Abstract

We present a new methodology to derive the positions of the Sgr B molecular clouds (MCs) along the line of sight, as an application study of the Galactic center diffuse X-rays (GCDX). The GCDX is composed of hot plasma emission of about 7 keV and 1 keV temperatures, and non-thermal continuum emission including the 6.4 keV line from neutral irons. The former, the Galactic center plasma emission (GCPE), is uniformly distributed over 1 degree in longitude, while the latter is clumpy emission produced by Thomson scattering and fluorescence from MCs irradiated by external X-rays (the X-ray reflection nebula emission: XRNE). We examined the Suzaku X-ray spectra of the GCPE and XRNE near to the Sgr B MC complex, and found that the spectra suffer from two different absorptions of $N_H$ (Abs1) $\geq 10^{23}$ H cm$^{-2}$ and $N_H$ (Abs2) $\approx 6 \times 10^{22}$ H cm$^{-2}$. Abs1 is proportional to the 6.4 keV-line flux, and hence is due to the MCs, while Abs2 is typical of interstellar absorption toward the Galactic center. Assuming that the GCPE plasma is spherically-extended around Sgr A* with a uniform density and the same angular distribution of the two temperature components, we quantitatively estimated the line-of-sight positions of the MCs from the flux ratio the GCPE spectrum suffered by Abs1 and that with no Abs1. The results suggest that the Sgr B MCs are located at the near side of Sgr A* in the GCPE.

Key words: Galaxy: center — ISM: molecules, clouds, structure — X-ray spectra

1. Introduction

The Galactic center (GC) region is complex with many molecular clouds (MCs), emission nebulae, supernova remnants (SNR), non-thermal radio emission, and so on. The major component is the central molecular zone (CMZ, $|l| \leq 1^\circ$; Morris & Serabyn 1996) which contains mass of $3 \times 10^5 M_\odot$ (Dahmen et al. 1998), approximately corresponds to 10% of the whole molecular gas in the Galaxy. Sgr B1 and B2 are the most well-known and massive MCs in the CMZ. The detail of the CMZ structure has been studied mainly based on radio observations. Using $(l,V)$ diagrams of the CO and CS lines and based on the assumption of the dynamical motions of the GC region, the line-of-sight distribution of MCs was investigated (e.g. Sofue 1995; Tsuboi et al. 1999; Nakanishi & Sofue 2003). On the other hand, Sawada et al. (2004) examined the spatial correlation between 2.6-mm CO line and 18-cm OH absorption line, and predicted the line-of-sight positions of MCs with no assumption of dynamical motions.

The GC region within the CMZ is also bright in the diffuse X-rays called the Galactic center diffuse X-ray (GCDX) (e.g. Koyama et al. 2007c). The GCDX has been found to have thermal emission from hot plasmas, and hence we refer to the emission as the Galactic center plasma emission (GCPE). The X-ray spectrum of the GCPE exhibits strong K-shell emission lines from highly ionized atoms such as Fe XXV (6.7 keV) and Si XV (2.45 keV). Koyama et al. (2007c) found that the line-intensity ratios of Fe XXVI Kα (6.97 keV)/Fe XXV Kα (6.7 keV) and Fe XXV Kβ (7.88 keV)/Fe XXV Kα (6.7 keV) are about 0.33 and 0.09, respectively. These values indicate that the plasma is in a collisional ionization equilibrium (CIE) at the temperature of kT $\approx 6.5$ keV. On the other hand, the K-shell emission from lighter elements, like the Sn XV Kα line (2.45 keV), is due to a lower temperature plasma of $\sim 1$ keV. The GCPE extends over the GC region of about 1 degree in longitude with a monotonic decrease as the distance from Sgr A* increases (Koyama et al. 1989, Yamauchi et al. 1990).

The GCDX has another component, non-thermal emission with the Fe I Kα line of 6.4 keV from neutral irons (hereafter 6.4 keV-line). The diffuse 6.4 keV-line in the Sgr B region was firstly found by the ASCA satellite (Koyama et al. 1996). The Suzaku satellite deeply observed the Sgr B region and found three bright 6.4 keV sources, Sgr B2 (M 0.66–0.02), M 0.74–0.09 (Koyama et al. 2007b), and Sgr B1 (M 0.51–0.10; Nobukawa et al. 2008), at the locations of the MCs identified by the CO line and the CS line (Sofue 1995; Tsuboi et al. 1999). The X-ray spectra of these sources have common features: a large equivalent width ($EW \geq 1$ keV) for the 6.4 keV-line and a strong absorption ($N_H \geq 10^{23}$ H cm$^{-2}$) feature for the continuum below $\sim 4$ keV. In addition, a time variability of the 6.4 keV-line has been discovered from Sgr B2 (M 0.66–0.02; Koyama et al. 2008). These facts suggest that the origin of the 6.4 keV-line and the related continuum emission is due to fluorescence and Thomson
scattering taking place in molecular clouds irradiated by an external source. We refer to this component as the X-ray reflection nebula emission (XRNE). The most probable external X-ray source is a past outburst of Sgr A* (Koyama et al. 1996; Inui et al. 2009).

In this paper, we propose a new methodology to derive positions of the Sgr B molecular clouds along the line of sight: a correlation study of the flux of the 6.4 keV-line from the MCs and the line-of-sight absorption (\( N_\text{H} \)) of the GCPE.
2. Observations and Data Reduction

Deep multiple pointing observations toward the Sgr B region were performed with the X-ray Imaging Spectrometer (XIS) at the focal planes of the X-ray Telescope (XRT) onboard the Suzaku satellite from October 2005 to September 2007. The XIS system consists of three sets of front-illuminated (FI) CCD cameras (XIS0, 2, and 3) and one set of back-illuminated (BI) CCD camera (XIS1); each CCD chip contains 1024×1024 pixels (1 pixel = 24 μm×24 μm) for the 18′×18′ field of view. Two calibration sources of 55Fe are installed to illuminate two corners of each CCD for absolute gain tuning. The details of Suzaku, the XIS and the XRT are given in Mitsuda et al. (2007), Koyama et al. (2007a), and Serlemitsos et al. (2007), respectively. The observations were made in the normal clocking mode with read-out cycle of 8 s. We screened the data by excluding the events observed below the low and day-Earth elevation angles at 5° and 20°, in addition to the removal of events during passage of the South Atlantic Anomaly. The total effective exposure time was about 400 ks. The observation log is shown in table 1.

We performed data reduction and analysis using HEADAS software version 6.5.1 and XSPEC version 11.3.2. The calibration database was the version released on 2008-06-02. We constructed the non-X-ray background (NXB) data from night-Earth observations, and subtracted the NXB from the images and the spectra. Since the relative gains and response functions of the FI CCDs (XIS0, 2 and 3) are essentially the same, we made merged spectra of the FI CCDs.

3. Analysis and Results

3.1. Overall Features of the X-Ray Images

Figure 1 shows XIS images of the Sgr B region in the (a) 6.3–6.5 keV and (b) 2.5–3.5 keV bands. The images were made by co-adding the FI and BI CCDs data, followed by correcting the exposure time and the vignetting effects of the XRTs. The data of the CCD corners illuminated (contaminated) by the calibration sources were excluded.

To increase the visibility, we binned the images with 4×4 pixels and smoothed them with a Gaussian kernel of σ = 1′.

The bright clumps in figure 1a are SgrB2 (M0.66–0.02), M0.74–0.09, and Sgr B1 (M0.51–0.10). These are reported to be candidates of the X-ray reflection Nebula (XRN; Koyama et al. 2007b; Nobukawa et al. 2008). In addition, we found a new diffuse structure in the 6.4 keV-line at the south of M0.74 (hereafter, M0.74-sub; figure 1a).

The GCDX flux in the 2.5–3.5 keV band (figure 1b) is sensitive to absorption in N_H ranges of 10^{22}–10^{24} H cm^{-2}. This range corresponds to the interstellar absorption toward the GC region and the intra-cloud absorption of the MCs. Comparing figure 1a and 1b, we found a hint of anti-correlation between the 6.3–6.5 keV (6.4 keV-line) and the 2.5–3.5 keV band fluxes near l = 0°75: the 2.5–3.5 keV band flux is relatively weak in contrast with the strong emission of the 6.4 keV-line from the Sgr B MCs.

To confirm this anti-correlation, we made one-dimensional flux profiles in the 2.5–3.5 keV band and the 6.4 keV-line band along the Galactic longitude of 1°0–
iron/nickel line flux ratios of K α and K β in the GC region. They concluded that component (1) is a plasma of temperature $kT \approx 6.5$ keV in collisional ionization equilibrium. The iron abundance was determined to be $\approx 1$ solar. We therefore use an APEC model\(^5\) for component (1) and express it as APEC1 with fixed temperature and abundances of 6.5 keV and 1 solar, respectively.

With the Suzaku GC survey observations, many SNR candidates were found in the 2.45 keV-line band images. The plasma temperatures are nearly the same at about 1 keV. (Nobukawa et al. 2008; Mori et al. 2008; Tsuru et al. 2009). The abundances are slightly different in each element, but are consistent with 1 solar. The abundances of S, the most prominent Kα line emitter, are 0.6–1.3 solar (hereafter, the numbers in the parenthesis are in 90% error range) for G 0.42–0.04 (Nobukawa et al. 2008), 1.2–1.5 solar for G 359.79–0.26 (Mori et al. 2008), and 1.1–2.7 solar for G 359.41–0.12 (Tsuru et al. 2009). Removing these SNR candidates, we still found the 2.45 keV line prevailing in all of the GC region (component (2)). Thus we use an APEC model for component (2) (APEC2), assuming that the temperature and abundances to be $\sim 1$ keV (free) and 1 solar (fixed), respectively, the same values to those of SNR candidates near the GC region.

Component (3) is emission possibly produced by the fluorescence and reflection from the MCs (XRNE): the fluorescent Fe Kα (6.4 keV-line) with Thomson scattering continuum. The spectra of XRNs in the Sgr B and Sgr C complexes were extensively studied with Suzaku (Koyama et al. 2007b; Nobukawa et al. 2008; Nakajima et al. 2009). Following these results, we use a phenomenological model: a power-law plus 2 Gaussian lines for the Fe Kα and Kβ as,

$$\text{XRNE} = A \times \left(\frac{E}{\text{keV}}\right)^{-\alpha} + \text{Gaussian1} + \text{Gaussian2}$$

where the Gaussian center energy and relative intensity ratio of the Fe Kα, K β lines are fixed to 6.4 keV and 7.05 keV, and 1:0.125, according to the theoretical values (Kaastra & Mewe 1993).

Component (4) is low energy ($\leq 2$ keV) emission extending to nearly 0.5 keV, indicating small or no absorption, and hence the foreground emission, which is unrelated to the GC region. The origin is unknown but would be either a local Galactic plasma (Ebisawa et al. 2008) or unresolved faint dM stars (Masui et al. 2009). Apart from the real origin, the spectra of component (4) contains faint line-like structure (see figure 3), we therefore used an APEC model (APEC3). Since the contribution of component (4) above $\sim 2$ keV is small, the fitting results of the spectra above $\sim 2$ keV depend very weakly on the model assumption of component (4).

Component (5) is the cosmic X-ray background (CXB). We applied the CXB model obtained from the Suzaku data at the north ecliptic pole,

\(^4\) The solar abundance in this paper is referred to Anders & Grevesse (1989).

\(^5\) Astrophysical Plasma Emission Code: A model of an emission spectrum from collisionally-ionized diffuse gas. (Smith et al. 2001).
Fig. 3. FI spectra of M0.74-0.09 (left column) and Sgr B2 (right column) as examples for different models. The best-fit spectra and the residuals (χ-distributions) of models A, B, and C are shown in the top, middle, and bottom rows, respectively. In each spectrum, components of the NGCE and the XRNE are shown by green and black solid lines; components of GCPE suffered by Abs1 × Abs2 and Abs2 are shown by the red and blue solid lines, respectively (see section 3.2.2).

\[
\text{CXB} = 7.4 \times 10^{-7} \times \left( \frac{E}{\text{keV}} \right)^{-1.486} \quad \text{[photons cm}^{-2} \text{s}^{-1} \text{arcmin}^{-2}] \quad (2)
\]

As a matter of fact, the surface brightness of the CXB (see also Kushino et al. 2002) in the Sgr B region is far lower than those of the other components by more than two orders of magnitudes, and hence the contribution of the CXB is almost negligible.

3.2.2. Model Constructions and Fitting

For the full-band spectra of the five components, we tried model fitting with many free parameters. However, due to large errors, no significant constraint on the best-fit parameters was obtained for any further scientific study and discussion. We therefore set several constraints on the model based on reasonable assumptions.

We assume that the spectral shape of the GCPE, which
comprises the two plasmas (APEC1 and APEC2), is the same in all of the Sgr B regions. We thus combine components (1) and (2),

$$\text{GCPE} = \text{APEC1} + \text{APEC2}$$

[photons cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$] (3)

The temperature and abundances of APEC1 are fixed to 6.5 keV and 1 solar, respectively. We define a parameter $\alpha$, the normalization ratio of APEC1 and APEC2, assuming the common value in all regions near Sgr B (see figure 6). Thus, free parameters for the GCPE spectra are the temperature and the normalization factor of APEC2, and $\alpha$ with the same value among the relevant regions.

The photon indices ($\Gamma$) of the continuum of XRNs in Sgr B are scattered. This may be due to the limited energy band fittings in former studies (section 4.2). On the other hand, the equivalent width values of the 6.4 keV-line are nearly the same (Koyama et al. 2007b, Nobukawa et al. 2008, Nakajima et al. 2009). Since the emission mechanisms would be the same for all Sgr B XRNs, we assume that the photon index ($\Gamma$) and the equivalent width ($EW$) of the 6.4 keV-line are the same in all regions of Sgr B.

Although each of components (1)–(5) should have a different absorption, we truncated them into three absorptions: Abs1, Abs2, and Abs3. Abs $i$ ($i = 1, 2, 3$) is the integrated value along the line of X-ray path into our sight, which is given as $\exp(-N_H \times \sigma(E))$; $N_H$ and $\sigma(E)$ are respectively the hydrogen column density and absorption cross section with solar abundance. A schematic view of these three absorptions is given in figure 4.

Abs1 is the largest absorption ($N_H \geq 10^{23} \text{ H cm}^{-2}$), which takes place in/through the MCs. Abs2 is the interstellar absorption to/beyond the GC of $N_H \sim 6 \times 10^{22} \text{ H cm}^{-2}$ (Sakano et al. 2002). Abs3 is the smallest absorption applied to the foreground emission ($N_H < 10^{22} \text{ H cm}^{-2}$).

In all 6 regions, we needed additional common components (4) and (5), which are not due to the emission from the GC region. We combined these components and define them as the non GC emission (NGCE):

$$\text{NGCE} = \text{Abs1} \times \text{Abs2} \times \text{Abs2} \times \text{CXB} + \text{Abs3} \times \text{APEC3}$$

[photons cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$] (4)

The term $\text{Abs1} \times \text{Abs2} \times \text{CXB}$ indicates that the CXB suffers from interstellar absorption (Abs2) two times: coming from the front and back sides of the GCPE. Here we assume that the absorption due to the back side on the GC is same as that on the front side of the GC.

Referring the schematic view of the geometry of the MCs (XRNE) and the GCPE, we tried two extreme cases (see figure 4). (A): a MC is located at the near-side edge of the GCPE, then the XRNE and GCPE would have nearly the same absorption of $\text{Abs1} \times \text{Abs2}$. (B): a MC is located at the far-side edge of the GCPE; thus, the XRNE and the GCPE would have independent absorptions, given as $\text{Abs1} \times \text{Abs2} \times \text{Abs2}$. Model A and Model B, therefore, are given as,

(A): $\text{Abs1} \times \text{Abs2} \times (\text{XRNE} + \text{GCPE}) + \text{NGCE}$

(B): $\text{Abs1} \times \text{Abs2} \times \text{XRNE} + \text{Abs2} \times \text{GCPE} + \text{NGCE}$

In the fittings, the free parameters are $\text{Abs1}$, $\text{Abs2}$, and the normalization factors of the 6.4 keV-line flux, the GCPE, and the APEC3. While the mixing ratio $\alpha$ of APEC1 and APEC2 (in the GCPE), Abs3, the temperature and the abundance of APEC3, the equivalent width ($EW$) of the 6.4 keV-line and the photon index ($\Gamma$) for the power-law spectrum of XRNE are also free, but are assumed to be the same (common) in all relevant regions. We list the fitting parameters according to their properties in table 2.

We performed a simultaneous fitting for the 2 $\times$ 6 spectra (the FI and BI spectra of 6 regions) with Model A and Model B. The best-fit parameters and $\chi^2$/d.o.f are listed in table 3. As a results, both models were rejected by the $\chi^2$/d.o.f test. Model A gave a large $\chi^2$/d.o.f of 1.87, and shows large residuals in the medium range of 1–3 keV and the hard range of 5–7 keV (see figure 3). The best-fit values of $\text{Abs1} \times \text{Abs2}$ (with Model A) is $\simeq 10 \times 10^{22} \text{ H cm}^{-2}$ (see table 3), which are close to the typical value toward the GC region. These values may be reasonable for the GCPE but could not be applied to the XRNE, because the absorption of each XRNE was found to be $> 10^{23} \text{ H cm}^{-2}$ by independent analysis of XRN (Koyama et al. 2007b; Nobukawa et al. 2008; Nakajima et al. 2009).

In Model B, the apparent residuals in the medium and hard range found in Model A disappeared partially, and hence $\chi^2$/d.o.f was improved to 1.77. We still see unat-
Table 2. Summary of free and fixed parameters in the fittings for Model A, B, and C.

| Parameter | Model A | Model B |
|-----------|---------|---------|
| $N_H$ (Abs1 x Abs2) | $1.09^{+0.87}_{-0.66}$ | $1.42^{+0.96}_{-0.67}$ |
| 6.4 keV-line $N_H$ (Abs1) | $3.0^{+0.1}_{-0.1}$ | $4.0^{+0.2}_{-0.2}$ |
| 6.4 keV-line $N_H$ (Abs2) | $5.8^{+0.4}_{-0.3}$ | $5.8^{+0.3}_{-0.2}$ |
| Fixed parameters | | |
| $kT$ (keV) (APEC2) | $0.70 (0.67-0.72)$ | $0.69 (0.66-0.74)$ |
| $\alpha$ (APEC2 norm) | $0.47 (0.46-0.48)$ | $0.59 (0.57-0.60)$ |
| Photon index $\Gamma$ | $0.52 (0.47-0.50)$ | $2.16 (2.10-2.23)$ |
| $E_{6.4keV}$ (keV) | $1.78 (1.75-1.80)$ | $1.31 (1.28-1.34)$ |
| Abs3 (10$^{22}$ H cm$^{-2}$) | $0.21 (0.21-0.22)$ | $0.20 (0.19-0.21)$ |
| $kT$ (keV) (APEC3) | $1.02 (0.99-1.05)$ | $0.93 (0.92-0.94)$ |
| $Z$ (solar) (APEC3) | $0.004 (0.002-0.006)$ | $0.008 (0.007-0.011)$ |
| $\chi^2$/d.o.f. | $4749/2537 = 1.872$ | $4479/2537 = 1.765$ |

The uncertainties are at 90% confidence level.

ural residuals between 2–4 keV. Although the $\chi^2$/d.o.f of 1.77 is large enough to reject Model B at more than the 99.9% confidence level, this value is slightly smaller than that of Model A. At the end of this section, we discuss why we reject Model B from a different point of view.

We then constructed Model C, adding a new free parameter $R$ (for each region), in which a MC/XRN is inside the GCPE with a relative position of $R$ (0–1); the smaller $R$ indicates the nearer (front) side.

\[
R = \frac{\text{Abs1} \times \text{Abs2} \times (\text{XRNE} + (1-R) \times \text{GCPE})}{\text{Abs2} \times (R \times \text{GCPE}) + \text{NGCE}}
\]

We performed a simultaneous fitting for Model C by the same procedure as for Model A and B. Although Model C has six new free parameters ($R$ for the six regions) more than Model A and Model B, the degree of freedom (d.o.f) of Model C (2531) is almost equal to that of Model A and B (2537). On the other hand, the $\chi^2$/d.o.f of Model C is largely improved to 1.34 from those of Model A (1.87) and Model B (1.77).

One may argue that the spectra are contaminated by unresolved point sources in the Sgr B region. In fact, Koyama et al. 2009 estimated that the point source fluxes provide a significant fraction of the GCDX (GCPE + XRNE) emission, up to about 1/6 near Sgr A*, which may partially contribute to the 6.7 keV-line and the 6.4 keV-line fluxes in the GCPE and XRNE, respectively.
According to the Chandra cataloged sources reported by Muno et al. (2006), the number of point sources per solid angle near Sgr B2 is \( \sim 10\% \) compared to that near Sgr A*, while Nobukawa et al. (2008) shows that the GCDX flux near Sgr B2 is also \( \sim 10\% \) of that near Sgr A*. We can infer that the contribution of point sources to GCDX would be roughly the same in the Sgr B region. The point source contribution may cause possible systematic errors in the present spectral analysis. The most serious errors, therefore, should be the region-to-region fluctuation of the fractions of the point source fluxes, which may be rather small effects in a relative comparison of the best-fit parameters. At this moment, we have no information on the exact flux and spectrum of the integrated point sources in the Sgr B region. We therefore ignore the point source contribution.

All together, taking account of possible systematic errors due to the point source contribution and those due to the simplified model, we regard Model C as a good approximation of the overall spectra in the Sgr B region, although the \( \chi^2/d.o.f \) of 1.34 is statistically marginal to be acceptable. The best-fit common parameters for all regions are as follows (hereafter, the numbers in the parenthesis are in 90% error range). The temperature of APEC2 is 0.87 (0.81–0.91) keV and the mixing ratio (\( \alpha \)) in the GCPE is determined to be 0.27 (0.26–0.28). The photon index (\( \Gamma \)) and the equivalent width (\( EW \)) of the 6.4 keV-line for the XRNE are 1.72 (1.64–1.80) and 1.59 (1.54–1.63) keV, respectively. The absorption (Abs3), temperature (\( kT \)) and the abundance of the foreground emission (APEC3) are 0.17 (0.16–0.18) \( \times 10^{22} \) H cm\(^{-2}\), 0.85 (0.83–0.87) keV, and 0.011 (0.009–0.014) of solar, respectively. The other best-fit parameters of Model C for each region are listed in table 4.

The 6.4 keV-line are likely to be fluorescence in the MC generated by an external X-ray source. Then the flux should be proportional to the product of the external X-ray flux and the number of iron atoms along the line-of-sight X-ray path in the MC, in the optically thin case at the energy near 6.4–7.1\(^6\) keV (\( N_{\text{H}} \leq 10^{24} \) H cm\(^{-2}\)). The number of iron atoms is approximately proportional to the column density \( N_{\text{H}} \) of the MC. Therefore, in the case that the external X-ray fluxes are the same among the MCs, Abs1 should be approximately proportional to the 6.4 keV-line flux.

In figure 5, we plot the best-fit Model C values of Abs1 and Abs2, as a function of the 6.4 keV-line flux. For a comparison, we also plot the results of Model B. A notable fact to support Model C is that Abs1 is in good proportionality to the 6.4 keV-flux. This feature is in contrast to the results of Model B, where the proportionality is not very good in the low-flux range. Most importantly, Model B requires an extra off-set of about \( 2 \times 10^{23} \) H cm\(^{-2}\), which is un-realistic. This leads us to exclude Model B in addition to the \( \chi^2/d.o.f \) test. We estimated \( N_{\text{H}} \) values of the Sgr B MCs from the data of the CO line (Sofue 1995; Dahmen et al. 1998) and the CS line (Tsuboi et al. 1999). They are in the range of \( N_{\text{H}} = 10^{23}–10^{24} \) H cm\(^{-2}\), in good agreement with the Model C prediction.

As shown in figure 5 for Model C, we found that Abs2 is almost constant at \( N_{\text{H}} \sim 6 \times 10^{22} \) H cm\(^{-2}\). This is consistent with the view that Abs2 is interstellar absorption (see figure 4) toward the GC of about \( N_{\text{H}} \sim 6 \times 10^{22} \) H cm\(^{-2}\) (Rieke et al. 1989; Sakano et al. 2002).

4. Discussions

4.1. Justifications of Model Constraints & Assumptions

In the previous section, we introduced a complicated model to described the spectra of the GCDX. In order to obtain meaningful values (no large errors) of physical parameters, we further added some constraints and assumptions. If, for example, we let the normalization ratio \( \alpha \) (APEC1/APEC2) to be free for all regions, we can not give a significant constraint on the absorptions of GCPE and/or the temperature of APEC1, because the two plasma emission become nearly the same in the band near 2 keV. We summarize the adopted constraints and assumptions below for further discussions:

- The 6.5 keV plasma and \( \sim 1 \) keV plasma, which comprise the GCPE, have nearly the same angular distribution near the Sgr B region. (see figure 6)
- The abundances of the GCPE are nearly 1 solar, the same value as those of nearby new SNR candidates.
- The XRNE has a common photon index (\( \Gamma \)) and \( EW_{6.4\text{keV}} \) near the Sgr B region.
- The point sources contribution to the GCDX is small and hence could be ignored in the Sgr B region.

The most fundamental constraint is the first item; the factor \( \alpha \) is constant from region to region. This implies that the angular distributions of the very hot (6.5 keV) and hot (\( \sim 1 \) keV) plasmas are nearly the same near Sgr B. In order to judge this constraint, we show the flux distribution of the 6.7 keV and 2.45 keV lines along the galactic

---

\(^6\) \( E = 7.1 \) keV is the K absorption-edge of neutral iron.
longitude of \( l = 1^\circ 2 - 0^\circ 4 \) at \( b = -0^\circ 15 \pm 0^\circ 05 \) (figure 6). The 6.7 keV and 2.45 keV lines are strong characteristic lines that well represent, respectively, the distributions of the 6.5 keV plasma and the \( \sim 1 \) keV plasma with the least systematic errors.

As is found in figure 6, the 2.45 keV line and the 6.7 keV line have almost the same slope (angular distribution). The small drop of the 2.45 keV-line flux near at \( l = 0^\circ 85 - 0^\circ 6 \) would be due to absorption by the M0.74–0.09 MC and the drop at \( l = 0^\circ 6 - 0^\circ 4 \) is due to the absorption by the Sgr B1 MC. This figure, therefore, indicates that the emission of the \( \sim 1 \) keV plasma (APEC2) and the 6.5 keV plasma (APEC1) have a common normalization ratio (\( \alpha \)) for the GCPE near the Sgr B regions. The justification of the other constraints and assumptions listed in the last three items are separately discussed in the previous sections. We thus conclude that Model C with the above listed constricts and assumptions provides a practical approximation for the overall spectra in the Sgr B region, although the \( \chi^2/\text{d.o.f} \) of 1.34 is statistically marginal to be acceptable.

### 4.2. Line-of-Sight Positions of MCs

From the results of section 3, we conclude that the MCs of Sgr B should be located in the GCPE (Model C), neither in the near-side edge (Model A) nor in the far-side edge (Model B) of the GCPE. For simplicity, we assume that the volume emissivity of the GCPE is approximately a uniform sphere with a uniform plasma density on the Galactic plane. Koyama et al. (1989) and Yamauchi et al. (1990) reported that the 6.7 keV line distributed with a Gaussian shape of 1.8 deg (FWHM) (in parallel to the Galactic plane). We therefore take the boundary (radius) at \( |l| = 1.25 \) deg, within which 90% of the GCPE is included. The center of the GCPE is approximately Sgr A* (at \( l = -0^\circ 056; \) Yusef-Zadeh et al. 1999). Then the parameter \( R \) gives the line-of-sight positions of the MCs within the GCPE\(^7\), where \( R = 0 \) and 0.5 indicate the anterior border line and the center line (Sgr A* is on this line) of the GCPE, respectively. We plot the best-fit position parameter (\( R \)) for the 6 regions (indicated in figure 1a) in the schematic view of figure 7.

As demonstrated in figure 7, the MCs in the Sgr B region are generally on the near-side with respect to Sgr A*.

---

**Fig. 6.** Flux distribution of the 6.7 keV line (6.5 keV plasma; dashed line) and the 2.45 keV line (\( \sim 1 \) keV plasma; solid line) along the galactic longitude from \( l = 1^\circ 2 - 0^\circ 4 \) at \( b = -0^\circ 15 \pm 0^\circ 05 \). Two parallel dotted lines guide eyes to see the same distribution of the 6.5 keV plasma and the \( \sim 1 \) keV plasma.

### Table 4. Detailed results of best-fit parameters with Model C.

| Region     | \( N_H \) (Abs1) | \( N_H \) (Abs2) | 6.4 keV-line\( ^\dagger \) | APEC3 norm\( ^\dagger \) | GCPE norm\( ^\dagger \) | Position \( R \)\( ^\# \) |

\† Flux in the unit of 10\(^{22}\) Hz cm\(^{-2}\).

\‡ The normalization factor for the foreground emission (c.f APEC3 in equation 4) of the APEC model re-normalized with the region size \( A [\text{arcmin}^2] \); it is expressed as 7.07 \times 10\(^{-38}\)/\((4\pi D^2 A) EM [\text{cm}^{-5}\text{arcmin}^{-2}] \), where \( D \) and \( EM \) are the distance to the source \( [\text{cm}] \), and the emission measure \( [\text{cm}^{-3}] \), respectively.

\§ In same expression as \( \dagger \), but the normalization factor of APEC2 in the GCPE (c.f equation 3 and text).

\# \( R \) is the fraction of the GCPE suffered by Abs2, which indicates the positions of MCs (see equation 6 and figure 7).

\** The results obtained by the simultaneous fitting of the 12 spectra (the FI and BI spectra of 6 regions).
Sgr B XRNs have been reported to be (1.1 keV, 3.2) for keV-line and the continuum photon index (Nobukawa et al. 2008), the equivalent width of the 6.4 keV-line should be modified by this distance effect. In general, the Sgr B2 XRNs, but the variation of \( EW \) is not very large. The GCPE flux is position-dependent, which means that a proper background-selection is difficult. The large scatter of \( \Gamma \) values in the former studies may be due to the nearby GCPE-subtraction and would also be due to the band limited (e.g. 5–8 keV) spectral fitting. In this work (section 3.2 with Model C), the \( EW \) and \( \Gamma \) values are estimated by an independent method, a simultaneous fitting of a wide energy band (0.5–10.0 keV), in which nearby GCPE was not subtracted but directly included as the GCPE model. We also note that these uncertainties do not largely affect the \( EW \) values. In fact, We found that the averaged \( EW \simeq 1.6 \) keV, which is consistent with the previous studies of the Sgr B XRNs. Koyama et al. (2009) studied the GCDX near the Sgr A region (\(|l| \leq 0.2^\circ\)), and found that the \( \Gamma \) of the continuum flux is 1.9: this reduced to 1.4 if we exclude the point sources contribution. Nakajima et al. (2009) studied the 6.4 keV clumps in the Sgr C region and found \( \Gamma \) to be in range of 1.6–1.9. We determined the common \( \Gamma \) in Sgr B to be \( \simeq 1.7 \); this value agrees with the results in Sgr A, B, and C. Thus, we infer that the XRNs may have a unified photon index of 1.4–1.9 in the overall GC region.

![Fig. 7. Relative positions of each MC (filled circles) along the line of sight, where the horizontal lines of \( R = 0.0 \) and 0.5 imply the anterior border line and the GC line (Sgr A* is on this line), respectively. The circles filled with darker colors indicate MCs of the larger \( N_{HI} \) values.](image)

Also if all of the MCs/6.4 keV clumps, Sgr B1, Sgr B2, M0.74–0.09, and M0.74-sub are the constituent parts of the CMZ, the results indicate that the CMZ at the positive Galactic longitude has a bar-like distribution that generally inclines toward us. Although no further quantitative comparison is available with the present data, the inclining trend of the Sgr B MCs toward us is consistent with the radio molecular observations results based on the \((l, v)\) diagrams study by Sofue (1995) and the spatial correlation study between 2.6-mm CO line and 18-cm OH absorption line by Sawada et al. (2004).

It may be suspicious that the best-fit values of \( R \) in Model C indicate that the MCs are all closer to the near-side edge of the GCPE rather than to the far-side edge, while \( \chi^2/d.o.f. = 1.872 \) of Model A (MCs at the near-side edge) is rather worse than \( \chi^2/d.o.f. = 1.765 \) of Model B (MCs at far-side edge). As shown in equation 5, Model B have the extra-part \( \text{Abs}_2 \times \text{GCPE} \) which Model A does not have. This gives a slightly better \( \chi^2/d.o.f. \) of Model B (1.765) than Model A (1.872). On the other hand, the improvement of Model C (\( \chi^2/d.o.f. = 1.336 \)) from Models A and B is far larger than that between Model A and B.

### 4.3. A Unified Picture of the XRN

According to former studies (Koyama et al. 2007b; Nobukawa et al. 2008), the equivalent width of the 6.4 keV-line and the continuum photon index \((EW, \Gamma)\) of the Sgr B XRNs have been reported to be (1.1 keV, 3.2) for Sgr B2, (1.55 keV, 1.4) for M 0.74-0.09, and (1.4 keV, 1.8) for Sgr B1. The \( \Gamma \) values are significantly scattered among the XRNs, but the variation of \( EW \) is not very large. The GCPE flux is position-dependent, which means that a proper background-selection is difficult. The large scatter of \( \Gamma \) values in the former studies may be due to the nearby GCPE-subtraction and would also be due to the band limited (e.g. 5–8 keV) spectral fitting. In this work (section 3.2 with Model C), the \( EW \) and \( \Gamma \) values are estimated by an independent method, a simultaneous fitting of a wide energy band (0.5–10.0 keV), in which nearby GCPE was not subtracted but directly included as the GCPE model. We also note that these uncertainties do not largely affect the \( EW \) values. In fact, We found that the averaged \( EW \simeq 1.6 \) keV, which is consistent with the previous studies of the Sgr B XRNs. Koyama et al. (2009) studied the GCDX near the Sgr A region (\(|l| \leq 0.2^\circ\)), and found that the \( \Gamma \) of the continuum flux is 1.9: this reduced to 1.4 if we exclude the point sources contribution. Nakajima et al. (2009) studied the 6.4 keV clumps in the Sgr C region and found \( \Gamma \) to be in range of 1.6–1.9. We determined the common \( \Gamma \) in Sgr B to be \( \simeq 1.7 \); this value agrees with the results in Sgr A, B, and C. Thus, we infer that the XRNs may have a unified photon index of 1.4–1.9 in the overall GC region.

![Fig. 8. The best-fit absorption (\( \text{Abs}_1 \)) vs the distance-corrected 6.4 keV-line flux from results of Model C in table 4 (open triangles), where the correction factors are estimated from the distances between MCs and Sgr A* with figure 7, and are normalized to that of Sgr B1.](image)

As discussed by Koyama et al. (2008) and Nobukawa et al. (2008), a possible external X-ray source is Sgr A*, therefore the X-ray flux at the Sgr B MCs should be proportional to \( L_0D^{-2} \), where \( L_0 \) and \( D \) are, respectively, the luminosity of Sgr A* and the distance between Sgr A* and MCs. Thus the flux of the fluorescent 6.4 keV-line should be modified by this distance effect. In figure 8, we plotted distance-corrected 6.4-keV fluxes as a function of \( \text{Abs}_1 \), where the distances are estimated using figure 7. We then fitted the correlation between

\[
\text{Abs}_1 = \frac{L_0}{D^2}
\]
the best-fit absorption (Abs1) and the 6.4 keV-line flux (distance-corrected), and obtained,

\[ N_H (\text{Abs1}) = 3.99 (\pm 0.56) \times I_{6.4 \text{keV}} \left[ 10^{22} \text{H cm}^{-2} \right], \]

\[ I_{6.4 \text{keV}} : \left[ 10^{-6} \text{photons s}^{-1} \text{cm}^{-2} \text{arcmin}^{-2} \right] \]

This relation is generally in agreement with the fluorescent process due to irradiation by Sgr A* with the past luminosity of 2–3 \times 10^{36} \text{ergs s}^{-1}. If \( L_0 \) was time constant, the relation between the distance-corrected 6.4 keV-line flux vs. Abs1 should be in good proportionality. However, we see some data scatters from the proportionality relation (figure 8). It can be explained by assuming a time variable flux of the irradiating source Sgr A* (Koyama et al. 2008; Inui et al. 2009).

### 4.4. The Correlation of CS line and 6.4 keV-line Flux

As shown in figure 2, the 2.5–3.5 keV band flux shows an intensity drop at the bump of the 6.4 keV-line and the CS line. The anti-correlation to the 2.5–3.5 keV band flux is clearer in the CS line than that in the 6.4 keV-line. This may be because that the CS line traces all (GC + foreground) MCs in the line of sight from which the GCPE may suffer absorption, while 6.4 keV-line only traces MCs near the irradiating source in the GC region.

The better anti-correlation of the CS line against the 2.5–3.5 keV band flux indicates that a large amount of MCs, identified by the velocity-integrated CS lines but not bright in 6.4 keV-line, is located in the near side of the GCPE. The angular size of the 6.4keV bump is slightly narrower than that of the CS line (\( l \sim 0^\circ 85 \) and \( 0^\circ 63 \)). The narrower angular size of the 6.4 keV bump than that of the CS line may also be explained if Sgr A* is the external X-ray source to produce the 6.4 keV clumps. The surface brightness of fluorescent X-rays is faint at the near and far sides of the cloud-limb because of small \( N_H \) values, but becomes brighter when the external X-rays go into the large \( N_H (\geq 10^{23} \text{H cm}^{-2}) \) region in the MCs. Another possible reason of the faint 6.4 keV-line flux at the far-side cloud limb from Sgr A* is due to the time variability of the Sgr A* X-rays; an X-ray front of possible X-ray outbursts about 300 years ago (Koyama et al. 2008; Inui et al. 2009) does not yet reach at the far-side limb of \( l \sim 0^\circ 85 \).

We are grateful to all members of the Suzaku team, especially H. Matsumoto and H. Uchiyama for their useful comments and supports. We also thank Y. Hyodo and M. Sawada for improving the draft quality. M.N. acknowledges financial supports from the Japan Society for the Promotion of Science. This work was supported by the Grant-in-Aid for the Global COE Program “The Next Generation of Physics, Spun from Universality and Emergence” from the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan. This work was also supported by Grant-in-Aid of the MEXT No. 18204015 and 20340043.
