We report the existence of flat bands in a p-wave superconducting Kitaev ladder. We identify two sets of parameters for which the Kitaev ladder sustains flat bands. These flat bands are accompanied by highly localized eigenstates known as compact localized states. Invoking a Bogoliubov transformation, the Kitaev ladder can be mapped into an interlinked cross-stitch lattice. The mapping helps to reveal the compactness of the eigenstates each of which covers only two unit cells of the interlinked cross-stitch lattice. The Kitaev Hamiltonian undergoes a topological-to-trivial phase transition when certain parameters are fine-tuned. Correlation matrix techniques allow us to compute entanglement entropy of the many-body eigenstates. The study of entanglement entropy affords fresh insight into the topological phase transitions in the model. Sharp features in entanglement entropy when bands cross indicate a deep underlying relationship between entanglement entropy and dispersion.

I. INTRODUCTION

In the last few years, dispersionless bands, also known as flat bands have received a great deal of attention within the condensed matter physics community [1–3]. In tight binding systems which have periodic lattice potentials, the Bloch theorem [4] assures the existence of a well defined band structure for a single particle, which in turn, uniquely defines the group velocity of the particle. Certain carefully tuned lattice Hamiltonians may exhibit one or more flat bands in the band structure, where the energy is independent of momentum resulting in zero group velocity. The study of the suppression of wave transport induced by flat bands has been carried out in a number of works [2, 5, 6]. Since the wave equations which govern the dynamics can be generalised, flat band physics has been explored in diverse systems ranging from Hubbard models [7, 8] to photonic crystals [9–11] and Bose-Einstein condensates [12, 13].

The eigenstates corresponding to flat bands are highly localized, covering a finite number of lattice sites, and are therefore referred to as compact localized states (CLS) [2]. One of the prime strategies for finding flat band systems has been to first identify CLS, and then engineer Hamiltonians that could support them. A number of recent studies [5, 14, 15] have searched for flat band generating algorithms with the aim of identifying more and more flat band networks. Many such studies have been based on non-interacting particles, and focus on geometries which support a flat band through destructive interference properties of the eigenstates [14, 16, 17]. In the present work, we report the existence of flat bands in a rather simple superconducting Kitaev ladder Hamiltonian system, which has hitherto been unexplored in this context. Subjecting the Kitaev ladder to a Bogoliubov transformation allows us to map it to an interlinked cross-stitch lattice and thus obtain the explicit compact localized states in the transformed basis. One key novelty in our work is that despite the very simple geometry of the lattice, a flat band becomes possible due to the p-wave superconducting term. Our tests indicate that the introduction of a pairing term to generate flat bands may well be quite general beyond the specifics of the current model, and could potentially open up a new avenue for flat-band engineering.

The Kitaev ladder [18] is a generalization of the Kitaev chain [19], which is a canonical system that admits a topological phase transition [20]. The simultaneous presence of both the superconducting term and the ladder geometry leads to many rich phenomena including some exotic transport properties [21]. Fur-
thermore, this system exhibits multiple topologically non-trivial phases characterized by different symmetry classes, which may be accessed by tuning different parameters. Quantum entanglement [6, 22, 25] has emerged as a key tool of study whenever quantum phase transitions are present. This includes topological-to-trivial phase transitions [26, 28], Meißen-vortex phase transitions [29, 30], localization/de-localization transitions [31, 32] and many others [33–35]. In this paper, we study entanglement in the many-body eigenstates of the Kitaev ladder. Since the computation of entanglement in the eigenstates of systems that feature a superconducting term is challenging, the literature [37] on this subject is rather sparse, and our work is to be seen as a contribution to filling this void. Thus, our paper is a study of the interplay of flat bands, topological properties, and entanglement properties of the Kitaev ladder.

The layout of the article is as follows: we start by introducing the Hamiltonian for the two-leg Kitaev ladder. The conditions for the flat bands and a discussion of compact localized states are provided in the subsequent section. The next section discusses the topological properties of the system before moving on to a study of entanglement entropy. Finally, we summarize our main findings in the last section.

II. KITAEV LADDER

The Kitaev ladder [19, 38] (Fig. 1(a)) consists of two Kitaev chains connected to one another through inter-leg hopping. This system is described by the tight-binding Hamiltonian:

\[ H = -t \sum_{n=1,2} c_{n+1,\sigma}^\dagger c_{n,\sigma} - \mu \sum_{n=1,2} c_{n,\sigma}^\dagger c_{n,\sigma} - t' \sum_{n} c_{n,1}^\dagger c_{n,2} - \Delta \sum_{n=1,2} e^{i\phi_n} c_{n+1,\sigma}^\dagger c_{n,\sigma} + H.c. \]

where, \( t \) is the intra-leg hopping amplitude, \( c_{n,\sigma}^\dagger, c_{n,\sigma} \) are creation (annihilation) operators on the \( n \)th site of the ladder with \( \sigma = 1, 2 \) running over two legs of the ladder, and \( \mu \) is the on-site chemical potential. The inter-leg hopping on the ladder is \( t' \) and the superconducting gap is \( \Delta \) with a phase factor \( e^{i\phi_n} \) in each leg of the ladder. As the annihilation of an electron is equivalent to the creation of a hole, one can write \( d_{n,\sigma}^\dagger = c_{n,\sigma}, d_{n,\sigma} = c_{n,\sigma}^\dagger \), and the Hamiltonian can be redefined in momentum space as [21, 38],

\[ H = \sum_k \Gamma_k^{\dagger} \mathcal{H}(k) \Gamma_k \]

Thus the overall Hamiltonian in \( k \)-space can be given as,

\[
\mathcal{H}(k) = \begin{bmatrix}
-\epsilon_{\mu,k} & t_{\Delta,\phi_1} & -t' & 0 \\
-t_{\Delta,\phi_1} & \epsilon_{\mu,k} & 0 & t' \\
0 & 0 & -\epsilon_{\mu,k} & t_{\Delta,\phi_2} \\
0 & t'_{\Delta,\phi_2} & \epsilon_{\mu,k} & 0
\end{bmatrix}
\]

with \( \epsilon_{\mu,k} = (2t \cos k + \mu) \) and \( t_{\Delta,\phi_j} = -2i\Delta \sin k e^{i\phi_j} \); \( j = 1, 2 \) and * denotes the complex conjugation. Diagonalizing the Hamiltonian, the dispersion relation is given by

\[
E(k) = \pm \sqrt{\epsilon_{\mu,k}^2 + t^2 + \tau_{\Delta,k} \pm 2t' \sqrt{\epsilon_{\mu,k}^2 + \tau_{\Delta,k} \sin^2 \Phi}}
\]

where, \( \tau_{\Delta,k} = 4\Delta^2 \sin^2 k \) and \( \Phi = \phi_2 - \phi_1 \). The ladder supports four bands in the band structure due to bonding and antibonding of both holes and electrons.

A. Flat band and localization

Flat bands are dispersionless bands in the energy spectrum of the translationally invariant lattice Hamiltonian. The Hamiltonian is fine-tuned to specific parameter values, leading to strictly flat bands in the entire Brillouin zone. A network could possess one or more flat bands that may be isolated or involve crossings with dispersive bands. In all the known cases, eigenstates corresponding to isolated flat bands are compact localized eigenstates (CLS) which reside on a finite volume of the lattice and absolutely vanishing in the rest of the lattice [17].
a careful choice of the parameters can help to engineer dispersionless bands. There are two main parameter sets that we consider in this study: 1) \( \Phi = 0, \mu = t', \Delta = t \) and 2) \( \Phi = \pi, \mu = 0, \Delta = t \). The first parameter set results in a band structure with two dispersive and two flat bands while the second results in four flat bands (Fig. 2). There maybe other parameter sets which yield flat bands, and perhaps they maybe found with the help of a recently proposed prescription [40]. We point out that the Kitaev chain itself admits flat bands - the flat band condition and the corresponding CLS here are discussed in the Appendix.

To obtain a finer understanding of the flat band conditions, it is useful to rewrite the Hamiltonian in Eq. 4 as:

\[
\mathcal{H}(k) = \begin{pmatrix}
-t e^{i k} - t e^{-i k} - \mu & -\Delta e^{i k} e^{i \phi_1} + \Delta e^{-i k} e^{i \phi_1} \\
\Delta e^{i k} e^{-i \phi_1} - \Delta e^{-i k} e^{-i \phi_1} & t e^{i k} + t e^{-i k} + \mu \\
-t' e^{i k} - t e^{-i k} - \mu & -\Delta e^{i k} e^{i \phi_2} + \Delta e^{-i k} e^{i \phi_2} \\
\Delta e^{i k} e^{-i \phi_2} - \Delta e^{-i k} e^{-i \phi_2} & t e^{i k} + t e^{-i k} + \mu
\end{pmatrix}
\]

In this form, the Hamiltonian maybe interpreted to represent a new lattice as shown in Fig. 1(b). Equations 4 and 6 are equivalent, with Eq. 6 representing the hopping configurations of the electron and hole explicitly. The new lattice, an interlinked cross-stitch lattice (ICS) consists of a unit cell with four sites which repeats in one spacial direction generating the whole lattice. The mapping leaves the dispersion relation (Eq. 4) unchanged resulting in the same four bands in the dispersion diagram. The ICS Hamiltonian also possesses the particle-hole symmetry. The ICS is a modified version of the well-studied cross-stitch lattice, which under certain conditions supports flat bands.

1. \( \Phi = 0, \mu = t', \Delta = t \)

The parameter set results in the dispersion relation \( E = \pm 2 t, \pm 2 \sqrt{t^2 + t'^2 + 2 t' t \cos k} \) which corresponds to two flat bands and two dispersive bands as shown in Fig. 2(a). Keeping the constraints \( \mu = t', \Delta = t \) and varying the parameters, the flat bands can be positioned to cross the dispersive bands or kept isolated from the dispersive bands. This choice of parameters brings forth some interesting topological properties which are discussed in the next section. The CLS corresponding to each flat band can be identified as shown in Fig. 3. The CLS resides on two unit cells, i.e., eight lattice sites, and has strictly zero amplitude outside the two unit cells which is guaranteed by the destructive interference of the probability amplitudes of the CLS at these sites. A translation of relevant unit cell across the length of the lattice results in the other CLS. Thus, the number of CLS for each flat band depends on the system size.

2. \( \Phi = \pi, \mu = 0, \Delta = t \)

This parameter set results in the dispersion relation \( E = \pm (2 t \pm t') \) yielding four flat bands as shown in Fig. 2(b). The eigenstates corresponding to the flat bands are the compact localized states (CLS) which are identified in Fig. 4. This CLS also resides on two unit cells, i.e., eight lattice sites, and has strictly zero amplitude outside the two unit cells as before. Thus, the eigenstate corresponding to the the original Kitaev ladder would also be localized and the transport will be prohibited for these parameter sets leaving the ladder in an insulating phase. Furthermore, the condition \( t' = 0 \) leads to two uncoupled regular cross-stitch chains, each possessing two flat bands.

FIG. 3. The compact localized states corresponding to (a) \( E = -2 \), (b) \( E = 2 \) and system parameters are \( \Phi = 0, \mu = t' = 1, \Delta = t = 1 \). The dotted lines represent hopping -1 and regular lines represents hopping +1. The CLS resides on eight lattice sites with amplitude \( \pm 1 \) on those sites.
FIG. 4. The compact localized states corresponding to (a) $E = 3$, (b) $E = 1$, (c) $E = -1$, (d) $E = -3$ and system parameters are $t = \Delta = 1$, $\mu = 0$, $t' = 1$, $\phi_1 = 0$, $\phi_2 = \pi$. The dotted lines represent hopping $-1$ and regular lines represent hopping $+1$. The CLS resides on eight lattice sites with amplitude $\pm 1$ on those sites.

B. Topological properties

One of the most striking features of the Kitaev ladder [19, 41] is its topological property. The Kitaev ladder encounters a change of topological class [20, 42] from BDI to D [18, 43] when subjected to a superconducting phase difference $\Phi$. The system undergoes a quantum phase transition when the winding number [18, 41] changes from two to one in the absence of superconducting phase [38]. The energy spectrum in the absence of superconducting phase difference $\Phi$ is shown in Fig. 5(a). The topological region is of two types. The region $|\mu| < 2t - t'$ is characterized by the presence of four zero energy Majorana edge states with winding number two, while the region $2t - t' < |\mu| < 2t + t'$ is characterized by the presence of two zero energy Majorana edge states with winding number one. The trivial phase with winding number zero lies beyond $|\mu| = 2t + t'$ featuring no zero energy Majorana states. Figure 5(b) shows the energy spectrum when the superconducting phase difference is set to be $\Phi = \pi$. We see two distinct two-fold degenerate states at $\pm \frac{\pi}{2}$ indicating a partial lifting of the four-fold degeneracy of the zero energy states in Fig. 5(a). Also, the system is now classified into the D class, because of the broken time-reversal symmetry. The topological-to-trivial phase transition is also signalled by the Majorana number $M$ [38, 44]. We see multiple crossings of energy bands starting from $|\mu| = 2t - t'$ to $|\mu| = 2t + t'$. These crossings of bands increase the degeneracies of the system and are nicely captured by entanglement entropy as shown in the next section.

III. ENTANGLEMENT ENTROPY

Entanglement [22, 23] is one of the most fundamental aspects of many body quantum systems. It reveals the quantum correlations between the different partitions under study. The most commonly used quantifier of entanglement $S_A$ for a pure state is the bipartite von Neumann entropy: $S_A = -\text{Tr}(\rho_A \ln \rho_A)$, with $\rho_A$ being the reduced density matrix of the subsystem $A$ calculated by tracing out the degrees of freedom of the subsystem $B$. In the non-interacting limit with no pairing term, the entanglement entropy of a subsystem can be effectively calculated with the help of the subsystem correlation matrix: $C_{mn} = (c_{in} c_{in}')$. It has been shown [23, 46, 47] that the entanglement entropy is connected to the eigenvalues of this correlation matrix. The correlation matrix approach can be further generalized to study Hamiltonians including a pairing term by considering an additional correlation matrix: $F_{mn} = (c_{im} c_{in}')$.

To study this system, we use the well known LSM method [48] introduced by Lieb, Schultz and Mattis. Using the LSM formalism, one can write the Hamiltonian in Eq. (1) as the sum of a Hermitian matrix $A$ and a non-Hermitian matrix $B$ as given in Eq. (7):

$$H = \sum_{i,j=1}^{N} c_{i}^\dagger A_{ij} c_{j} + \frac{1}{2} \sum_{i,j=1}^{N} (c_{i}^\dagger B_{ij} c_{j} - c_{i} B_{ij}^\dagger c_{j}),$$

where, $c_{i}$ is a fermionic annihilation operator on the $i^{th}$ site of the leg $a$ for $i = 1, 2, \ldots, L$ and on
the \((i - L)^{th}\) site of the leg \(b\) for rest of the values of \(i\). \(N = 2L\) being the total number of sites of the ladder system. Upon diagonalization with the help of the Bogoliubov transformation \(\eta_\alpha = \sum_{i=1}^{N} \left( \frac{1}{2} (\Phi_\alpha(i) + \Psi_\alpha(i)) c_i + \frac{1}{2} (\Phi_\alpha(i) - \Psi_\alpha(i)) c_i^\dagger \right)\), the Hamiltonian takes the form:

\[
H = \sum_{\alpha=1}^{N} \Lambda_\alpha (\eta_\alpha^\dagger \eta_\alpha - 1/2).
\]

The normalized vectors \(\Phi_\alpha, \Psi_\alpha\) and the energy spectrum \(\Lambda_\alpha\) can be obtained by solving two coupled equations \[49\] for \(\Phi_\alpha\) and \(\Psi_\alpha\):

\[
(A - B) \Phi_\alpha = \Lambda_\alpha \Psi_\alpha \tag{9}
\]

\[
(A + B) \Psi_\alpha = \Lambda_\alpha \Phi_\alpha \tag{10}
\]

In order to compute \[50\] the entanglement entropy, one has to calculate the correlation matrix of the system. The full system correlation matrix is given by

\[
G_{ij} = \langle GS| (c_i^\dagger - c_j) (c_i^\dagger + c_j) |GS \rangle \tag{11}
\]

where \(i, j = 1, 2, \ldots, N\). This correlation matrix can be computed using normalized functions \(\Phi_\alpha\) and \(\Psi_\alpha\) as

\[
G_{ij} = - \sum_{\alpha=1}^{N} \Psi_\alpha(i) \Phi_\alpha(j). \tag{12}
\]

The anticommutation properties of the \(\eta\) operators allow us to obtain the useful relations: \(\langle \eta_i^\dagger \eta_j \rangle = \delta_{ij}\) and \(\langle \eta_i \eta_j \rangle = 0\). To compute von Neumann entanglement entropy, one first selectively takes out the part of the full correlation matrix which connects to the subsystem of interest as \(G_s\). Then the entanglement entropy is computed using the method discussed in Ref. \[37\]. Thus, we have

\[
S = - \frac{1 + \nu_\alpha}{2} \ln \left( \frac{1 + \nu_\alpha}{2} \right) - \frac{1 - \nu_\alpha}{2} \ln \left( \frac{1 - \nu_\alpha}{2} \right) \tag{13}
\]

where, \(\nu_\alpha\) is the square root of the eigenvalues of the matrix \(G_s G_s^T\).

In this work, we analyze two sets of parameters that yield flat bands, and employ entanglement entropy to study the similarities and differences of their properties. Furthermore, in each of these cases, it is useful to consider two types of partitions of the system, which we call horizontal and vertical divisions. The horizontal division makes the two legs of the ladder as two partitions of the system whereas the vertical division considers the two halves of the ladder with ladder length \(\frac{L}{2}\) as the two subsystems of interest.

### A. Phase difference \(\Phi = 0\)

In this subsection, the superconducting phase difference between the two legs of the ladder is maintained at \(\Phi = 0\) \((\phi_1 = \phi_2 = 0)\). The dispersion relation of the Kitaev ladder system under this condition is (shown in Fig. 5(a))

\[
E(k) = \pm \sqrt{2t \cos k + \mu^2} + 4\Delta^2 \sin^2 k. \tag{14}
\]

The inter-leg hopping \(t'\) results in intermixing of two Kitaev chain bands, whose effects are well studied with the help of entanglement entropy. Firstly, the behaviour of entanglement entropy for various inter-leg hopping \(t'\) of the Kitaev ladder is shown for the two type of partitions in Fig. 6. As depicted in Fig. 6(a) in the absence of inter-leg hopping \(t\) along with different \(\mu\) values under periodic boundary conditions.

The same behavior can be seen in Fig. 6(b) when the system is divided vertically. In the absence of inter-leg hopping \(t'\) the two legs of the ladder behave as two independent Kitaev chains each contributing \(\ln(2)\) to entanglement entropy. However, strong inter-leg hopping \(t'\) increases the quantum correlations between the two

![Fig. 6](image-url)
legs of the ladder, and weakens the quantum correlations along the legs of the ladder. This causes the vertical division entanglement entropy $S_v$ to fall with $t'$. The other striking feature from this figure is the occurrence of a kink in $S_v$ at the quantum phase transition.

![Fig. 7](image1.png)

FIG. 7. The entanglement entropy ($S_h$) in units of $\ln 2$ of Kitaev ladder under horizontal division with various filling $\mu$, for different rungs hopping $t'$. The parameters are set to $L = 50, t = \Delta = 1.0, \phi = 0$ and periodic boundary conditions are imposed.

In Fig. 7 the behavior of the horizontal division entanglement entropy ($S_h$) with filling $\mu$ is shown. For large $|\mu|$ the system tends to approach either the fully filled state or the fully empty state, yielding zero entanglement entropy ($S_h$) in each case as shown in Fig. 7. A discontinuity in the entropy is seen at the four quantum phase transition points i.e. $|\mu| = 2t \pm t'$. The system possesses two types of quantum phases as described in Fig. 5(a). The entropy features different behavior in different topological regions. The case $t' = 2t$ is special, where two of the discontinuities merge at the origin ($\mu = 0$, corresponding to half-filling). We expect a maximum entanglement entropy close to half filling (i.e. $\mu \sim 0$) for $t' > 2t$ as confirmed in Fig. 7. In contrast, for $t' < 2t$ in the topological region, we see that the entanglement entropy features a broader flat region close to $\mu \sim 0$ due to weakened singlets between the legs of the ladder. This broader region goes to zero for $t' \to 0$ but under open boundary conditions it starts from $\ln 2$ due to the presence of degenerate Majorana edge modes.

![Fig. 8](image2.png)

FIG. 8. The entanglement entropy ($S_v$) in units of $\ln 2$ of Kitaev ladder under vertical division with various filling $\mu$, for different rungs hopping $t'$ for set of parameters $L = 50, t = \Delta = 1.0, \phi = 0$, and under imposed periodic boundary conditions.

The vertical division entanglement entropy ($S_v$) between two halves of the ladder, shown in Fig. 8 is also very revealing. The peaks signal the critical points ($|\mu| = 2t \pm t'$) corresponding to quantum phase transitions. The entanglement entropy ($S_v$) close to half filling ($\mu \sim 0$) signifies the change from $2\ln 2$ to zero when the system switches from a topological to a trivial phase, just like in the normal Kitaev chain. In contrast to $S_h$ this entanglement entropy ($S_v$) is small in the limit of strong inter-leg hopping $t'$ and high in the limit of small $t'$ due to formation of strong quantum correlations along the legs of the superconducting ladder.

![Fig. 9](image3.png)

FIG. 9. The flat band entanglement entropy (a) $S_h$ (b) $S_v$ of the Kitaev ladder with various $t'$ for the set of parameters $L = 50, t = \Delta = 1.0, \phi = 0$, $t' = \mu$ in units of $\ln 2$.

As we know, the flat band is a special case leading to high degeneracy in the system. In the absence of superconducting phases $\Phi = 0$ with $t = \Delta$ and $\mu = t'$ (in Eq. 14) the Kitaev ladder possesses two flat bands and two dispersive bands (Fig. 2(a)). The behavior of the entanglement entropy under such conditions is shown in Fig. 9 with $\mu = t'$. The flat band limit is attained by varying filling in the system which results in low saturation values of $S_h$ as shown in Fig. 9(a). There is only one quantum phase transition point at $t' = t$. The discontinuity in entanglement entropy in both Fig. 9(a,b) is a clear signatures of this quantum phase transition at $t' = t$.

B. Phase difference $\Phi = \pi$

In this subsection, the superconducting phase difference is maintained at $\Phi = \pi (\phi_1 = 0, \phi_2 = \pi)$. Again the focus of the study will be the two types of entanglement
entropy i.e. $S_h$ and $S_v$. The role of the flat band that appears on a further fine-tuning of the parameters, is then studied as a special case. Fig. 10 illustrates the nature of the horizontal division entanglement entropy ($S_h$) as a function of the inter-leg hopping $t'$.

The dispersion relation for the Kitaev ladder with $\Phi = \pi$ is given by

$$E(k) = \pm \left( \sqrt{(2t \cos k + \mu)^2 + 4\Delta^2 \sin^2 k \pm t'} \right).$$

(15)

So the Kitaev ladder with $\Phi = \pi$ may be thought of as being effectively made up of two independent Kitaev chains with the origin of the energy shifted by $\pm t'$ in one case and $-t'$ in the other. We see from Fig. 10 that the entanglement entropy remains zero, until $t'$ hits a threshold value. This feature is to be contrasted with Fig. 6(a) where the entanglement begins to rise for the tiniest of $t'$. We can understand this feature as a consequence of the system effectively being two independent chains; entanglement entropy ($S_h$) remains zero until the energy levels of the two chains cross each other as can be seen from the inset of Fig. 10.

As the coupling strength $t'$ is increased, we see a staircase-like increase in the entanglement entropy. We are able to identify the jumps to coincide with a simultaneous crossing of bands in the energy spectrum as shown in the inset of Fig. 10. The point at which bands cross is also a point of degeneracy. Each degenerate state contributes an amount $\ln 2$ to entanglement entropy and so the magnitude of the jump in $S_h$ is $2 \ln 2$ times the degeneracy at the band-crossing point in question. It can be seen that the derivative $[51]$ of entanglement entropy nicely captures this feature. The staircase structure starts at $t' = 2t - \mu$ and saturates at $t' = 2t + \mu$. Furthermore, the two critical values are the points where the band closes and the entanglement entropy nicely captures these quantum phase transitions of the system. The entanglement entropy saturates at the maximum possible value of $S_{sat} = L \ln 2$ where $L$ is the number of rungs of the ladder system. We infer this is due to the formation of singlets along every rung of the ladder. With open boundary conditions, degenerate Majorana edge modes are present at $\pm \frac{t'}{2}$ separately for each of the two independent Kitaev chains of the ladder. These Majorana edge modes again yield higher entanglement entropy ($S_h$) of $\ln 2$ (as opposed to zero, for periodic boundary conditions) for small inter-leg hopping amplitudes ($t'$).

The flat band condition is a special case involving highly degenerate states in the system. It appears when $t = \Delta$, $\mu = 0$, in addition to $\Phi = \pi$. For this parameter set, all the four bands are flat, in contrast to the earlier case where two bands were dispersive and two were flat (Fig. 6). It can be seen from Fig. 10 that when the system is tuned to the flat band condition, the horizontal division entanglement entropy ($S_h$) of the system shows a large and sudden jump from the minimum value i.e. zero all the way up to the maximum value i.e. $L \ln 2$ at $t' = 2t$. This is due to the crossing of highly degenerate flat energy bands at $t' = 2t$. It is worth noting that for the parameter set that we have imposed here, it turns out that each of the constituent Kitaev chains itself is subject to its own flat band condition (i.e., $t = \Delta$).

The vertical division entanglement entropy ($S_v$) confirms the above observations as shown in Fig. 11. Before crossing the lower critical point $t' = 2t - \mu$, the entanglement entropy ($S_v$) is locked at a value of $2 \ln 2$. Once again, this can be understood if we think of the Kitaev ladder as being made of two individual Kitaev chains,
each contributing an amount of \( \ln 2 \) to the entanglement entropy. Also beyond the higher critical point \( t' = 2t + \mu \), the entanglement entropy becomes zero confirming the formation of a state made up of singlets along each rung of the ladder. In between these critical bounds the entanglement entropy shows discontinuous behavior. This is once again understood as a consequence of the crossing of bands at these points. Once again strikingly, when the system is tuned to the flat band condition, there is a single big jump in \( S_v \) from \( 2 \ln 2 \) to zero at the quantum phase transition.

A study of the dependence of the entanglement entropy as a function of the chemical potential \( \mu \) is also instructive. The entanglement pertaining to horizontal division is shown in Fig. 12 while that related to the vertical division is shown in Fig. 13. When the rungs coupling \( t' \) is very small, the system behaves as two independent Kitaev chains and the topological-to-trivial phase transition occurs at \( \mu = \pm (2t \pm t') \) as already shown in Fig. 5(b).

Let us first look at Fig. 12. We see that for any value of \( t' \), the entanglement entropy \( (S_h) \) is a symmetric function of \( \mu \) about the origin. We recall from Fig. 5(b) that for \( \mu = \pm (2t + t') \), the bands cross, and therefore in the regime \( |\mu| > (2t + t') \) where the two chains behave independently, \( S_h \) remains zero. In the regime \( 2t - t' < |\mu| < 2t + t' \), we see the entanglement grow in a staircase-like shape, with the jumps happening at points where two bands cross, and whose jump height is given by \( \ln 2 \) times the degeneracy. We observe that \( S_h \) first increases and reaches a maximum value which is characteristic of the particular \( t' \) in question, and has to do with the degree of degeneracy in the dispersion. It then falls again with the overall curve being symmetric in \( \mu \). For \( \mu = 0 \), the flat band condition holds (along with \( t = \Delta \) and \( \Phi = \pi \), which have already been imposed in this section), and we see striking behaviour in \( S_h \) as the system undergoes a transition from the topological to the trivial phase. As we have already seen in Fig. 10, \( S_h \) undergoes a sudden jump from zero entropy for \( t' < 2t \) to \( \ln 2 \) entropy for \( t' > 2t \). In Fig. 12 we see that the size of the flat zero entropy region around the origin keeps on shrinking as \( t' \) approaches \( 2t \) from below, and then flips over to a flat maximum entropy region around the origin, whose size increases with \( t' \) away from \( 2t \). However, under open boundary conditions close to half filling \( (\mu = 0) \), the entanglement entropy \( (S_h) \) features a flip from \( \ln 2 \) to \( \ln 2 \) due to the presence of Majorana edge modes.

Next we look at the vertical division entanglement entropy \( (S_v) \) shown in Fig. 13. Like \( S_h \), \( S_v \) is also symmetric in \( \mu \) about the origin. In the regime \( |\mu| > (2t + t') \) where the two chains behave independently, \( S_v \) is small but not zero, because of weak quantum correlations along the legs of the ladder. At these conditions \( |\mu| = 2t + t' \), and \( |\mu| = 2t - t' \), we see jumps in \( S_v \), like before. We observe that in regions where \( S_h \) is high, \( S_v \) tends to be small, presumably because of the underlying monogamy restrictions, which forbids high entanglement of one subsystem with multiple others. The special case of \( \mu = 0 \) corresponding to the flat band condition displays a sharp dramatic change as the system undergoes a topological phase transition. In the topological phase \( t' < 2t \), \( S_v = 2 \ln 2 \), and is zero beyond \( t' > 2t \), in the trivial phase. We also observe a flat zero entropy region close to \( \mu = 0 \) in the trivial phase, which flips over to a flat region of value \( 2 \ln 2 \) about \( \mu = 0 \) in the topological phase.

IV. SUMMARY

In this work, we report the existence of flat bands in a Kitaev ladder that includes a p-wave superconducting term. These flat bands in dispersion are associated with
strongly localised eigenstates known as compact localized states (CLS). With the help of a Bogoliubov transformation, we are able to map the Hamiltonian of the p-wave superconductor onto an interlinked cross-stitch lattice, and thus explicitly obtain the underlying compact localized eigenstates.

Studying the dispersion allows us to propose two different parameter sets of the Hamiltonian that yield flat bands. Firstly, we discuss the presence of flat bands for the Kitaev ladder in the absence of superconducting phase difference $\Phi = 0$ featuring two dispersive and two flat bands. Next, tuning the superconducting phase difference to $\Phi = \pi$ results in a band structure with only flat bands leaving the system completely insulating. The CLS corresponding to these flat bands are localised on two unit cells of the lattice and with zero amplitude elsewhere. The high localisation of these states is responsible for the suppression of transport in the system.

Building on the techniques of Vitagliano et al [37], we are able to compute many body entanglement entropy in the eigenstates of the Kitaev ladder. Analogous to numerous other quantum phase transitions, entanglement entropy proves to be a striking diagnostic of the underlying topological-to-trivial phase transition in this system. The inclusion of superconducting phase in the Kitaev ladder gives rise to a change in topological class from BDI to D but entanglement entropy remains a robust diagnostic in both topological classes. For the computation of entanglement entropy, we consider two bi-partitions of the system namely the horizontal and vertical divisions, which offer complementary insight.

The entanglement entropy is found to strongly depend on the choice of inter-leg hopping $t'$ in both the partitions of the system. Due to underlying monogamy constraints, the trends of the horizontal division entanglement entropy contrast those of the vertical division entanglement entropy. In the absence of superconducting phase difference ($\Phi = 0$), strong inter-leg hopping connecting the two legs of the ladder, tends to enhance the tendency to form singlets along the rungs, and results in high horizontal division entanglement entropy. When the parameters admit a flat band, the horizontal division entanglement entropy seems to be generally suppressed, in particular featuring lower maximum values compared to non-flat band tuning. In the presence of superconducting phase difference ($\Phi = \pi$), the Kitaev ladder can be mapped to two independent Kitaev chains with shifts in energies by $\pm t'$. The horizontal division entanglement entropy shows a staircase behaviour where the sizes of the steps closely match the degeneracy of the crossing bands. Also, the entanglement entropy features a sharp jump at the flat band condition ($t = \Delta$, $\mu = 0$ and $\Phi = \pi$) due to the crossing of highly degenerate bands.

We envisage that our work could open up a range of new avenues for further exploration. The conventional way to analyse flat bands is to first discover the compact localised states and then to identify the corresponding Hamiltonian. Here, we take the opposite direction; we uncover the existence of flat bands in the very simple Kitaev ladder, followed by detection of corresponding compact localization states. It appears that the p-wave pairing symmetry is critical to enabling flat-bands in the present system. Our own preliminary calculations (not reported here) indicate that the introduction of the pairing terms along the rungs of the ladder can also yield flat bands. We speculate that this method may be general and may help in engineering other simple geometry lattices that support flat bands. Furthermore, we believe that the study of many-body entanglement entropy could offer fresh insights in other systems. For example, the emergence of Majorana flat bands in s-wave and d-wave superconductors [53, 54] is connected to their underlying compact localization states. A study of many-body entanglement entropy in such systems may provide a finer understanding of the topological properties and edge state behaviour of such lattice structures.

APPENDIX 1: FLAT BANDS IN KITAEV CHAIN

The Kitaev ladder discussed in the present article has been shown to possess two or four flat bands according to the parameter set chosen for the Hamiltonian. Further, the Kitaev ladder has been mapped on to an interlinked cross-stitch lattice and the eigenstates corresponding to flat bands have been shown as CLS. In this Appendix, we show that setting the rungs hopping \( t' = 0 \) separates the Kitaev ladder into two Kitaev chains and the latter can be mapped into a well-known flat band lattice known as cross-stitch lattice.

When \( t' \) is set to zero, the tight-binding Hamiltonian for Kitaev ladder leads to that for a Kitaev chain and can be represented as:

\[
H = -t \sum_n c_{n+1}^\dagger c_n - \mu \sum_n c_n^\dagger c_n - \Delta \sum_n c_{n+1}^\dagger c_{n}^\dagger + H . c ,
\]

where \( t \) is the intra-leg hopping amplitude, \( c_n^\dagger (c_n) \) are creation (annihilation) operators on the \( n^{th} \) site of the chain. Through a Bogoliubov transformation \[21, 38\], the overall Hamiltonian in \( k \)-space is given as

\[
H(k) = \begin{bmatrix}
-\epsilon_{\mu,k} & t_{\Delta} \\
t_{\Delta} & \epsilon_{\mu,k}
\end{bmatrix}
\]

with \( \epsilon_{\mu,k} = (2t \cos k + \mu) \) and \( t_{\Delta} = 4\Delta^2 \sin^2 k \). The dispersion relation corresponding to both flat bands which reflect the particle-hole symmetry of the Hamiltonian.

To understand the flat band properties of the Kitaev chain better, the Hamiltonian can be rearranged as

\[
H = \begin{pmatrix}
-\mu - e^{-ik}t - e^{ik}t & \Delta e^{-ik} - \Delta e^{ik} \\
\Delta e^{ik} - \Delta e^{-ik} & \mu + e^{-ik}t + e^{ik}t
\end{pmatrix}
\]

(19)

The resulting Hamiltonian can be mapped onto a cross-stitch chain as shown in Fig. [14](a). The cross-stitch chain consists of two sites per unit cell represented by \( A \) and \( B \) in the figure. For \( \mu = 0, \ t = \Delta = 1 \), the Kitaev chain and hence the cross-stitch chain supports two flat bands at \( E = \pm 2 \). The CLS corresponding to both flat bands in the cross-stitch chain are shown in Fig. [14](b) and (c). The CLS for both bands reside on two unit cells (i.e., four sites) with strictly zero amplitudes in the rest of the chain.

With \( \epsilon_{\mu,k} = (2t \cos k + \mu) \) and \( t_{\Delta} = 4\Delta^2 \sin^2 k \). The dispersion relation corresponding to both flat bands which reflect the particle-hole symmetry of the Hamiltonian.

To understand the flat band properties of the Kitaev chain better, the Hamiltonian can be rearranged as

\[
H = \begin{pmatrix}
-\mu - e^{-ik}t - e^{ik}t & \Delta e^{-ik} - \Delta e^{ik} \\
\Delta e^{ik} - \Delta e^{-ik} & \mu + e^{-ik}t + e^{ik}t
\end{pmatrix}
\]

(19)

The resulting Hamiltonian can be mapped onto a cross-stitch chain as shown in Fig. [14](a). The cross-stitch chain consists of two sites per unit cell represented by \( A \) and \( B \) in the figure. For \( \mu = 0, \ t = \Delta = 1 \), the Kitaev chain and hence the cross-stitch chain supports two flat bands at \( E = \pm 2 \). The CLS corresponding to both flat bands in the cross-stitch chain are shown in Fig. [14](b) and (c). The CLS for both bands reside on two unit cells (i.e., four sites) with strictly zero amplitudes in the rest of the chain.
