Abstract

In this work, we propose a simple model that provides permutation invariant maximally predictive prototype generator from a given dataset, which leads to interpretability of the solution and concrete insights to the nature and the solution of a problem. Our aim is to find out prototypes in the feature space to map the collection of instances (i.e. bags) to a distance feature space and simultaneously learn a linear classifier for multiple instance learning (MIL). Our experiments on classical MIL benchmark datasets demonstrate that proposed framework is an accurate and efficient classifier compared to the existing approaches.

1 Introduction

Classification problems can be divided into two with respect to the labeling characteristics of the data, single instance (SI) and multiple instance (MI) problems. In single instance learning (SIL) problems, each instance is individually labeled. However, multiple instance learning (MIL) concentrates on bags of instances, not individually labeled instance data. Two different labeling characteristics of these problems can be seen in Table 1.

| Bag | Instance | Label |
|-----|----------|-------|
| B1  | $X_1$    | 1     |
|     | $X_2$    |       |
| B2  | $X_3$    | 0     |
|     | $X_4$    |       |
|     | $X_5$    |       |

(a) MIL Problem

| Instance | Label |
|----------|-------|
| $X_1$    | 1     |
| $X_2$    | 0     |
| $X_3$    | 1     |
| $X_4$    | 1     |
| $X_5$    | 0     |

(b) SIL Problem

Table 1: Labeling in MIL and SI Problems

Unlike many common problems in machine learning, multiple instance learning problems do not have a fixed input size. The number of instances in a bag is often variable, hence the most widely used architectures like deep neural networks are not straightforward to apply to these problems. Mainly...
there are two different approaches to address this issue, first one is instance level approaches and
the second one is embedding approaches. The instance level approaches try to reward a probability
per each instance that exists in a bag, then apply some pooling function to probabilities to obtain the
final bag probability. In the second type of approaches, an arbitrary function, often a neural
network, is used to come up with an embedding for each instance, then again some pooling function
is applied to aggregate information from each embedding which is fed to a classifier. In this work,
we propose an embedding approach with some modifications. The idea is to find some representative
prototypes in the feature space so that bags are linearly separable when they are represented as
their distances to the prototypes.

The rest of the paper is organized as follows: Section 2 gives an overview of the previous studies
of the field. Section 3 explains learning algorithm and the solution method of the problem. Finally,
results of the solution approach on various data sets and our conclusions can be found in Sections 4
and 5.

2 Related Work

Previous research on MIL problems start with a standard assumption of the problem. Standard MIL
assumption tells that if a bag has at least one positive instance, then bag’s label is positive [Dieterich
et al., 2001]. Later, solution approaches are proposed for problem’s different variations and extensions
[Weidmann et al., 2003, Li et al., 2013, Wang and Zucker, 2000]. Mainly, two different approaches
are adopted for all extensions of MIL problems. First one is instance level [Xu and Frank, 2004, Xu,
2003, Raykar et al., 2008] or bag level [Amores, 2013, Zhou et al., 2005] approaches as indicated
previously. However, instance level approaches have dimensionality problem and it is not always
possible to solve MIL problems with instance based approaches. Bag level approaches overcome
dimensionality but have a disadvantage of losing information that can be gathered from instances.
Embedding approaches are developed to overcome these disadvantages [Cheplygina et al., 2013,
2016, Gehler and Chapelle, 2007].

Just like every other differentiable task, application of neural network based approaches to MIL
problems has been drawing attention from several different domains in the recent years [Ilse et al.,
2018, Wang et al., 2018]. Well known problems have also been reformulated for this particular
purpose, such as common computer vision tasks like image classification [Wu et al., 2015], weakly
supervised object detection [Tang et al., 2018, Wan et al., 2019], sequence predictions [Dennis et al.,
2018], sentiment analysis [Angelidis and Lapata, 2017] and sound event detection [McFee et al.,
2018].

3 Method

3.1 Joint Learning of Prototypes and Classification

The model has two main objectives: First one is learning the feature vectors or prototypes that is
maximally predictive of the bag class after finding an embedding in the distance space. A simple
illustration of the idea is presented in Figure 1. Suppose there are two positive and two negative bags
each of which have two instances in two-dimensional feature space shown in Figure 1a. Our aim is
to identify prototypes such that the bags are linearly separable when each bag is represented by its
minimum distance to each prototype. Figure 1b represents the bags in the new feature space. In other
words, proposed model is optimized over both the linear classifier parameters and the prototypes.
An overview of architecture can be seen in Figure 2. Depending on the application, our proposal is
flexible in generating average and maximum type of features which are famous in multiple instance
learning domain [Cheplygina et al., 2015].

In our setting, for a given training task we choose a fixed number of prototypes, \( D \), of a fixed size,
\( L \), to be learned, we initialize these prototypes randomly. We combine each instance of length \( L \)
in a given bag, which yields \( K_i \) (number of instances in bag i) vectors representing bag i. \( K_i \) is not
constant between different bags, since each bag potentially has different number of instances. At
each training step, we calculate the distance from each instance to the prototypes to extract distance
features. Given these features, the model learns a classifier to predict the bag class.
(a) Bag 1 and Bag 2 are negative labeled bags. Bag 3 and Bag 4 have positive labels. All bags and prototypes have two features.

(b) Distances of bags to prototypes. A good prototype candidate separates negative and positive labeled bags.

Figure 1: Representation of Bags and Prototypes.

Figure 2: Overview of the architecture. Blue color shows the variables, which the model will be optimized over. $L$: Number of features in an instance, constant; $D$: Number of prototypes, hyperparameter; $K_i$: Number of instances bag $i$, varies between different bags

3.1.1 Distance Feature Extraction

Just as in instance-level approaches in MIL problems, our model also needs to pool information that is extracted from instances in a given bag with potentially variable number of instances. To be more specific, for a given bag after the distance from each instance to each prototype is calculated, the model needs to aggregate the information before being fed into a linear classifier. These pooling operations should be differentiable to be optimized with a gradient based approach. Most basic and widely used pooling operators having these characteristics are min, mean and max operators [Cheplygina et al., 2015]. These are also intuitively informative in our case, since we have distance metrics as features, such that these should provide information about defining characteristics of an instance, assuming the existence of prototypes which are described above.

3.1.2 Feature Normalization

The distance features are prone to scale issues. This can cause problems with both gradient updates and the learning of linear classifier parameters. To overcome this, we adapt a similar approach to Ba et al. [2016], Ioffe and Szegedy [2015]. In other words, for each bag, we normalize the aggregated distance vector. Note that the information related to "shape" of the distance features will be preserved under the normalization operation that is only recentering and rescaling, which is what we aim to achieve.

A detailed formulation of the described method can be found in Appendix A.

4 Experiments

Solution approach is tested on five MIL datasets from two categories, molecular activity prediction and image annotation. We repeat a stratified 10-fold cross-validation five times and report the average of the classification accuracy with standard error in Table 2. For all experiments, prototypes are generated randomly and logistic regression is used as default classifier. Important parameters are the number of prototypes to learn and learning rate for weights and prototypes. The model was
implemented in PyTorch [Paszke et al., 2017] and we use the same parameters for each dataset. Namely, the number of epochs is set to 100 with a minibatch size of 1. Adam optimizer from [Kingma and Ba, 2015] was used, with the learning rate of prototypes as 0.0001 and learning rate for weight updates of the linear classifier as 0.00005. We applied stepwise learning rate decay, namely in every 40 epochs, we decreased the learning rate to the half. L2 regularization was applied to prototypes and L1 regularization was applied to the classifier parameters. The number of prototypes is set to 24 (i.e. \( D = 24 \)). We apply layer normalization as in [Ba et al., 2016] to the distance features.

4.1 Classification Accuracy

Solution approach in this study outperforms or at least does as good as all other well-known methods in terms of classification accuracy. Besides this approach has much less parameters compared to a neural network, namely only prototypes and few parameters for linear classifier.

4.2 Interpretability

As indicated previously, interpretability of the solution is one of the main aspects of prototype learning. To demonstrate this interpretability, here we apply our approach to the MNIST MIL problem which was introduced in [Ilse et al., 2018]. In this case, each instance is an image and each bag consists of images. The task is finding whether a target number exists in images in a bag. To keep things simple, we chose the number of prototypes to be 2.

Examples of prototypes from 2 different runs can be seen in Figure 3. In this application, we only used min as the aggregator for better interpretation. For instance, looking at Figure 3a, we see that the second prototype looks a lot like a 9, and the classifier found a negative coefficient for minimum distance to this prototype. This indicates, if the minimum distance to this prototype is larger the output probability will suffer. Moreover, since the first prototype has a positive coefficient, if the minimum distance of the bag to this prototype is larger, the output probability will be higher. Same analysis can be done for Figure 3b.

(a) Prototype results when the method is applied to MNIST dataset with finding the 9 problem. (b) Bags are labeled positive if number 5 is an instance in the bag.

Figure 3: MNIST Prototypes.
5 Conclusion

This work presents a prototype learning framework for MIL problems. This simple architecture can be applied to data from all kinds of domains and offers interpretability of the solutions. Although the method is applied to the classical MIL datasets, its modification to different problems is an interesting research direction. Our aim is to present the simplicity of the approach and hence sticked to the logistic regression classifiers and Euclidean distance. However, considering the flexibility of the architecture, one could incorporate more complex classifiers, different distance metrics and different aggregation procedures to obtain more powerful models.

Below we give a formulation for the discussed method. We will only demonstrate the formulation for \( \min \) features for simplicity, which could easily be generalized to any combination of \( \min, \max \) and \( \text{mean} \). Also below we use sigmoid for binary classification, but the same framework could easily be extended to multinomial case utilizing a softmax function.

\[ D: \text{Number of prototypes} \]
\[ K_i: \text{Number of instances in bag } i \]
\[ L: \text{Number of features in any instance} \]
\( P \): set of prototypes, \( P_d \): \( d^{th} \) prototype, a vector with length \( L \)

\( X_i \): set of instances in bag \( i \), \( X_{ik} \): \( k^{th} \) instance in bag \( i \)

\( y_i \): Label, class of the bag \( i \).

\( Dist(v_1, v_2) \): Distance between vectors \( v_1 \) and \( v_2 \)

\( \beta_d \): Weight in linear classifier that corresponds to \( d^{th} \) prototype

\( \Phi_{id} \): \( d^{th} \) element of the output vector for bag \( i \). Corresponds to the minimum distance of bag \( i \) to prototype \( d \) after layer normalization.

\( \sigma(Y) = \frac{1}{1 + e^{-Y}} \) is the sigmoid function

\( L_{ce}(y_i, \hat{y}_i) \): Cross-entropy loss where \( y_i \) is the label and \( \hat{y}_i \) is the prediction

\( \lambda_w \): Regularization parameter for linear classifier weights

\( \lambda_p \): Regularization parameter for prototypes

\( \min_{P,\beta} \sum_{i=1}^{N} L_{ce}(y_i, \hat{y}_i) + \lambda_w \|\beta\|_1 + \lambda_p \sum_{d=1}^{D} \|P_d\|_2 \) \hfill (1)

\( \Phi_{id} = \min_{X_{ik} \in X_i} Dist(X_{ik}, P_d) \) \hfill (2)

\( \hat{y}_i = \sigma(\beta_0 + \sum_{d=1}^{D} \beta_d \Phi_{id}) \) \hfill (3)

The objective function given in Equation 1 is optimized over the prototypes, \( P \), and the linear classifier weights, \( \beta \). Different learning rates are used for prototypes and the classifier parameters, namely \( \alpha_w \) for weights and \( \alpha_p \) for prototypes. The model is trained for 100 epochs, minibatch size 1 is used with Adam optimizer \cite{Kingma2015Adam}. We also perform layer normalization. Namely, each row in the transformed distance space is scaled to zero mean and unit variance as illustrated in Equations 4a, 4b. Layer normalization is important because it stabilizes the issues that could occur during optimization due to the scale of distance features and it reduces the sensibility of linear classifier to the scale of distances but it keeps the relative distance information. As a side benefit, we observe that as argued in \cite{Ba2016Layer}, it speeds up the convergence.

\[ \mu_i = \frac{1}{D} \sum_{d=1}^{D} \Phi_{id}, \sigma_i = \sqrt{\frac{1}{D} (\Phi_i - \mu_i)^2} \] \hfill (4a)

\[ \Phi_i = \frac{\Phi_i - \mu_i}{\sigma_i} \] \hfill (4b)

The parameters of our experiments are as the following: \( D = 24 \), \( \lambda_p = 0.05 \), \( \lambda_w = 0.05 \), \( Dist \) calculates Euclidean distance, \( \alpha_p = 0.0001 \), \( \alpha_w = 0.00005 \). In practice, any differentiable distance metric could be used in this framework with gradient based optimization methods.
