Higgs boson production in $e^+e^-$ and $e^-e^-$ collisions

PER OSLAND

Department of Physics, University of Bergen, N-5007 Bergen, Norway

(Received March 27, 2022)

When Higgs boson candidates will be found at future colliders, it becomes imperative to determine their properties, beyond the mass, production cross section and decay rates. Other crucial properties are those related to the behaviour under $CP$ transformations, and the self-couplings. This paper addresses the question of measurability of some of the trilinear couplings of MSSM neutral Higgs bosons at a high-energy $e^+e^-$ collider, and the possibilities of exploring the Higgs boson $CP$ properties at $e^+e^-$ and $e^-e^-$ colliders.

1. Introduction

The Higgs particle is expected to be discovered at the LHC, if not already at LEP [1]. Current estimates from precision electroweak data [2] suggest that it is rather light. A light Higgs particle would be consistent with both the Standard Model (SM) and the Minimal Supersymmetric Standard Model (MSSM). A detailed measurement of its branching ratios should enable one to distinguish between these two most favoured models.

However, there is more to the MSSM Higgs sector than branching ratios. For a complete analysis, one should also measure the trilinear and quartic self-couplings, which in the MSSM are determined by the gauge couplings.

The measurability of couplings involving the light Higgs particle was investigated by Djouadi, Haber and Zerwas [3]. It was concluded that the trilinear couplings $\lambda_{Hhh}$ and $\lambda_{hhh}$, where $h$ and $H$ denote the two neutral, $CP$-even Higgs bosons, could be measured at a high-energy linear collider. This early study neglected squark mixing, but, with some limitations, the conclusion was confirmed also for the case of squark mixing [4]. A recent study also accounts for the dominant two-loop effects [5].

* Presented at Cracow Epiphany Conference on Electron-Positron Colliders, 5–10 January 1999, Cracow, Poland
One should keep in mind that the Higgs sector might be more rich than suggested by the MSSM [6]. Thus, it would be most useful to establish the $CP$ properties of the Higgs particle from basic principles. A straightforward method to determine the parity is to study the angular distribution of the Higgs particle itself [7, 8]. A second approach makes use of the orientation of the plane spanned by the fermions from the accompanying $Z$ boson in the Bjorken process [9, 10, 11].

We also review the production of scalar Higgs-like particles in high-energy electron-electron collisions, via the fusion of electroweak gauge bosons. The emphasis is on how to distinguish a $CP$-even from a $CP$-odd Higgs particle [12]. Among the more significant differences, we find that in the $CP$-odd case, the Higgs spectrum is much harder, and the dependence of the total cross section on the product of the polarizations of the two beams is much stronger, as compared with the $CP$-even case. We also briefly discuss parity violation, and the production of charged Higgs bosons.

2. Trilinear Higgs couplings

Trilinear couplings of the neutral $CP$-even Higgs bosons in the Minimal Supersymmetric Standard Model (MSSM) can be measured through the multiple production of the lightest $CP$-even Higgs boson at high-energy $e^+e^-$ colliders. The relevant production mechanisms are the production of the heavier $CP$-even Higgs boson via $e^+e^- \rightarrow ZH$, in association with the $CP$-odd Higgs boson ($A$) in $e^+e^- \rightarrow AH$, or via the fusion process $e^+e^- \rightarrow \nu \bar{\nu} H$, with $H$ subsequently decaying through $H \rightarrow hh$.

The trilinear Higgs couplings that are of interest are $\lambda_{Hhh}$, $\lambda_{hhh}$, and $\lambda_{hAA}$, involving both the $CP$-even and $CP$-odd Higgs bosons. The couplings $\lambda_{Hhh}$ and $\lambda_{hhh}$ are rather small with respect to the corresponding trilinear coupling $\lambda_{SM}^{hhh}$ in the SM (for a given mass of the lightest Higgs boson $m_h$), unless $m_h$ is close to the upper value (decoupling limit). The coupling $\lambda_{hAA}$ remains small for all parameters.

We have considered the question of possible measurements of the trilinear Higgs couplings $\lambda_{Hhh}$ and $\lambda_{hhh}$ of the MSSM [13] at a high-energy $e^+e^-$ linear collider that will operate at an energy of 500 GeV with an integrated luminosity per year of $L_{int} = 500$ fb$^{-1}$ [14]. In a later phase one may envisage an upgrade to an energy of 1.5 TeV.

The multiple production of the light Higgs boson through Higgsstrahlung of $H$, and through production of $H$ in association with the $CP$-odd Higgs boson can be used to extract the trilinear Higgs coupling $\lambda_{Hhh}$. The non-resonant fusion mechanism for multiple $h$ production, $e^+e^- \rightarrow \nu \bar{\nu} h hh$, involves two trilinear Higgs couplings, $\lambda_{Hhh}$ and $\lambda_{hhh}$, and is useful for extracting $\lambda_{hhh}$. 
In units of $gm_Z/(2\cos\theta_W) = (\sqrt{2}G_F)^{1/2}m_Z^2$, the tree-level trilinear Higgs couplings involving $h$ are given by

\begin{align*}
\lambda_{Hhh}^0 &= 2\sin 2\alpha \sin(\beta + \alpha) - \cos 2\alpha \cos(\beta + \alpha), \\
\lambda_{hhh}^0 &= 3\cos 2\alpha \sin(\beta + \alpha), \\
\lambda_{hAA}^0 &= \cos 2\beta \sin(\beta + \alpha),
\end{align*}

with $\alpha$ the mixing angle in the $\text{CP}$-even Higgs sector, which is determined by the parameters of the $\text{CP}$-even Higgs mass matrix.

![Trilinear Higgs couplings](Fig. 1. Trilinear Higgs couplings $\lambda_{Hhh}$, $\lambda_{hhh}$ and $\lambda_{hAA}$ as functions of $m_h$ for $\tan\beta = 2.0$ and $\tan\beta = 10.0$. Each coupling is shown for $\tilde{m} = 1 \text{ TeV}$, and for three cases of the mixing parameters: no mixing ($A = 0$, $\mu = 0$, solid), mixing with $A = 1 \text{ TeV}$ and $\mu = -1 \text{ TeV}$ (dotted), as well as $A = 1 \text{ TeV}$ and $\mu = 1 \text{ TeV}$ (dashed).]

We include one-loop radiative corrections [15, 16] to the Higgs sector in the effective potential approximation. In particular, we take into account the parameters $A$ and $\mu$, the soft supersymmetry breaking trilinear parameter and the bilinear Higgs(ino) parameter in the superpotential. These parameters enter through the stop masses,

$$m_{\tilde{t}}^2 = m_t^2 + \tilde{m}^2 + m_t(A + \mu \cot \beta)$$

which again enter through the radiative corrections to the Higgs masses as well as to the Higgs trilinear couplings. The dominant one-loop radiative corrections are proportional to $(m_t/m_W)^4$, multiplying functions depending on the squark masses [15, 16].
The trilinear couplings depend significantly on $m_A$, and thus also on $m_h$. This is shown in Fig. 1 where we compare $\lambda_{Hhh}$, $\lambda_{hhh}$ and $\lambda_{hAA}$ for three different values of $\tan \beta$, and the SM quartic coupling $\lambda_{\text{SM}}$ (which also includes one-loop radiative corrections [17]). For a given value of $m_h$, the values of these couplings significantly depend on the soft supersymmetry-breaking trilinear parameter $A$, as well as on $\mu$.

As is clear from Fig. 1, at low values of $m_h$, the MSSM trilinear couplings are rather small. For some value of $m_h$ the couplings $\lambda_{Hhh}$ and $\lambda_{hhh}$ start to increase in magnitude, whereas $\lambda_{hAA}$ remains small. The values of $m_h$ at which they start becoming significant depend crucially on $\tan \beta$.

To sum up the behaviour of the trilinear couplings, we note that $\lambda_{Hhh}$ and $\lambda_{hhh}$ are small for $m_h < \sim 100–120$ GeV, depending on the value of $\tan \beta$. However, as $m_h$ approaches its maximum value, which requires $m_A > \sim 200$ GeV, these trilinear couplings become reasonably large.

3. Production mechanisms

Different mechanisms for multiple production of the MSSM Higgs bosons in $e^+e^-$ collisions have been discussed by DHZ. The dominant mechanism for the production of multiple $CP$-even light Higgs bosons is through the mechanisms

\[
e^+e^- \rightarrow ZH, AH \nonumber \}
\]
\[
e^+e^- \rightarrow \nu_e\bar{\nu}_e H \nonumber \}
\]
\[
H \rightarrow hh,
\]
shown in Fig. 2. The heavy Higgs boson $H$ can be produced by $H$-strahlung, in association with $A$, and by the resonant $WW$ fusion mechanism. All the diagrams of Fig. 2 involve the trilinear coupling $\lambda_{Hhh}$.

\[
\]

Fig. 2. Feynman diagrams for the resonant production of $hh$ final states in $e^+e^-$ collisions.

A background to (5) comes from the production of the pseudoscalar $A$ in association with $h$ and its subsequent decay to $hZ$

\[
e^+e^- \rightarrow hA, \quad A \rightarrow hZ,
\]

(6)
leading to $Zhh$ final states. A further mechanism for $hh$ production is
double Higgs-strahlung in the continuum with a $Z$ boson in the final state,
\[ e^+e^- \rightarrow Z^* \rightarrow Zhh. \]  
(7)

There is also a mechanism of multiple production of the lightest Higgs
boson through non-resonant $WW$ fusion in the continuum:
\[ e^+e^- \rightarrow \bar{\nu}_e\nu_e W^*W^* \rightarrow \bar{\nu}_e\nu_e hh, \]  
(8)
as shown in Fig. 3.

It is important to note that all the diagrams of Fig. 2 involve the trilinear
Higgs coupling $\lambda_{Hhh}$ only. In contrast, the non-resonant analogues of Figs. 2a, 2b
and 2c (or 3c) involve both the trilinear Higgs couplings $\lambda_{Hhh}$ and $\lambda_{hhh}$.

3.1. Higgs-strahlung and associated production of $H$

The dominant source for the production of multiple light Higgs bosons
in $e^+e^-$ collisions is through the production of the heavier $CP$-even Higgs
boson $H$ either via Higgs-strahlung or in association with $A$, followed, if
kinematically allowed, by the decay $H \rightarrow hh$.

In Fig. 4 we plot the relevant cross sections [18, 19] for the $e^+e^-$ centre-
of-mass energy $\sqrt{s} = 500$ GeV, as functions of the Higgs mass $m_H$ and
for $\tan \beta = 2.0$. For a fixed value of $m_H$, there is seen to be a significant
sensitivity to the squark mixing parameters $\mu$ and $A$. We have here taken
$\tilde{m} = 1$ TeV, a value which is adopted throughout, except where otherwise
specified.

A measurement of the decay rate $H \rightarrow hh$ directly yields $\lambda_{Hhh}^2$. But
this is possible only if the decay is kinematically allowed, and the branching
ratio is sizeable (but not too close to unity). In Fig. 5 we show the branching
ratios (at $\tan \beta = 2$) for the main decay modes of the heavy $CP$-even Higgs
boson as a function of the $H$ mass [20]. Apart from the $hh$ decay mode, the
other important decay modes are $H \rightarrow WW^*$, $ZZ^*$. For increasing values
of tan β (but fixed $m_h$), the $Hhh$ coupling gradually gets weaker (Fig. 1), and hence the prospects for measuring $\lambda_{Hhh}$ diminish. Also, the decay rates can change significantly with $\tilde{m}$, the over-all squark mass scale (see Fig. 5).

There is a sizeable region in the $m_A$–tan β plane where the decay $H \to hh$ is kinematically forbidden, shown in Figs. 6 and 7, as an egg-shaped region at the upper left. The boundary of the region depends crucially on the precise Higgs mass values. This is illustrated by comparing two cases of mixing parameters $A$ and $\mu$ at each of two values of the squark mass parameter $\tilde{m}$. We also display the regions where the $H \to hh$ branching ratio is in the range 0.1–0.9. Obviously, in the forbidden region, the $\lambda_{Hhh}$ cannot be determined from resonant production.

### 3.2. Double Higgs-strahlung

As discussed above, for small and moderate values of tan β, a study of decays of the heavy $CP$-even Higgs boson $H$ provides a means of determining the triple-Higgs coupling $\lambda_{Hhh}$. For the purpose of extracting the coupling $\lambda_{hhh}$, non-resonant processes involving two-Higgs ($h$) final states must be considered. The $Zhh$ final states produced in the non-resonant double Higgs-strahlung $e^+e^- \to Zhh$, and whose cross section involves the coupling $\lambda_{hhh}$, could provide one possible opportunity.

However, the non-resonant contribution to the $Zhh$ cross section is
rather small, as is shown in Fig. 8 for $\sqrt{s} = 500$ GeV, $\tan \beta = 2$, and $\tilde{m} = 1$ TeV. In this case, the cross section is rather different for the two sets of mixing parameters shown in Fig. 9. In the case of no mixing, there is a broad minimum from $m_h \simeq 78$ to 90 GeV, followed by an enhancement around $m_h \sim 90$–100 GeV. This structure is in part due to the fact that the decay $H \rightarrow hh$ is kinematically forbidden in the region $m_h \simeq 78$–90 GeV, see Figs. 6 and 7 (this coincides with the opening up of the channel $H \rightarrow WW$), followed by an increase of the trilinear couplings.

Since the non-resonant part of the cross section, which depends on $\lambda_{hhh}$, is rather small, this channel is not suitable for a determination of $\lambda_{hhh}$ [2]. In the case of large squark mixing, the cross section can be considerably larger [3], but only at Higgs masses which are essentially ruled out. At higher values of $\tan \beta$, the cross section is even smaller. For lower values of the squark mass parameter $\tilde{m}$, the cross section can be larger, but again at Higgs masses which are ruled out.

---

1. The LEP experiments have obtained strong lower bounds on the mass of the lightest Higgs boson, and are beginning to rule out significant parts of the small-$\tan \beta$ parameter space. ALEPH finds a lower limit of $m_h > 72.2$ GeV, irrespective of $\tan \beta$, and a limit of $\sim 88$ GeV for $1 < \tan \beta \lesssim 2$ [2].

---

Fig. 5. Branching ratios for the decay modes of the $CP$-even heavy Higgs boson $H$, for $\tan \beta = 2.0$ and $\tilde{m}$ equal to 1 TeV or 500 GeV, as indicated. Solid curves are for no mixing, $A = 0$, $\mu = 0$. For $\tilde{m} = 1$ TeV, the dashed curves refer to $A = 1$ TeV and $\mu = 1$ TeV, whereas for $\tilde{m} = 500$ GeV, the dashed (dotted) curves refer to $A = 500$ GeV (800 GeV) and $\mu = 1$ TeV (800 GeV).
Fig. 6. The region in the $m_A$–$\tan \beta$ plane where the decay $H \to hh$ is kinematically forbidden is indicated by a solid line contour. Also given are contours at which the branching ratio equals 0.1 (dotted), 0.5 (dashed) and 0.9 (dash-dotted, far left).

Fig. 7. Similar to Fig. 6, for squark mass parameter $\tilde{m} = 500$ GeV.

3.3. Fusion mechanism for multiple-h production

A two-Higgs ($hh$) final state can also result from the WW fusion mechanism in $e^+e^-$ collisions. There is a resonant contribution (through $H$) and a non-resonant one.

The resonant WW fusion cross section for $e^+e^- \to H \bar{\nu}_e \nu_e$ is plotted
in Fig. 4 for the centre-of-mass energy $\sqrt{s} = 500 \text{ GeV}$, and for $\tan \beta = 2.0$, as a function of $m_H$.

Besides the resonant $WW$ fusion mechanism for the multiple production of $h$ bosons, there is also a non-resonant $WW$ fusion mechanism:

$$e^+e^- \rightarrow \nu_e\bar{\nu}_e hh,$$

through which the same final state of two $h$ bosons can be produced. The cross section for this process (see Fig. 3), can be written in the effective $WW$ approximation as a $WW$ cross section, at invariant energy squared $\hat{s} = xs$, folded with the $WW$ “luminosity” [24]. Thus,

$$\sigma(e^+e^- \rightarrow \nu_e\bar{\nu}_e hh) = \int_0^1 dx \frac{dL}{dx} \tilde{\sigma}_{WW}(x),$$

where $\tau = 4m_h^2/s$, and

$$\frac{dL(x)}{dx} = \frac{G_F^2m_W^4}{2} \left( \frac{1}{2\pi^2} \right)^2 \frac{1}{x} \left\{ (1 + x) \log \frac{1}{x} - 2(1 - x) \right\}.$$  

The $WW$ cross section receives contributions from several amplitudes, according to the diagrams (a)–(d) in Fig. 3, only one of which is proportional to $\lambda_{hhh}$. We have evaluated these contributions [4], following the approach of Ref. [25], ignoring transverse momenta everywhere except in
the $W$ propagators. Our approach also differs from that of \cite{3} in that we do not project out the longitudinal degrees of freedom of the intermediate $W$ bosons.

We show in Fig. 9 the resulting $WW$ fusion cross section, at $\sqrt{s} = 1.5$ TeV, and for $\tilde{m} = 1$ TeV. The structure is reminiscent of Fig. 8, and the reasons for this are the same. Notice, however, that the scale is different. Since this is a fusion cross section, it grows logarithmically with energy.

For high values of $m_h$ we see that there is a moderate contribution to the cross section from the non-resonant part. For a lower squark mass scale $\tilde{m}$, the situation is somewhat different. In the absence of mixing, the light Higgs particle then tends to be lighter (for $\tilde{m} = 500$ GeV, $\tan \beta = 2$: $m_h \lesssim 90$ GeV — which is mostly ruled out already \cite{22}). With mixing, however, higher Higgs masses can be reached.

4. Sensitivity to $\lambda_{Hhh}$ and $\lambda_{hhh}$

We are now ready to combine the results and discuss in which parts of the $m_A$–$\tan \beta$ plane one might hope to measure the trilinear couplings $\lambda_{Hhh}$ and $\lambda_{hhh}$. In Figs. 10 and 11 we have identified regions according to the following criteria \cite{3,4}:

(i) Regions where $\lambda_{Hhh}$ might become measurable are identified as those where $\sigma(H) \times \text{BR}(H \rightarrow hh) > 0.1$ fb (solid), while simultaneously
0.1 < \text{BR}(H \rightarrow hh) < 0.9 \text{ [see Figs. 4, 7]}. In view of the recent, more optimistic, view on the luminosity that might become available, we also give the corresponding contours for 0.05 fb (dashed) and 0.01 fb (dotted).

(ii) Regions where \(\lambda_{hhh}\) might become measurable are those where the continuum \(WW \rightarrow hh\) cross section [Eq. (10)] is larger than 0.1 fb (solid). Also shown are contours at 0.05 (dashed) and 0.01 fb (dotted).

We have excluded from the plots the region where \(m_h < 72.2\) GeV \text{ [22]}. This corresponds to low values of \(m_A\) and low \(\tan \beta\).

![Fig. 10. Regions where trilinear couplings \(\lambda_{Hhh}\) and \(\lambda_{hhh}\) might be measurable at \(\sqrt{s} = 500\) GeV. Inside contours labelled \(\lambda_{Hhh}\), \(\sigma(H) \times \text{BR}(H \rightarrow hh) > 0.1\) fb (solid), while \(0.1 < \text{BR}(H \rightarrow hh) < 0.9\). Inside (to the right or below) contour labelled \(\lambda_{hhh}\), the continuum \(WW \rightarrow hh\) cross section exceeds 0.1 fb (solid). Analogous contours are given for 0.05 (dashed) and 0.01 fb (dotted). Two cases of squark mixing are considered, as indicated.}

These cross sections are small, the measurements are not going to be easy. With an integrated luminosity of 500 fb\(^{-1}\), the contours at 0.1 fb correspond to 50 events per year. This will be reduced by efficiencies, but should indicate the order of magnitude that can be reached.

With increasing luminosity, the region where \(\lambda_{Hhh}\) might be accessible, extends somewhat to higher values of \(m_A\). Note the steep edge around \(m_A \simeq 200\) GeV, where increased luminosity does not help. This is determined by the vanishing of \(\text{BR}(H \rightarrow hh)\), see Figs. 3 and 7.

The coupling \(\lambda_{hhh}\) is accessible in a much larger part of this parameter space, but “large” values of \(\tan \beta\) are accessible only if \(A\) is small, or if the
Fig. 11. Similar to Fig. 10 for $\tilde{m} = 500$ GeV.

luminosity is high.

The precise region in the $\tan \beta - m_A$ plane, in which these couplings might be accessible, depends on details of the model. As a further illustration of this point, we show in Fig. 11 the corresponding plots for a squark mass parameter $\tilde{m} = 500$ GeV. In the case of no mixing, there is now a band at small $m_A$ and small $\tan \beta$ that is excluded by the Higgs mass bound [22]. Furthermore, where the Higgs mass is low, the coupling $\lambda_{hhh}$ is small [see Fig. 1], and a corresponding band is excluded from possible measurements.

5. CP studies

In the MSSM, the Higgs sector contains also a particle that is odd under CP. Such particles, as well as Higgs-like particles which are not eigenstates of CP, would be expected in more general electroweak theories. One example would be the two-Higgs-doublet model [26]. Model-independent determinations of the Higgs particle CP are possible in the Bjorken process as well as in the electron-electron channel.

There could also be CP violation in the Higgs sector, in which case the Higgs bosons would not be CP eigenstates [27]. Such mixing could take place at the tree level [28], or it could be induced by radiative corrections. It has also been pointed out that such mixing might take place in the MSSM, and be resonant [29].
5.1. The Bjorken process

Certain distributions for the Bjorken process are sensitive to the $CP$ parity. Suitable observables may also demonstrate presence of $CP$ violation. Below, we present an effective Lagrangian which contains $CP$ violation in the Higgs sector. $CP$ violation usually appears as a one-loop effect, since the $CP$-odd coupling introduced below is a higher-dimensional operator and in renormalizable models these are induced only at loop level. Thus, the effects are expected to be small and the confirmation of presence of any $CP$ violation could be rather difficult.

The $ZZh$ coupling is taken to be

$$i2^{5/4}\sqrt{G_F}\begin{cases} m_Z^2 g^{\mu\nu} & \text{for } h = H \text{ (CP even)}, \\ \eta \epsilon^{\mu\nu\rho\sigma} k_1^\rho k_2^\sigma & \text{for } h = A \text{ (CP odd)}, \end{cases}$$

(12)

where $k_1$ and $k_2$ are the momenta of the gauge bosons. The $CP$ odd term originates from the dimension-5 operator $\epsilon^{\mu\rho\sigma} Z_{\mu\nu} Z_{\rho\sigma} H$. Simultaneous presence of $CP$-even and $CP$-odd terms leads to $CP$ violation, whereas presence of only the last term describes a pseudoscalar coupling to the vector bosons.

It is well known that the correlation between the two decay planes spanned by the Dalitz pairs from a $\pi^0$ decay reveal its pseudoscalar nature. In complete analogy, the orientation of the decay plane spanned by the momenta of the fermions from the $Z^0$ which is accompanying the Higgs particle in the Bjorken process can be used to determine the $CP$ of the Higgs particle. Other methods have also been suggested. These include studies of correlations among momenta of the initial electron and final-state fermions.

In fact, a semi-realistic Monte Carlo study shows that (at 300 GeV) it should be possible to verify the scalar character of the Standard Model Higgs after three years of running at a future linear collider. Also, various ways of searching for $CP$ violation have been suggested.

5.2. Electron-electron collisions

The electron-electron collider mode is interesting since one may produce states not accessible in the annihilation channel; also, a large electron polarization will be readily available. Furthermore, at high energies, the Higgs production at an electron-electron collider will proceed via gauge boson fusion, and thus not be suppressed by the $s$-channel annihilation.
mechanism. Certain models also predict doubly charged Higgs particles \cite{36}, some of which can be produced more readily at an electron-electron collider.

Scalar ("Higgs") particles, $h$, $h^{-}$ and $h^{--}$, are produced in the $t$-channel via $Z$- or $W$-exchange:

\begin{align}
  e^{-}(p_{1}) + e^{-}(p_{2}) & \rightarrow e^{-}(p'_{1}) + e^{-}(p'_{2}) + h(p_{h}), \\
  e^{-}(p_{1}) + e^{-}(p_{2}) & \rightarrow e^{-}(p'_{1}) + \nu_{e}(p'_{2}) + h^{-}(p_{h}), \\
  e^{-}(p_{1}) + e^{-}(p_{2}) & \rightarrow \nu_{e}(p'_{1}) + \nu_{e}(p'_{2}) + h^{--}(p_{h}).
\end{align}

(In some models, including the left–right symmetric model \cite{37}, the doubly-charged Higgs boson has practically no coupling to the ordinary, left-handed $W$ bosons and would not be produced by this mechanism.)

Several distributions are quite sensitive to the \textit{CP} of the Higgs particle. We see immediately from (12) that near the forward direction, where $k_{1}$ and $k_{2}$ are antiparallel, the production of a \textit{CP}-odd Higgs boson will be suppressed.

In the \textit{CP}-even case, the Higgs particle tends to be softer, and events are more aligned with the beam direction than in the \textit{CP}-odd case. In fact, the Higgs energy distribution may be one of the better observables for discriminating the two cases, as illustrated in Fig. 12.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig12.png}
\caption{Higgs energy spectra for the case $E_{c.m.} = 500$ GeV, and for Higgs masses $m_{h} = 120$ GeV and 150 GeV. The solid curves give the distributions in the absence of any cut. The dashed and dotted curves show the corresponding distributions when cuts at $5^\circ$ and $15^\circ$ are imposed on the electron momenta.}
\end{figure}

The dependence on longitudinal beam polarization ($P_{1}$ and $P_{2}$) enters
in the following way

\[ d^4\sigma^{(h)} = d^4\sigma_0^{(h)} \left[ 1 + A_1^{(h)} P_1 P_2 + A_2^{(h)} (P_1 + P_2) \right]. \]  

(16)

It turns out that the dependence on the product of the two beam polarizations is much larger in the CP-odd case. This dependence, which is represented by the observable \( A_1 \) (see Fig. 13), becomes a better “discriminator” for increasing Higgs masses, when the Higgs momentum decreases, and other methods therefore tend to become less efficient.

If the two final-state electrons are observed, a certain azimuthal distribution, as well as the electron polar-angle distributions, will also be useful for discriminating the two cases \[12\]. There are also ways to search for possible parity-violating effects in the ZZ-Higgs coupling.

6. Conclusions

We have reviewed the results of a detailed investigation \[4\] of the possibility of measuring the MSSM trilinear couplings \( \lambda_{Hhh} \) and \( \lambda_{hhb} \) at an \( e^+e^- \) collider, focusing on the importance of mixing in the squark sector, as induced by the trilinear coupling \( A \) and the bilinear coupling \( \mu \).
At moderate energies ($\sqrt{s} = 500$ GeV) the range in the $m_A$–$\tan \beta$ plane that is accessible for studying $\lambda_{Hhh}$ changes quantitatively for non-zero values of the parameters $A$ and $\mu$. As far as the coupling $\lambda_{hhh}$ is concerned, however, there is a qualitative change from the case of no mixing in the squark sector. If $A$ is large, then high luminosity is required, in order to reach “high” values of $\tan \beta$. At higher energies ($\sqrt{s} = 1.5$ TeV), the mixing parameters $A$ and $\mu$ change the accessible region of the parameter space only in a quantitative manner.

We have also given a brief review of some ways to investigate $CP$ properties of the Higgs particles, in $e^+e^-$ as well as in $e^-e^-$ collisions.

This research was supported by the Research Council of Norway. It is a pleasure to thank the organizers of the Epiphany conference for creating a most stimulating meeting. The topics reported on here have been explored with various colleagues whom I would like to thank for stimulating collaborations. Finally, it is with profound gratitude I acknowledge the inspiration that has been provided by Bjørn H. Wiik, whose enthusiasm for basic physics challenges influenced so many of us.
