0}^{k} \sum_{i=1}^{m} \frac{p_j|T^j_i|}{k^2} \right) \]

Since \( k = \lceil \log n \rceil \), and \( \text{OPT} \geq H_{v_i}(T_i) \), from Lemma 2.3 and Equation (6), it follows that

\[ \sum_{j=0}^{k} p_j|T^j_i| \geq \Omega \left( v_i(T_i) - \frac{|T_i|\text{OPT}}{2n} \right) \]

Thus we have

\[ E[R] = \Omega \left( \frac{1}{k^2} \left( \sum_{i=1}^{m} v_i(T_i) - \sum_{i=1}^{m} \frac{|T_i|\text{OPT}}{2n} \right) \right) \]

\[ = \Omega \left( \frac{1}{k^2} \left( \text{OPT} - \frac{\text{OPT}}{2} \right) \right) = \Omega \left( \frac{\text{OPT}}{\log^2 n} \right) \]

\[ \square \]

### 4.2 Lower Bound for Dynamic Uniform Pricing

We shall now construct a family of instances of the problem, where the buyers have distinct XOS valuations, with \( O(\log n/\log \log n) \) additive components in each valuation function, such that no dynamic uniform strategy can achieve an \( o(\log^2 n/\log \log n) \)-approximation, even in the full information setting, and when the seller can even specify the order in which the buyers should arrive.

**Theorem 4.2** There exists a set of buyers with XOS valuations, such that if the seller is restricted to using a dynamic uniform pricing strategy, then even when the seller has full information of buyer valuation functions and can even choose the order of arrival of the buyers, the revenue produced is \( O((\log \log n)^2/\log^2 n) \) times \( \text{OPT} \), where \( n \) is the number of items.

**Proof:** Let \( B_1, B_2 \ldots B_m \) denote the buyers. Our construction will use three integer parameters \( k, F, \) and \( Y \), to be specified later. These parameters will satisfy the conditions that \( k > 1 \), \( F > 1 \), \( Y > 4 \), and \( m \geq 2Y \geq 4k \). Let \( f(i) = (i + 1)F/Y^i \). Then, \( f(0) > f(1) > \ldots > f(k) > f(k+1) \).

For each buyer \( B_i \), we create \( 2(k+1) \) disjoint sets of items \( S_{i0}, S_{i1} \ldots S_{ik} \) and \( S'_{i0}, S'_{i1} \ldots S'_{ik} \) such that \( |S_{ij}| = |S'_{ij}| = Y^2 \) items each. Let \( S_i = \cup_{0\leq j \leq k} S_{ij} \) and \( S'_i = \cup_{0\leq j \leq k} S'_{ij} \). We call the items in \( S_i \) as *shared* and those in \( S'_i \) as *private*. The private items of \( B_i \) are valued by buyer \( i \) only, and has zero value to all other buyers.

The valuation function \( v_i \) of buyer \( B_i \) is constructed as an XOS valuation with \( k+2 \) additive functions \( v_{i0}, v_{i1} \ldots v_{i(k+1)} \) in its support, that is, \( v_i = \max_{0 \leq j \leq k+1} v_{ij} \). For \( 0 \leq j \leq k \), the valuation function \( v_{ij} \) has positive value only for private items, and is defined as

\[
v_{ij}(x) = \begin{cases} 
  f(j) & \text{if } x \in S'_{ij} \\
  0 & \text{otherwise}
\end{cases}
\]

The valuation function \( v_{i(k+1)} \) has positive values only for shared items:
Let $v(x) = \begin{cases} f(j) & \text{if } x \in S_{ij} \text{ for } 0 \leq j \leq k \\ f(j + 1) & \text{if } x \in S_{ij} \text{ for } 1 \leq \ell \leq m, \ell \neq i, \text{ and } 0 \leq j \leq k \end{cases}$

This completes the description of the instance. Note that $v(S'_{ij}) = f(j)|S'_{ij}| = (j + 1)F$, and that

$$v_i(S_i) = \sum_{j=0}^{k} f(j)|S_{ij}| = \sum_{j=0}^{k} (j + 1)F = \Omega(k^2F)$$

Thus if we allocate each set $S_i$ to buyer $B_i$ for $i = 1, 2, \ldots m$, the social welfare obtained is $\Omega(mk^2F)$, and hence OPT is $\Omega(mk^2F)$.

Consider now the arrival of some buyer $B_i$ at time $t$. By our construction of the valuation function, $B_i$ will either buy only shared items or buy only private items, but not both. If the buyer $B_i$ were to buy shared items, and the price of each item is set at $f(j) \geq p > f(j + 1)$, then $B_i$ would pick up all remaining items in

$$\left( \bigcup_{0 \leq t \leq j} S_{it} \right) \setminus \bigcup_{0 \leq t \leq j} \bigcup_{0 \leq \ell \leq j} S_{\ell t}$$

Since $\sum_{0 \leq t \leq j} Y^t \leq 2Y^j$, the total price that $B_i$ would pay to the seller is bounded by

$$f(j)(2Y^j + 2mY^{j-1}) = 2(j + 1)F + 2m(j + 1)F/Y = 2(1 + m/Y)(j + 1)F$$

We now consider the maximum revenue generated if $B_i$ were to buy a subset of its private items. Note that when $B_i$ arrives, all private items of $B_i$ are still unsold. Suppose $B_i$ were to buy private items. What is the maximum revenue we can get? For this, note that if the price of each item is $(j + 1)F/jY^j$, then the utility from buying $S'_{ij}$ is

$$(j + 1)F - (j + 1)F/j = (j + 1)(j - 1)F/j = (j - 1/j)F,$$

and the utility from buying $S'_{ij}(j-1)$ is

$$jF - (j + 1)F/jY > (j - 1/j^2)F > (j - 1/j)F, \quad \text{since } Y > 2j.$$
\[ 2(1 + m/Y)(j + 1)F \leq O((m/Y)kF) \]

However, consider any time when a price in the range \((f(j - 1), f(j)]\) appears again, and let \(B_\ell, \ell \neq i\) be the buyer who faces this price. If \(B_\ell\) were to buy shared items, the only items that are valued higher than the price and still remaining are those in \(S_{\ell j}\), since \(B_\ell\) took away whatever was remaining of \(S_{\ell t}\) for all \(t < j\). Note that the only reason the shared items could have given \(B_i\) a better utility was that the shared items had additive valuation, while the private items had XOS valuation, so she got no benefit in picking up multiple sets of private items. However, since only one feasible set \(S_{\ell j}\) of the shared items is left, this advantage has vanished, and the revenue from \(B_\ell\) is the same as the revenue if there were no shared items at all. As discussed above, the revenue from \(B_\ell\) in this case is at most \(2F\).

Finally, since a \(j\)-good sale can happen at most once for any \(1 \leq j \leq (k + 1)\), the total revenue generated from all \(j\)-good sales is \(O\left((mk^2F)/Y\right)\). The remaining rounds each give a revenue of at most \(2F\), contributing in total \(O(mF)\) to the revenue. Thus the revenue obtained by any dynamic uniform strategy, for any ordering of buyers, is \(O\left((1 + k^2/Y)mF\right)\).

Now since the maximum social welfare is \(\Omega(k^2mF)\), the approximation factor achieved is bounded from below by \(\Omega\left((k^2Y)/(k^2 + Y)\right)\). For any \(k > 10\), if we set \(Y = k^2\) and \(m = 2Y\), then \(n = \Theta(Y^{k+1}) = k^{\Theta(k)}\), and the approximation factor is \(\Omega(k^2)\). As \(k = \Theta(\log n/\log \log n)\), we get that the smallest approximation factor that can be achieved is \(\Omega\left(((\log n/\log \log n)^2\right)\).

### 5 Dynamic Monotone Uniform Pricing Strategies

We now present a simple strategy that uses a monotonically decreasing uniform pricing for the items. When the number of buyers \(m\) is at least \(2\log n\), the strategy gives an \(O(\log^2 n)\)-approximation to the revenue provided the buyers arrive in a uniformly random order, that is, all permutations of the buyers are equally likely to be the arrival order. As a corollary of this result, we conclude that if the buyers are identical, no matter the order in which they arrive, this pricing scheme gives an \(O(\log^2 n)\)-approximation. The strategy assumes that the seller knows the number of buyers \(m\) (and also \(\text{OPT}\)), and is deterministic. Knowing estimates of \(m\) and \(\text{OPT}\) up to constant factors are also sufficient for the performance of our strategy.

Let \(k = \log n + 1\), and let \(\gamma = 2k^2 \geq 1\). Thus \(\gamma^m > 2n\). The strategy gives a good guarantee only when \(m \geq \log n + 1\). The strategy is as follows: When the \(t\)th buyer arrives, the seller prices all unsold items uniformly at

\[ p[t] = \frac{\text{OPT}}{2\gamma^t}. \]

Thus the price decreases with time. For \(m = \omega(\log n)\), the relative decrease in the price for consecutive buyers is

\[ \frac{p[t] - p[t + 1]}{p[t]} = \left(1 - \frac{1}{\gamma}\right) = \Theta\left(\frac{\log n}{m}\right), \]

which tends to zero, and so the price decreases smoothly with time.

**Theorem 5.1** Suppose \(m \geq \log n + 1\), and suppose that the buyer valuations are subadditive. If the ordering of buyers in which they arrive is uniformly random (that is, all permutations are
equally likely), then the expected revenue of the dynamic monotone uniform pricing scheme above is \( \Omega\left(\frac{OPT}{\log^2 n}\right) \).

**Proof:** Let \( (T_1, T_2, \ldots, T_m) \) be an optimal allocation of items to buyers \( B_1, B_2 \ldots B_m \), who has valuation functions \( v_1, v_2 \ldots v_m \) respectively, such that \( \sum_{i=1}^m v_i(T_i) = OPT \) is the maximum social welfare. Also, let \( T_i^j \) be the subset of \( T_i \) that would be bought by \( B_i \) if it were shown only the items in \( T_i \), and all items were uniformly priced at \( OPT/\gamma^j = 2p[j] \).

Fix a buyer \( B_i \). Let \( R_i \) be a random variable that denotes the revenue obtained by the seller from \( B_i \). Let \( R'_i \) be a random variable that denotes the revenue obtained by the seller by selling items in \( T_i \). Then, if \( R \) is a random variable that denotes the total revenue obtained by our strategy, we have \( R = \sum_{i=1}^m R_i \) and \( R \geq \sum_{i=1}^m R'_i \), so \( R \geq \sum_{i=1}^m \frac{R_i + R'_i}{2} \).

Fix a permutation \( \pi \) of all buyers except \( B_i \). We shall say that the event \( \pi \) occurs if these buyers arrive in the relative order given by \( \pi \), with \( B_i \) arriving somewhere in between. We shall now compute \( E[R_i + R'_i | \pi] \).

Let \( \pi_j \) denote the permutation of all the buyers formed by inserting \( B_i \) after the \((j - 1)\)th but before the \(j\)th position in \( \pi \), whichever exists, for \( 1 \leq j \leq m \). That is \( B_i \) comes in as the \( j \)th buyer in \( \pi_j \). Let \( Z_i^j \) denote the number of items that were sold before the arrival of \( B_i \) when the arrival sequence of buyers is \( \pi_j \). Note that \( Z_i^j \) is no longer a random variable once \( \pi_j \) is fixed, and neither are \( R_i \) and \( R'_i \). Also note that \( \Pr [\pi_j | \pi] = 1/m \). Thus,

\[
E[R'_i | \pi] \geq \frac{1}{m} \sum_{j=1}^m p[j - 1] |Z_i^j| \geq \frac{1}{m} \sum_{j=1}^m p[j] |Z_i^j| \tag{7}
\]

Let \( S_i^j \) be the set of items bought by \( B_i \) when the permutation of buyers is \( \pi_j \), let \( U_i^j \) be the utility derived by \( B_i \) in this process, and let \( R_i^j \) be the revenue obtained from \( B_i \) in the process. For \( 1 \leq j < m \), note that when the permutation is \( \pi_j \), then when \( B_i \) arrives, the set \( S_i^{j+1} \) is also available, and \( B_i \) prefers \( S_i^j \) over this set at price \( p[j] \). Thus

\[
U_i^j = v_i(S_i^j) - p[j]|S_i^j| \\
\geq v_i(S_i^{j+1}) - p[j]|S_i^{j+1}| = v_i(S_i^{j+1}) - p[j]|S_i^{j+1}| - (\gamma - 1)p[j+1]|S_i^{j+1}| \\
= U_i^{j+1} + (\gamma - 1)R_i^{j+1}
\]

This implies that \( R_i^{j+1} \geq \frac{1}{\gamma - 1}(U_i^{j+1} - U_i^j) \), for \( 1 \leq j < m \). Also note that \( v_i(S_i^1) - p[0]|S_i^1| \leq 0 \), since no bundle of items can have value greater than \( p[0] = OPT \). So \( v_i(S_i^1) - p[1]|S_i^1| - (\gamma - 1)p[1]|S_i^1| = U_i^1 - (\gamma - 1)R_i^1 \leq 0 \), or \( R_i^1 \geq \frac{1}{\gamma - 1}U_i^1 \). Thus, adding the terms \( R_i^t \), we find that the terms telescope, and

\[
\sum_{t=1}^j R_i^t \geq \frac{1}{\gamma - 1} \left( \sum_{t=2}^j (U_i^t - U_i^{t-1}) + U_i^1 \right) = \frac{1}{\gamma - 1}U_i^1
\]

By Lemma 2.1, we have \( v_i(T_i^j \setminus Z_i^j) \geq 2p[j]|T_i^j \setminus Z_i^j| \). So the utility of \( T_i^j \setminus Z_i^j \) to buyer \( B_i \) at price \( p[j] \) is \( (2p[j] - p[j])|T_i^j \setminus Z_i^j| = p[j]|T_i^j \setminus Z_i^j| \), which is at most \( U_i^j \). Thus

\[
\sum_{t=1}^j R_i^t \geq \frac{1}{\gamma - 1}U_i^j = \frac{p[j]|T_i^j \setminus Z_i^j|}{\gamma - 1}
\]
Using the above equation, we get
\[ m \sum_{j=1}^{m} R^i_j \geq \sum_{j=1}^{m} \sum_{t=1}^{j} R^i_t = \frac{1}{\gamma - 1} \sum_{j=1}^{m} p[j] |T^j_i \setminus Z^j_i| \]
\[ \Rightarrow \sum_{j=1}^{m} R^i_j \geq \sum_{j=1}^{m} \frac{p[j] |T^j_i \setminus Z^j_i|}{(\gamma - 1)m} \geq \Omega \left( \frac{p[j] |T^j_i \setminus Z^j_i|}{\log n} \right) \]

The last inequality follows from the fact that \( \gamma - 1 = \Theta \left( \frac{\log n}{m} \right) \).

Note that \( \mathbb{E}[R_i] = \frac{1}{m} \sum_{j=1}^{m} R^i_j \). Combining with equation (7), we get that
\[ \mathbb{E}[R_i + R'_i] = \frac{1}{m} \Omega \left( \sum_{j=1}^{m} \frac{p[j] (|T^j_i \setminus Z^j_i| + |Z^j_i|)}{\log n} \right) \]
\[ \geq \frac{1}{m} \Omega \left( \sum_{j=1}^{m} \frac{p[j] |T^j_i|}{\log n} \right) = \Omega \left( \frac{1}{m} \log n \left( \sum_{j=1}^{m} \frac{OPT}{\gamma^j |T^j_i|} \right) \right) \]

Using Lemma 2.3, we get that
\[ \sum_{j=1}^{m} \frac{OPT}{\gamma^j |T^j_i|} \geq \frac{1}{\gamma - 1} \left( v_i(T_i) - \frac{|T^j_i|OPT}{\gamma^m} \right) \geq \frac{1}{\gamma - 1} \left( v_i(T_i) - \frac{|T^j_i|OPT}{2n} \right) \]

Again using the fact that \( \gamma - 1 = \Theta \left( \frac{\log n}{m} \right) \), we get that
\[ \mathbb{E}[R_i + R'_i] \geq \Omega \left( \frac{1}{\log^2 n} \left( v_i(T_i) - \frac{|T^j_i|OPT}{2n} \right) \right) \]

Since the right-hand-side of the above equation is independent of \( \pi \), we conclude that \( \mathbb{E}[R_i + R'_i] \geq \Omega \left( \frac{1}{\log^2 n} \left( v_i(T_i) - \frac{|T^j_i|OPT}{2n} \right) \right) \). Thus we get that the expected revenue is
\[ \mathbb{E}[R] = \frac{1}{2} \mathbb{E}[R_i + R'_i] \geq \Omega \left( \frac{1}{\log^2 n} \left( \sum_{i=1}^{m} v_i(T_i) - \sum_{i=1}^{m} |T^j_i|OPT \right) \right) \]
\[ = \Omega \left( \frac{1}{\log^2 n} \left( OPT - \frac{OPT}{2} \right) \right) = \Omega \left( \frac{OPT}{\log^2 n} \right) \]

\[ \square \]

6 Static Non-Uniform Pricing

Another approach to get around the weak performance barrier for static uniform pricing, is to consider static non-uniform pricing, which allows the seller to post different prices for different items but the prices remain unchanged over time. In Section 3 we showed that there exist instances with identical buyers where no static uniform pricing can achieve better than \( 2^{\Omega(\sqrt{\log n})} \)-approximation even in the full information setting. Surprisingly, this hardness result breaks down if we consider non-uniform pricing using only two distinct prices.
6.1 Full Information Setting

We first introduce the \((p, \infty)\)-strategies, i.e. the seller posts price \(p\) for a subset of the items and posts \(\infty\) for all other items. The intuition is by using this strategy the seller can prevent the buyers from buying certain items (high utility but low revenue) and thus achieve better revenue. The proof of the theorem below depends on the performance of the following dynamic monotone strategy. Let \(k = \lceil \log n \rceil + 1\) and \(m' = \lfloor m/(k + 1) \rfloor\). Recall that \(p_i = \OPT/2^i\) for \(i = 1, 2, \ldots, k\). The seller posts a single price \(p_1\) for the first \(m'\) buyers, then she posts a single price \(p_2\) for the next \(m'\) buyers, and so on and so forth. We call each time period that the seller posts a fixed price a phase, and we call this strategy the \(k\)-phase monotone uniform strategy. The proof of Theorem 5.1 can be easily modified to show that this strategy gives \(O(\log^2 n)\)-approximation as well.

**Theorem 6.1** In the full information setting, if \(m \geq \log n + 1\), and all buyers share the same subadditive valuation function, then there exists a \((p, \infty)\)-strategy which obtains revenue at least \(\Omega(\OPT/\log^2 n)\).

**Proof:** Given that the \(k\)-phase dynamic monotone uniform strategy for identical buyers obtains revenue at least \(\Omega(\OPT/\log^2 n)\), at least one of the \(k = \lceil \log n + 1 \rceil\) phases contributes \(1/k\) fraction of the revenue. Without loss of generality, assume the \(i^{\text{th}}\) phase contributes at least \(\Omega(\OPT/k \log^2 n) = \Omega(\OPT/\log^3 n)\) revenue. Recall that \(m' = \lfloor m/(k + 1) \rfloor\). Suppose \(T\) is the set of items unsold at the beginning of phase \(i\).

Consider the following \((p, \infty)\)-strategy. The seller posts price \(p = p_{i+1}\) for each item in \(T\), and posts \(\infty\) for all other items. Then when the first \(m'\) buyers come, they will behave the same as the \(m'\) buyers in phase \(i\) in the dynamic strategy scenario. So the revenue collected is at least \(\Omega(\OPT/\log^3 n)\). \(\square\)

6.2 Buyers with \(\ell\)-XOS Valuations

The above theorem shows a clear gap between the power of uniform pricing and the power of non-uniform pricing in the full information setting. However, it crucially uses the knowledge of the valuation function and the fact that all buyers are identical; information that is usually not known to the seller. Hence strategies in the limited information setting are more desirable in practice.

Fortunately, we find that considering static non-uniform pricing is also beneficial in the limited information setting. We first note that if the buyer order is randomized, then it is quite easy to get an \(O(m \log n \log \OPT (\log \log \OPT)^2)\) approximation using static uniform pricing, even with general valuations, and without the assumption of knowing \(\OPT\). This can be done as follows: Just focus on selling items to the first buyer. If \(B_i\) is the first buyer, and the algorithm knew the value \(v_i(T_i)\), then using the single buyer (unlimited supply setting) algorithm in [4], the algorithm gets \(\Omega(v_i(T_i)/\log n)\) in expectation from the first buyer, and we do not care what it gets from the other buyers. Thus the expected revenue of the algorithm is \(\frac{1}{m} \left( \sum_{i=1}^{m} \frac{v_i(T_i)}{\log n} \right) = \frac{\OPT}{m \log n}\). This algorithm would have to guess \(v_i(T_i) \leq \OPT\) of the first buyer \(B_i\), up to a constant factor, and can do so by incurring an additional factor of \(O(\log \OPT (\log \log \OPT)^2)\) as described in Lemma 2.4.

However, if we require a strategy to give guarantees on expected revenue against any order of buyers, and in particular an adversarial ordering, then static uniform pricing cannot give a better bound than \(2^{\Omega(\sqrt{\log n})}\) even when there are only two buyers, with \(3\)-XOS valuations. This is evident from the proof of Theorem 3.1. We now show a static non-uniform strategy which achieves
polylogarithmic approximation if we assume the valuation functions are $\ell$-XOS functions where $\ell$ is quasi-polynomial in $n$ and the number of buyers is polylogarithmic, for all ordering of buyers.

Let $k = \lceil 2 \log n \rceil$. With probability half, the seller assigns a single price $p$ randomly drawn from $\{p_1, p_2, \ldots, p_k\}$ to all items. With probability half, the seller assigns one of $p_1, p_2, \ldots, p_{k+1}$ uniformly at random for each item. The price assignment remains unchanged over time.

**Theorem 6.2** For $m$ buyers with $\ell$-XOS valuations functions, the expected revenue of the above strategy is $\Omega\left(\frac{\text{OPT}}{m \log \ell \log^4 n}\right)$.

Suppose the XOS valuation function of the $i$th buyer is $v_i(S) = \max_{1 \leq j \leq \ell} a_{i,j}(S)$. For each $m$-tuple $z = (z_1, z_2, \ldots, z_m) \in [\ell]^m$, define $a_z$ to be an additive function such that for each item $g \in I$, $a_z(g) = \max_{1 \leq i \leq m} a_{i,z_i}(g)$. For each $z$ and each $1 \leq i \leq k$, let $\Gamma_{z,i}$ denote the set of items $g$ such $a_z(g) \in [p_i, p_{i-1})$. We say such a set $\Gamma_{z,i}$ is large if its size is at least $16m \log \ell$ and we say it is small otherwise. Define $A_z$ and $B_z$ as follows:

$$A_z = \bigcup_{\Gamma_{z,i} \geq 16m \log \ell} \Gamma_{z,i} \quad \quad B_z = \bigcup_{\Gamma_{z,i} < 16m \log \ell} \Gamma_{z,i}.$$

In the case where the seller posts one of $p_1, p_2, \ldots, p_{k+1}$ uniformly at random for each item, let $\Pi_i$ denote the set of items which are priced $p_i/2$. The following two lemmas are crucial to the proof of Theorem 6.2.

**Lemma 6.1** If the seller posts a single price $p$ randomly drawn from $\{p_1, p_2, \ldots, p_k\}$ for all items, then the expected revenue is at least $\Omega(a_z(B_z)/m \log \ell \log n)$ for any $z \in [\ell]^m$.

**Proof:** Let $R_i$ denote the revenue if the seller posts a single price $p_i$. When the seller posts a single price $p_i$ for all items, the buyers will buy at least one item if $B_z \cap \Gamma_{z,i}$ is not empty. Note that $|B_z \cap \Gamma_{z,i}| < m \log \ell$, we have $R_i \geq a_z(B_z \cap \Gamma_{z,i})/m \log \ell$. Since $k = \lceil 2 \log n \rceil$, the expected revenue is at least

$$\frac{1}{k} \sum_{i=1}^k R_i \geq \frac{1}{k} \sum_{i=1}^k \frac{a_z(B_z \cap \Gamma_{z,i})}{km \log \ell} = \frac{a_z(B_z)}{km \log \ell} = \Omega\left(\frac{a_z(B_z)}{m \log \ell \log n}\right).$$

**Lemma 6.2** If the seller posts one of $p_1, p_2, \ldots, p_{k+1}$ uniformly at random for each item, then with probability at least $3/4$ we have for every $z \in [\ell]^m$, $|\Pi_i \cap \Gamma_{z,i}| \geq |A_z \cap \Gamma_{z,i}|/2k$.

**Proof:** If $\Gamma_{z,i}$ is small then $|A_z \cap \Gamma_{z,i}| = 0$ and the given equation is trivially true. Now suppose $\Gamma_{z,i}$ is large, that is, $|\Gamma_{z,i}| \geq 16m \log \ell$. Note that each item in $\Gamma_{z,i}$ has probability $1/k$ of being priced $p_i/2$. Using Chernoff bounds and we get that the probability that less than $1/2k$ fraction of $\Gamma_{z,i}$ are priced $p_i/2$ is at most $1/2^{2m \log \ell} = 1/\ell^{2m}$. There are at most $\ell^m$ distinct $m$-tuples $z$. For each $z$ there are at most $k = \lceil 2 \log n \rceil$ sets $\Gamma_{z,i}$. So the total number of different $\Gamma_{z,i}$ is at most $\ell^m k < \ell^{2m}/4$. By using union bound we finish the proof of this lemma.

We can now complete the proof of Theorem 6.2.
Proof of Theorem 6.2. If there exists some vector \( z \) such that \( a_z(B_z) \geq \OPT / 320 \log^2 n \) then we know from Lemma 6.1 that the expected revenue is at least \( \Omega(\OPT/m \log \ell \log n) \). Now let us assume \( a_z(B_z) < \OPT / 320 \log^2 n \) for any \( z \).

By Lemma 6.2, it suffices to prove that the expected revenue is high if for each \( z \in [\ell]^m \) \( |\Pi_i \cap \Gamma_{z,i}| \geq |A_z \cap \Gamma_{z,i}| / 2k \). Suppose \( T = (T_1, T_2, \ldots, T_m) \) is the allocation that maximizes the social welfare, then \( \OPT = \sum_{i=1}^m v_i(T_i) \). There exists \( m \)-tuple \( z' \in [\ell]^m \) such that \( a_{i,z'_i}(T_i) = v_i(T_i) \) and thus

\[
\OPT = \sum_{i=1}^m a_{i,z'_i}(T_i) \leq a_{z'}(I) = a_{z'}(A_{z'}) + a_{z'}(B_{z'}) .
\]

By our assumption \( a_{z'}(A_{z'}) \geq \OPT - \OPT / 320 \log^2 n \geq \OPT / 2 \) and hence \( a_{z'}(A_{z'} \cap \Gamma_{z',j}) \geq \OPT / 2k \) for some \( j \in [k] \). Let \( Z \) denote the set \( \Pi_j \cap \Gamma_{z',j} \) and we have \( |Z| \geq |\Gamma_{z',j}| / 2k \). Since \( k = [2 \log n] \), we have

\[
p_j |Z| \geq \frac{p_j |\Gamma_{z',j}|}{2k} \geq \frac{a_{z'}(\Gamma_{z',j})}{4k} \geq \frac{\OPT}{8k^2} \geq \frac{\OPT}{40 \log^2 n} .
\]

Suppose the \( i^{th} \) buyer buys the set \( S_i \) for \( 1 \leq i \leq m \) and let \( S \) denote the union of all \( S_i \). If \( |S \cap Z| \geq |Z| / 2 \) then the revenue is at least \( (p_j / 2) |S \cap Z| \geq (p_j / 2)(|Z| / 2) = \Omega(\OPT / \log^2 n) \). Otherwise, \( |Z \setminus S| \geq |Z| / 2 \). Let \( u_i(S_i) \) denote the utility of set \( S_i \) to the \( i^{th} \) buyer. We have

\[
\sum_{i=1}^m u_i(S_i) \geq \sum_{i=1}^m u_i(Z \setminus S) \geq a_{z'}(Z \setminus S) - \frac{p_j}{2} |Z \setminus S| \geq \frac{p_j}{2} |Z \setminus S| \geq \frac{\OPT}{160 \log^2 n} .
\]

Hence \( \sum_{i=1}^m v_i(S_i) \geq \sum_{i=1}^m u_i(S_i) = \Omega(\OPT / \log^2 n) \). Note that there exists an \( m \)-tuple \( z'' \in [\ell]^m \) such that \( a_{i,z''_i}(S_i) = v_i(S_i) \). So

\[
a_{z''}(B_{z''}) + a_{z''}(A_{z''}) = a_{z''}(I) \geq \sum_{i=1}^m a_{i,z''_i}(S_i) \geq \frac{\OPT}{160 \log^2 n} .
\]

By our assumption, \( a_{z''}(B_{z''}) < \OPT / 320 \log^2 n \), so \( a_{z''}(A_{z''}) = \Omega(\OPT / \log^2 n) \). Note that an item \( g \) is bought if and only if its price is less than \( a_{i,z''_i}(g) \) for some \( i \). So all items in \( \Gamma_{z'',i} \cap \Pi_i \) are bought and with high probability the revenue is at least

\[
\sum_{i=1}^k \frac{p_i}{2} |\Gamma_{z'',i} \cap \Pi_i| \geq \sum_{i=1}^k \frac{p_i}{2} |\Gamma_{z'',i} \cap A_{z''}| = \Omega \left( \frac{a_{z''}(A_{z''})}{k} \right) = \Omega \left( \frac{\OPT}{\log^2 n} \right) .
\]

Hence the proof is complete, the expected revenue is at least \( \Omega(\OPT / m \log \ell \log^3 n) \).
