Region-specific proteolysis differentially modulates type 2 and type 3 inositol 1,4,5-trisphosphate receptor activity in models of acute pancreatitis

Fine-tuning of the activity of inositol 1,4,5-trisphosphate receptors (IP₃R) by a diverse array of regulatory inputs results in intracellular Ca²⁺ signals with distinct characteristics. These events allow the activation of specific downstream effectors. We reported previously that region-specific proteolysis represents a novel regulatory event for type 1 IP₃R (R1). Specifically, caspase-fragmented R1 display a marked increase in single-channel open probability. More importantly, the distinct characteristics of the Ca²⁺ signals elicited via fragmented R1 can activate alternate downstream effectors. In this report, we expand these studies to investigate whether all IP₃R subtypes are regulated by proteolysis. We now show that type 2 and type 3 IP₃R (R2 and R3, respectively) are proteolytically cleaved in rodent models of acute pancreatitis. Surprisingly, fragmented IP₃R retained tetrameric architecture, remained embedded in endoplasmic reticulum membranes and were not functionally disabled. Proteolysis was associated with a marked attenuation of the frequency of Ca²⁺ signals in pancreatic lobules. Consistent with these data, expression of DNAs encoding complementary R2 and R3 peptides mimicking fragmented receptors at particular sites, resulted in a significant decrease in the frequency of agonist-stimulated Ca²⁺ oscillations. Further, proteolysis of R2 resulted in a marked decrease in single-channel open probability. Taken together, proteolytic fragmentation modulates R2 and R3 activity in a region-specific manner, and this event may contribute to the altered Ca²⁺ signals in pancreatic acinar cells during acute pancreatitis.

Inositol 1,4,5-trisphosphate receptors (IP₃R)² are ubiquitous, intracellular Ca²⁺ release channels expressed predominantly in endoplasmic reticulum (ER) membranes (1–4). IP₃R can encode Ca²⁺ changes with distinct spatial and temporal characteristics, and these signals subsequently play essential roles in controlling a plethora of biological processes (1, 2, 5–7). The versatility of these signals is a consequence, in large part, of the regulation of IP₃R activity at multiple levels. First, there are three isoforms of IP₃R, termed R1, R2, and R3, encoded by three different genes (1). IP₃R can either form homo- or heterotetrameric channels. The composition of the assembled tetramer either dictates or contributes to the channel activity (8). Further, binding of numerous molecules can regulate IP₃R properties, including biophysical characteristics, together with receptor localization (9, 10). Another level of modulation occurs as a function of posttranslational modifications, including phosphorylation and ubiquitination events, which can either alter channel activity or determine channel abundance (2, 11). Recently, our laboratory has demonstrated that region-specific proteolytic fragmentation dramatically alters R1 activity and thereby allows the receptor to potentially activate alternative downstream effectors (12). However, whether this is a regulatory event specific to R1 or a general form of regulation relevant to all isoforms of IP₃R requires further investigation. Moreover, whether proteolysis of R2 and R3 has similar effects on the biophysical properties of all subtypes remains to be established.

R2 and R3 play pivotal roles in exocrine secretory systems (13–15). For example, R2- and R3-mediated Ca²⁺ signals play a functionally dominant role in the exocytosis of storedzymogens from the pancreas, which, along with the production of an NaCl-rich fluid, is the primary function of acinar cells. The central role of R2/R3 is most strikingly demonstrated by the observation that R2 and R3 compound knockout mice failed to thrive after weaning because of a severe disruption of exocrine function. Indeed, Ca²⁺ transients and amylase secretion in response to secretagogue stimulation were reported to be completely abolished in pancreatic acinar cells isolated from R2 and R3 double knockouts (13).

R2 and R3 have the same general primary structure as R1 and, therefore, are predicted to be subject to cleavage by proteases at similar solvent-exposed sites (16). An early report suggested that R2 and R3 are substrates of caspase and calpain, respectively (17). In addition, our laboratory reported that, in a model of acute pancreatitis, R3 were cleaved into low-molecular-weight receptor fragments and that inhibition of proteasome activity failed to completely prevent receptor fragmentation (18). These observations imply that R3 were cleaved intracellularly by inappropriately activated digestive enzymes, such as...
trypsin and chymotrypsin, within pancreatic acinar cells during acute pancreatitis (16, 19, 20). Of note, both proteases are reported to cleave IP$_{3}$R in vitro (16, 19–21). This evidence suggests that models of acute pancreatitis may represent an ideal experimental platform to investigate the in vivo consequences of R2 and R3 fragmentation and subsequent effects on agonist-stimulated [Ca$^{2+}$]$_{i}$ signals.

In this study, utilizing both in vivo and in vitro rodent models of acute pancreatitis, we demonstrate that R2 and R3 are substrates for proteases. Moreover, proteolysis results in channels that retain a fundamental tetrameric architecture and remain in ER membranes but exhibit dramatically altered channel activity. Specifically, in both pancreatitis models and in expression systems mimicking fragmentation, agonist-stimulated Ca$^{2+}$ oscillations are attenuated, and channel activity is reduced. This study therefore indicates that proteolysis is a novel mechanism for regulating R2 and R3 activity. Furthermore, although proteolysis modulates the activity of all IP$_{3}$R isoforms, intriguingly, it does so in a subtype- and fragmentation pattern–specific manner.

**Results**

**Generation of fragmented R2 and R3 in an in vivo acute pancreatitis model**

To model acute pancreatitis, mice received three consecutive intraperitoneal (i.p.) injections of a supramaximal concentration of the secretagogue analogue caerulein (50 µg/kg/injection) or saline as a control. This approach represents a well-established, reversible, and relatively noninvasive mouse model of the disease (22, 23). Previous studies have reported that, although isolated pancreatic acinar cells (PAC) from healthy mice displayed robust Ca$^{2+}$ oscillations in response to low concentrations of secretagogues, those from mice treated with this protocol evoked a single Ca$^{2+}$ transient or repetitive Ca$^{2+}$ transients with a significantly lower frequency (24). We first performed [Ca$^{2+}$]$_{i}$ measurements in PAC within excised pancreatic lobules, as described previously (15). This paradigm allows analysis of Ca$^{2+}$ signaling dynamics in PAC in a more native environment and without the time-consuming process of enzymatic digestion of pancreatic tissue needed to produce isolated acinar cells. Upon carbachol (CCh) stimulation (300 nM), PAC from control mice elicited robust Ca$^{2+}$ oscillations, with each spike returning close to the basal Ca$^{2+}$ level between each elevation. The oscillatory Ca$^{2+}$ signals persisted beyond 30 min of the recording (Fig. 1, A and D). Consistent with previous studies (24, 25), PAC from acute pancreatitis mice elicited Ca$^{2+}$ signals with a significantly lower frequency (Fig. 1, B and D). Moreover, a higher concentration of CCh (500 nM) failed to rescue the ability to induce strong Ca$^{2+}$ oscillations in PAC from caerulein-treated mice (Fig. 1, C and D). This strongly indicates that the alteration of Ca$^{2+}$ signals during acute pancreatitis is not likely due to desensitization to the stimuli but may result from modifications of the constituent components promoting Ca$^{2+}$ signaling.

It is well accepted that Ca$^{2+}$ oscillations in pancreatic acinar cells are absolutely dependent on the activity of IP$_{3}$R in the initial phase and, subsequently, on both IP$_{3}$R and Orai-based channels during sustained stimulation (13, 26). We therefore postulated that the remarkable reduction in oscillatory Ca$^{2+}$ signals observed (Fig. 1, B–D) resulted from altered regulation of IP$_{3}$R-induced Ca$^{2+}$ release. Although all three isoforms of IP$_{3}$R are expressed in the pancreas, R2 and R3 are most abundant and functionally dominant (27, 28). Therefore, we performed Western blot assays to investigate whether R2 and R3 are modified in this model of acute pancreatitis. Consistent with our previous report, secretagogue-induced hyperstimulation significantly down-regulated both the full-length R2 and R3 (Fig. 2, A, B, F, and G) (18). In addition, we also observed the generation of both fragmented R2 and R3 receptors in mice treated with caerulein (Fig. 2, A, C, D, F, H, and I). The strong evidence that digestive enzymes such as trypsin and chymotrypsin are prematurely activated as an early event in PAC in models of acute pancreatitis (29–32), we speculated that IP$_{3}$R were fragmented by intracellularly active digestive enzymes. Previous studies demonstrated that exposure of IP$_{3}$R to low concentrations of trypsin and chymotrypsin in vitro results in five receptor fragments (16, 21, 33). These results have been interpreted to indicate that IP$_{3}$R, structurally consists of five compact globular domains (IP$_{3}$R fragments I, II, III, IV, and V) interconnected with four solvent-exposed linker regions. To estimate the relative sizes of receptor fragments and the cleavage sites on the IP$_{3}$R in PAC from mice treated with caerulein, we constructed a library of cDNAs encoding R2- or R3-complementary receptor fragments based on the previously reported tryptic cleavage sites of the receptors (Fig. 3, A and D) (16). Each cDNA was then stably transfected into an IP$_{3}$R-null back-

![Figure 1. Altered temporal Ca$^{2+}$ release profile in pancreatic lobules in the in vivo acute pancreatitis model.](image-url)

A–D, pancreatic lobules were excised from mice given three consecutive i.p. injections of either 0.9% saline or caerulein (50 µg/kg/injection), followed by loading with the Ca$^{2+}$ indicator Fluo-2/AM (25 µM) for 1 h. [Ca$^{2+}$]$_{i}$ dynamics were measured using a multiphoton microscope. PAC from mice treated with saline elicited robust Ca$^{2+}$ oscillations in response to 300 nM carbachol (A and D). In contrast to the control saline injection condition, PAC from mice subjected to caerulein treatment elicited Ca$^{2+}$ transients with a significantly lower frequency (B and D), which could not be rescued by increasing the concentration of the stimulus (C and D). Experiments for each condition were repeated in preparations from three different animals, with more than 20 calcium responses analyzed in each repeat. Two representative traces (black and red) were given for each of the conditions. * statistical significance determined by one-way ANOVA followed by Tukey’s multiple comparisons test.

Proteolytic regulation of IP$_3$R2 and IP$_3$R3

Fragmented R2 mimicking cleavage at the tryptic site in the second solvent-exposed region was named R2 I-II+III-V (tryp). According to this nomenclature, we generated R2 I-II+III-V (tryp) and R2 I-III+IV-V (tryp) for R2 and R3 I-II+III-V (tryp), R3 I-III+IV-V (tryp), and R3 I-IV+V (tryp) for R3. In addition, we also generated R2 I-IV+V (calpain) based on the sequence homology between IP$_3$R1 (R1) and R2 (Fig. 3, A–F). Notably, receptor fragments in PAC from caerulein-treated mice mainly migrated between 250 and 150 kDa, which were similar to molecular weights for R2 I-III (tryp), R2 I-IV (calpain), R3 I-III (tryp), and R3 I-IV (tryp), indicating that R2 and R3 were preferentially fragmented at the third and fourth solvent-exposed domains (Fig. 2, A and F). Moreover, the N-terminal fragments of cleaved R2 co-immunoprecipitated with the C-terminal fragments (Fig. 2E) in the pancreatic sample prepared from mice treated with caerulein, strongly suggesting that IP$_3$R remained associated after proteolysis during the development of models of acute pancreatitis. Trypsin, one of the essential digestive enzymes, is activated during acute pancreatitis, which has been shown to cleave R2 and R3 in vitro ($^{20, 34}$). To test the involvement of trypsin activity in receptor fragmentation, we used the in vivo acute pancreatitis model in trypsinogen 7 knockout mice. These animals are reported to have a 60% reduction in total trypsinogen content, the precursor of trypsin ($^{35}$). Although genetic knockout of trypsinogen 7 had less of an effect on the generation of R2 fragments (Fig. 4, A and C), the elevation of R3 fragments was significantly reduced in this model of acute pancreatitis (Fig. 4, B and D). Therefore, although these data suggest a role of trypsin in receptor frag-

**Figure 2. Generation of fragmented R2 and R3 in the in vivo acute pancreatitis model.** A–I, mice received three injections of saline or caerulein hourly. Pancreata were then removed, homogenized, and prepared for Western blot (WB) detection. Samples from DT40–3KO cells stably expressing R2 I-III and R2 I-IV or R3 I-III and R3 I-IV were run on the same gels to indicate the relative sizes of the fragmented receptors. R2 and R3 were fragmented in pancreata from mice treated with caerulein (A and F). Statistics showed that there was a significant reduction in the full-length receptors (B and G) and a concomitant substantial increase in the fragmented receptors (D–F and G–I). The N-terminal fragments of R2 were co-immunoprecipitated (IP) with the C-terminal fragments using the C-terminal R2 antibody CT2, suggesting that the receptor remains associated after proteolysis (E). Each experiment was repeated four times. The arrows in A, E, and F indicate major receptor fragments. *, statistical significance determined by Student’s t test. mentation, they also indicate that other proteases likely participate in receptor proteolysis.

**Generation of fragmented R2 and R3 in an in vitro acute pancreatitis model**

To further investigate R2 and R3 receptor fragmentation specifically in PAC, we next exploited a well-established *in vitro* pancreatitis model using isolated rat PAC (36). To mimic features of pancreatitis *in vitro*, isolated rat PAC were incubated with two supramaximal concentrations of CCh for different time periods followed by Western blot analysis (37). PAC had a relatively low level of fragmented R2 (Fig. 5A) and R3 (Fig. 5B) under control conditions, presumably as a result of prematurely activated proteolytic enzymes resulting from the inevitable cell damage occurring during pancreatic acinar cell preparation and manipulation. However, we cannot exclude the possibility that there is a basal level of fragmented R2 and R3 under physiological conditions. Nevertheless, in agreement with our *in vivo* findings, despite the appearance of low amounts of fragmented R2 and R3 without treatment, supramaximal concentrations of CCh consistently, in a concentration-dependent manner, further increased the levels of fragmented R2 (Fig. 5A) and R3 (Fig. 5B), accompanied by a concomitant reduction of full-length receptor. To demonstrate that fragmentation of IP3R in PAC was not limited to the hyperstimulation model of acute pancreatitis, PAC were exposed to the bile acid taurocholic acid 3-sulfate disodium salt (TLCS) (38–40). This paradigm is often utilized as a pathologically relevant stimulus to mimic pancreatic duct obstruction and subsequent bile reflux. TLCS exposure consistently resulted in increased fragmentation of R2 and R3 (Fig. 5C–E). Importantly, the generation of receptor fragments could be reversed by preincubation of the cells with cell-permeable trypsin inhibitors (Fig. 5C and D). Together with Fig. 4, these data confirm that trypsin activity, directly or indirectly, is responsible for R2 and R3 fragmentation during the development of acute pancreatitis.

Our previous studies investigating the consequences of R1 fragmentation have demonstrated that R1 fragments remain associated within the ER despite the loss of peptide continuity and retain the ability to be gated by IP3 (41). Thus, we next investigated whether R2 and R3 similarly retain tetrameric architecture and ER membrane localization after receptor frag-
mentation. Isolated rat PAC were incubated with supramaximal concentrations of CCh to induce acute pancreatitis in vitro. Membrane and cytosolic fractions were then prepared by differential centrifugation. Glyceraldehyde-3-phosphate dehydrogenase was used as a marker for the cytosol fraction. No detectable R2 and R3 signals were observed in the cytosol fraction, and both N- and C-terminal fragments of R2 (Fig. 6A) and R3 (Fig. 6B) were present in the membrane fraction, indicating that, like R1, R2 and R3 remained ER-associated after proteolytic fragmentation. Native nondenaturing gel analysis showed that fragmented R2 (Fig. 6C) and R3 (Fig. 6D) in PAC from rats subjected to the in vitro model of acute pancreatitis migrated at the same molecular weight as that of the full-length tetramers. Further, no detectable receptor fragments of lower molecular weights were present in any cell lysates under the pancreatitis conditions. In total, these data strongly suggest that all R2 and R3 exist as tetramers on the ER membrane after proteolytic fragmentation.

Region-specific fragmentation regulates the temporal characteristics of Ca²⁺ signals mediated by R2 and R3

Given the critical roles of IP₃R in Ca²⁺ signaling in PAC (13), our data so far led us to posit that proteolytic fragmentation mediates the alteration of R2 and R3 activities and, consequently, contributes to the altered Ca²⁺ signals in pancreatic acinar cells during the development of acute pancreatitis. To unambiguously study the function of only fragmented R2 and R3 without the potential confounding impact of contaminating signals from endogenous receptors, we performed single-cell Ca²⁺ imaging assays using DT40–3KO cells stably expressing complementary peptides to mimic R2 or R3 fragmented at different sites (Fig. 3). We have previously demonstrated that, after expression, these fragments are assembled into functional tetrameric IP₃R on the ER membrane and are properly gated by IP₃ (41). Consistent with our previous findings, all R2 and R3 generated from cDNAs encoding complementary fragments were capable of supporting Ca²⁺ signals in response to maximal protease-activated receptor 2 (PAR2) activation with trypsin (Fig. 7, A–H).

Next we investigated whether receptor fragmentation has an impact on the temporal characteristics of IP₃R-mediated Ca²⁺ signals. Anti-IgM cross-links B-cell receptors on the cell surface of DT40–3KO cells and results in continuous production of IP₃. Upon anti-IgM stimulation, DT40–3KO cells stably expressing either full-length R2 or R3 elicited robust Ca²⁺ oscillations in an isoform-specific manner (Fig. 8, A and G) (42–44). When cDNAs encoding complementary polypeptides to mimic receptor fragmentation introduced at the second solvent-exposed region were expressed, R2 I-II/III-V (tryp) and R3 I-II+III-V (tryp) were still capable of evoking strong oscillatory Ca²⁺ signals (Fig. 8, B, E, H, and K). However, anti-IgM stimulation of cells expressing constructs mimicking receptor fragmentation in R2 and R3 at solvent-exposed sites more
toward to the C terminus resulted in Ca$^{2+}$/H11001 oscillations with a significantly lower frequency (Fig. 8, C–E and I–K). Further, increasing the concentration of anti-IgM failed to rescue the loss of Ca$^{2+}$/H11001 oscillations mediated by R2 I-III/H11001 IV-V (tryp), R2 I-IV/H11001 V (calpain), R3 I-III/H11001 IV-V (tryp), or R3 I-IV/H11001 V (tryp) (Figs. 7L and 8F). These data strongly suggest that region-spe-
Proteolytic regulation of IP₃R2 and IP₃R3

Figure 8. Region-specific fragmentation alters the temporal Ca²⁺ release profile of R2 and R3. A–L, a panel of DT40–3KO cells, each stably expressing a pair of complementary polypeptides representing fragmented R2 or R3 at particular sites, were loaded with Fura-2/AM, followed by stimulation of B-cell receptor activation with anti-IgM. Single-cell Ca²⁺ imaging recording showed that fragmentation at the proximal N-terminal solvent-exposed region had no impact on the frequency of Ca²⁺ oscillations mediated by R2 (A, B, and E) and R3 (G, H, and K). However, receptor fragmentation more toward the C terminus resulted in a significant decrease in Ca²⁺ oscillations mediated by fragmented R2 (C–E) and fragmented R3 (I–L). This decrease in the frequency of Ca²⁺ oscillations could not be rescued by increasing the concentrations of stimuli (F and I). *, statistical significance determined by one-way ANOVA followed by Tukey’s multiple comparisons test.

Specific receptor fragmentation regulates R2 and R3 activities. These results were consistent with those obtained from the ex vivo pancreatic acini Ca²⁺ imaging assays (Fig. 1, A–D) and provide a possible explanation for the reduction of Ca²⁺ oscillations in PAC isolated from mice subjected to caerulein treatment. Based on these data, it can be envisioned that prematurely activated digestive enzymes cleave R2 and R3 at the third and fourth solvent-exposed regions and, as a consequence, significantly reduce the frequency of oscillatory Ca²⁺ signals of IP₃R in PAC during the development of pancreatitis.

One caveat of studying the functional consequences of receptor fragmentation by using complementary receptor fragments is that fragmented IP₃R are assembled from polypeptides but not generated in situ. In addition, measurements of global [Ca²⁺], an indirect measurement of channel activity. Therefore, we next performed single-channel patch clamp recording with the “on-nucleus” configuration to study the potential biochemical alteration of the R2 activity resulting from proteolytic fragmentation. An initial attempt was made to induce fragmentation of R2 with trypsin. However, no channel activity was recorded in the presence of trypsin, even at picomolar levels of enzyme, presumably because of the receptor destruction resulting from failure to control the amount of receptor proteolysis under these conditions. To circumvent this difficulty and fragment the receptor specifically at the fourth solvent-exposed region in situ in a controlled manner, we constructed a R2 with a tobacco etch virus (TEV) protease cleavage sequence inserted immediately after the tryptic site (Arg-1884) in this region. This construct, termed R2 (TEV), was stably expressed in DT40–3KO cells. TEV protease was capable of specifically cleaving purified R2 (TEV) at the fourth solvent-exposed region to result in fragments corresponding to R2 I-IV+V (TEV) (Fig. 9C). In contrast, incubation of purified full-length R2 with TEV protease failed to result in any receptor fragment (Fig. 9A), con-
firming the specificity of TEV protease–mediated receptor fragmentation. Patch clamp recording in the on-nucleus configuration demonstrated no difference in the single-channel open probability ($P_o$) or mode of gating between R2 (TEV) and full-length R2 WT in the absence of TEV protease (Fig. 9, B and D–G). However, when R2 (TEV) was exposed to TEV, a significant decrease in channel $P_o$, accompanied by a significant increase in interburst interval but no change in burst length (C–G). The NT2 antibody was used to detect R2 in the Western blot assays. Each experimental condition was repeated five times. *, statistical significance determined by one-way ANOVA followed by Tukey’s multiple comparisons test. CTRL, control.

Figure 9. Receptor fragmentation alters R2 activity at the single-channel level. A–G, a TEV protease cleavage sequence was inserted into R2 to achieve a specific receptor cleavage at the fourth solvent-exposed region. TEV protease neither cleaved the R2 WT nor had an impact on its channel activity (A, B, and E–G). In contrast, TEV protease specifically cleaved R2 (TEV) at the predicted site and significantly decreased the channel open probability and increased interburst interval with no impact on burst length (C–G). The NT2 antibody was used to detect R2 in the Western blot assays. Each experimental condition was repeated five times. *, statistical significance determined by one-way ANOVA followed by Tukey’s multiple comparisons test. CTRL, control.

Discussion

This study represents a comprehensive investigation of a novel modification of R2 and R3 and its consequences in PAC in the context of two rodent models of acute pancreatitis. A previous study, in which PAC were isolated by enzymatic digestion following induction of experimental pancreatitis, reported a significant decrease in the ability of PAC from the experimental pancreatitis animals to display sustained oscillatory Ca$^{2+}$ signals. These data are established as strong evidence that the characteristics of the cytosolic Ca$^{2+}$ signal, important for driving physiological secretion, is disrupted in experimental pancreatitis (24). However, the underlying mechanism for this striking transition in Ca$^{2+}$ signaling was not elucidated. In this study, we first confirmed this alteration of Ca$^{2+}$ signals in PAC in situ in excised pancreatic lobules prepared from control mice or from mice subjected to the experimental acute pancreatitis paradigm. This preparation has the significant advantage that the tissue is not exposed to prolonged enzymatic isolation and better reflects the heterogeneity of the impact on different regions of the tissue in the pancreatitis model. Notably, Western blot analysis demonstrated that, concurrent with a significant reduction in the ability of PAC from experimental pancreatitis animals to support sustained Ca$^{2+}$ oscillations, these mice showed a marked decrease in the abundance of full-length R2 and R3 with the concomitant appearance of various species of fragments of R2 and R3. These observations, coupled with data showing that proteolytic cleavage of R1 alters the receptor activity without disabling the channel, led us to hypothesize that, during pancreatitis, proteases are prematurely activated, resulting in fragmentation of R2 and R3 and, in turn, altered [Ca$^{2+}$]$_i$ signals.

To explore this hypothesis, experiments were designed to answer four major questions. Do R2 and R3 retain their tetrameric architectures after proteolytic fragmentation? Do fragmented R2 and R3 remain associated with ER membranes? Do fragmented R2 and R3 retain the ability to be gated by IP$_3$ binding? Does receptor fragmentation alter the temporal profile of agonist-evoked Ca$^{2+}$ signals? First, non-denaturing native gel analysis combined with co-immunoprecipitation assays strongly suggested that, although peptide continuity was lost, R2 and R3 were still tetrameric in structure after receptor fragmentation. Further, membrane fractionation followed by Western blot analysis indicated that all fragments of R2 and R3 were still...
Proteolytic regulation of IP$_3$R2 and IP$_3$R3

located on ER membranes. To study the function of fragmented receptors, we generated a library of DT40–3KO cells stably expressing R2 or R3 assembled from complementary peptides representing one type of fragmented IP$_3$R. Consistent with our previous findings for R1, all fragmented IP$_3$R could support Ca$^{2+}$ release in response to IP$_3$ binding. However, when receptors were fragmented more toward the C terminus, the temporal characteristics of Ca$^{2+}$ signals were greatly altered. Indeed, compared with full-length receptors, R2 I-III+IV-V, R2 I-IV+V, R3 I-III+IV-V, and R3 I-IV+V exhibited a significantly lower frequency of Ca$^{2+}$ oscillations. At a biophysical level, this observation was supported mechanistically by single-channel patch clamp data, which revealed that receptor fragmentation dramatically decreased the single-channel open probability.

This study and our previous report have thoroughly investigated the functional consequences of IP$_3$R fragmentation (12, 45, 46). Early studies showed that exposure of purified R1 to a low concentration of trypsin in vitro resulted in five receptor fragments (16, 21, 33). This result was interpreted as the overall structure of R1 consisting of five compact globular domains linked by four solvent exposed regions. Based on the sequence homology among all three isoforms of IP$_3$R, R2 and R3 were also predicted to have the same overall structure (16, 19). It is worth noting that all putative fragmentation sites, including those reported in this study, are located in these solvent-exposed regions and may be explained by the relatively easy accessibility of these regions to protease activity (16, 21, 33, 47, 48). The coupling domain (amino acids 586–2276) of IP$_3$R generates interfaces where Ca$^{2+}$, regulatory proteins, and nucleotides bind to mediate channel activities (1, 2, 49). The distinct regulatory events among the three isoforms of IP$_3$R confer subtype-specific Ca$^{2+}$ signals. We postulate that some of the regulatory events rely on peptide continuity for an appropriate communication between regulatory inputs and the channel domain. As a result, disruption of receptor continuity by proteases in specific regions of the coupling domain would potentially impact such communication and, subsequently, alter the single-channel Po and temporal characteristics of Ca$^{2+}$ signals evoked by agonist stimulation.

Consistent with the idea that overall regulation of IP$_3$R activity is altered following loss of peptide continuity, we reported previously that fragmented R1 at either the third or fourth solvent-exposed regions in the coupling domain, corresponding to the activity of caspase or calpain, significantly increased the ability of R1 to induce Ca$^{2+}$ oscillations in cells (12, 41, 46). Notably, we have also reported that caspase-cleaved R1 exhibited a significantly augmented single-channel open probability (12). Here we extend this finding by showing that region-specific receptor fragmentation is a general regulatory event for all isoforms of IP$_3$R, including R2 and R3. Interestingly, in marked contrast to R1, proteolytic fragmentation significantly decreased the single-channel open probability of R2 and the ability of R2 and R3 to induce oscillatory Ca$^{2+}$ signals in cells. How does proteolysis result in subtype-specific effects on single channel activity and the temporal pattern of stimulated Ca$^{2+}$ signals? Although extrapolating the effects on single channel activity to the global pattern of cellular Ca$^{2+}$ signals is challenging, a current mathematical model for the generation of Ca$^{2+}$ oscillations suggests that the oscillation frequency is dictated by the rate at which Ca$^{2+}$ activates and subsequently inactivates the particular IP$_3$R (46). We speculate that this form of regulation differs between IP$_3$R subtypes in the native state and is altered by proteolysis. An increase in R1 Po following cleavage might reflect an increase in susceptibility to be activated (or, equally possible, a decreased sensitivity to be inactivated) by the fixed [Ca$^{2+}$] in the patch pipette, with the opposite occurring for R2. In this scenario, differentially altering the relationship between IP$_3$R activation and deactivation could result in changes to the oscillation period.

What is the role of IP$_3$R fragmentation in acute pancreatitis? We used both in vitro and in vivo rodent models with different toxic stimuli to characterize the modification of IP$_3$R. Consistently, IP$_3$R were fragmented in all tested models, indicating that IP$_3$R fragmentation may be a general event occurring in acute pancreatitis. Our studies show that IP$_3$R fragmentation likely occurs at an early stage in models of acute pancreatitis. Repetitive injections of supramaximal concentrations of caerulein are widely used to induce acute pancreatitis in mice, and commonly seven to 12 injections are utilized (24, 35, 50, 51). Our data demonstrate that fragmentation of IP$_3$R is already initiated after the third injection. Based on these data, we speculate that IP$_3$R fragmentation occurs at an early stage of acute pancreatitis and may represent a protective strategy employed by the cell to limit Ca$^{2+}$ signaling. The signaling cascade linking pathological Ca$^{2+}$ signals to acute pancreatitis has been well characterized. Specifically, a globally sustained increase of [Ca$^{2+}$], in PAC is thought to contribute to secretory inhibition, premature intracellular digestive enzyme activation, cell death, and, eventually, acute pancreatitis (52–54). Based on these ideas, experimental strategies aimed at inhibiting pathological Ca$^{2+}$ signals, such as attenuating Ca$^{2+}$ channel activity (55–57), chelating intracellular Ca$^{2+}$ (58–60), or promoting Ca$^{2+}$ clearance (61), have been shown to be protective in acute pancreatitis. Notably, we demonstrated that fragmented R2 and R3 may play a similar functional role by reducing the frequency of Ca$^{2+}$ oscillations and essentially decreasing the overall [Ca$^{2+}$], in PAC in models of acute pancreatitis. Specifically, R2 and R3 fragmentation transformed sustained Ca$^{2+}$ responses or robust elevated Ca$^{2+}$ oscillations into lower-frequency Ca$^{2+}$ transients and, thereby, would be predicted to decrease the total amount of Ca$^{2+}$ release into the cytosol by both internal Ca$^{2+}$ release and, subsequently, store-dependent Ca$^{2+}$ influx. This process may either delay or suppress the premature intracellular digestive enzyme activation and, thereby, be protective at the early stage of acute pancreatitis. In conclusion, combined with our previous reports (12, 45), our data are the first to systemically investigate and characterize the functional consequences of proteolytic fragmentation of all three isoforms of IP$_3$R. Further, to our knowledge, this is the first report to show the modification of IP$_3$R in acute pancreatitis and provide a possible explanation for the alteration of the spatial and temporal properties of Ca$^{2+}$ signals observed in the early stages of acute experimental pancreatitis.
Materials and methods

Reagents

All restriction enzymes and T4-DNA ligase were from New England Biolabs. RPMI 1640 medium, penicillin/streptomycin, G418 sulfate, β-mercaptoethanol, and chicken serum were purchased from Invitrogen. Fetal bovine serum was from Gemini Bio-products. Fura-2/AM was from TEF Labs. Enhanced chemiluminescent substrate and 800CWTM secondary antibodies were from Thermo Scientific. The Dc protein assay kit, Tris base, glycine, horseradish peroxidase–conjugated secondary antibodies, and all reagents used for SDS-PAGE were from Bio-Rad. Mouse anti-chicken IgM was from SouthernBiotech. The antibody against the N terminus of R2 (NT2) was generated by Pocono Rabbit Farms and Laboratories. The mouse mAb against the N terminus of R3 (NT3) was from BD Transduction Laboratories. Both NT2 and NT3 were diluted (1:1000) for Western blotting. CT2 and CT3 were gifts from the Richard Wojcikiewicz laboratory. CT2 and CT3 were raised against the extreme carboxyl aa 2686–2701 of R2 and aa 2658–2670 of R3, respectively (28). Both CT2 and CT3 were diluted (1:200) for Western blotting. All IP3R antibodies used in this study have been shown to be subtype-specific based on appropriate recognition of a single isoform by Western blotting cell lysates containing only a specific isoform (10, 18, 28, 42). Caerulein and tauroliothocholic acid 3-sulfate disodium salt were from Sigma-Aldrich. Gabexate mesylate and camostat mesilate were from Serva. tert-taurolithocholic acid 3-sulfate disodium salt were from Sigma-Aldrich. RPMI 1640 medium, penicillin/streptomycin, 5% CO2. DT40–3KO cell transfection and generation of stable cell lines were performed as described previously using the Riken Institute (Japan) and Amaxa nucleofector (Lonza Laboratories). DT40–3KO were obtained directly from this source (38). Amaxa nucleofector (Lonza Laboratories). DT40–3KO were generated and authenticated in the Riken Institute (Japan) and originally obtained directly from this source (62).

Animal husbandry

Experiments with animals were conducted in accordance with protocol 100783/UCAR-2001-214R, approved by the University of Rochester. The mice used for this work were 12-week-old C57/BL6NJ mice. The rats used for this work were adult male Wistar rats.

Cell culture and plasmid transfection

DT40–3KO cells were grown in RPMI 1640 medium supplemented with 1% chicken serum, 10% fetal bovine serum, 100 units/ml penicillin, and 100 μg/ml streptomycin at 39 °C with 5% CO2. DT40–3KO cell transfection and generation of stable cell lines were performed as described previously using the Amixa nucleofector (Lonza Laboratories). DT40–3KO were generated and authenticated in the Riken Institute (Japan) and originally obtained directly from this source (62).

Construct preparation

The method for generation of fragmented IP3R was first described elsewhere in details (41). cDNAs encoding R2 I-II+III-V (trypsin), R2 I-III+IV-V (trypsin), R2 I-IV+V (calpain), R3 I-II+III-V (trypsin), R3 I-III+IV-V (trypsin), and R3 I-IV+V (trypsin) were constructed using the corresponding primers: forward, 5’-GCCGTAGCATGGGTCACCAGATCCATTC-3’; forward, 5’-CTTGGTGTGCAAGATGTGCGGAGGTAGAATTCGCGGCCG-GGCCGCTAGCTAGTCCATCCAGGGGTGGGACACA-3’; forward, 5’-GCCCACTAAGAGCCAGCAGCTAGTGGGAGAGATGA-3’. To introduce a TEV protease cleavage site after the Arg-1884 in R2, primer 5’-AGCATCTGTGTGACGAGAAACCTGTACATTC-3’ was used.

Native gel analysis

Cells were harvested by centrifugation and lysed in CHAPS lysis buffer (40 mM NaCl, 25 mM HEPES, 10 mM CHAPS, and 1 mM EDTA (pH 7.4)) supplemented with protease inhibitors. After 20 min on ice at 4 °C, lysates were cleared by centrifugation at 16,000 × g for 10 min at 4 °C. Cleared lysates were mixed with of 4× sample buffer, 5% G-250 sample additive, and fractionated 3–12% native PAGE Novex gels. Separated proteins were transferred to polyvinylidene difluoride membranes and probed using the indicated primary antibodies and the appropriate horseradish peroxidase–conjugated secondary antibodies. Protein bands were detected using enhanced chemiluminescent substrate.

Subcellular fractionation

Cells were harvested with ice-cold PBS and then resuspended in homogenization buffer containing 20 mM HEPES, 5 mM NaH2PO4, 0.5 mM EGTA, and 320 mM sucrose (pH 7.4) supplemented with protease inhibitors. Cells were homogenized using a Teflon glass homogenizer. Homogenates were cleared by centrifugation at 1000 × g for 10 min at 4 °C. The resulting supernatants were centrifuged at 100,000 × g at 4 °C for 1 h. The supernatants designated as the cytosolic fraction were removed, and the microsomal pellet was resuspended in lysis buffer. Equivalent amounts of proteins were fractionated and processed for immunoblot analyses with the indicated antibodies.

Fluorescence imaging

DT40 cells expressing defined IP3R constructs were loaded with 2 μM Fura-2/AM on a glass coverslip mounted onto a Warner chamber at room temperature for 20–30 min. Loaded cells were perfused with HEPES imaging buffer (137 mM NaCl, 4.7 mM KCl, 1.26 mM CaCl2, 1 mM Na2HPO4, 0.56 mM MgCl2, 10 mM HEPES, and 5.5 mM glucose (pH 7.4)) and stimulated with the indicated agonist. Ca2+ imaging was performed using an inverted epifluorescence Nikon microscope with a ×40 oil immersion objective (numerical aperture = 1.3). Cells were alternately excited at 340 and 380 nm, and emission was monitored at 505 nm. Images were captured every second with an exposure of 10 ms and 4 × 4 binning using a digital camera (Cooke Sensicam QE) driven by TILL Photonics software.

In vivo acute pancreatitis model

Twelve-week-old C57/BL6NJ mice were starved overnight and then given three consecutive i.p. injections of caerulein...
Single-channel patch clamp with the on-nucleus configuration

Mice were euthanized, and pancreata were removed and placed into oxygen-bubbled ice-cold imaging buffer (137 mM NaCl, 4.7 mM KCl, 1.26 mM CaCl2, 1 mM Na2HPO4, 0.56 mM MgCl2, 10 mM HEPES, and 5.5 mM glucose (pH 7.4)). Pancreatic lobules were excised and exposed to liberase for 10 min, followed by loading with Fluo-2/AM. Fluo2-loaded lobules were excited at 810 nm using a Spectra Physics tunable fs pulsed Ti-Sapphire laser controlled by Fluoview software on an Olympus FV1000MP microscope using a ×25 water immersion objective (1.03 numerical aperture). The clusters were stimulated with various concentrations of CCh. Images were acquired at a resolution of 512 × 512 pixels. Regions of interest were selected, and fluorescence intensity in that region was determined as a function of time and expressed relative to the initial fluorescence.

Isolation of rat pancreatic acinar cells

Rat pancreata were obtained from male adult Wistar rats. Pancreata were enzymatically digested with type II collagenase (Sigma) in Dulbecco’s modified Eagle’s medium (Invitrogen) with 0.1% BSA and 1 mg/ml soybean trypsin inhibitor for 30 min, followed by gentle trituration. Acini were then filtered through 350-μm nylon mesh, centrifuged at 75 g for 5 min, followed by 1% BSA in Dulbecco’s modified Eagle’s medium, and resuspended in 1% BSA in Dulbecco’s modified Eagle’s medium.

Single-channel patch clamp with the on-nucleus configuration

Isolated DT40 nuclei were prepared by homogenization as described previously (63). Single IP₃R channel potassium currents were measured in the on-nucleus patch clamp configuration using pCCLAMP 9 and an Axopatch 200B amplifier (Molecular Devices) as described previously (63). TEV protease was included in the pipette solution for the corresponding experiments. Gigaohm seals were attained, and channel activity was verified at ~100 mV. Patches were then depolarized to 0 mV for 15 min to allow TEV protease to cleave the receptor. The patches were again repolarized to ~100 mV, and channel activity was measured. Traces were consecutive 3-s sweeps sampled at 20 kHz and filtered at 5 kHz. Pipette resistances were typically 20 megaohm and seal resistances were >5 gigaohm.
