Multiple myeloma is a malignant tumour characterized by proliferation of a single clone of plasma cells, this cell line will produce large amount of ineffective immunoglobulins that are ineffective at fighting infection resulting in immunosuppression.

These are medullary tumours most of the time; however, in rare cases they may arise extra medullary.

The incidence of extramedullary plasmocytoma is about 5% and they arise in the chest most of the time; but they can also arise in other body systems like gastrointestinal system, which is involved in 10% of the time. We present a very rare case of primary plasmocytoma involving the pancreas. According to our research, there are only 25 cases of primary pancreatic plasmocytoma reported in english literature.

1. Case report

A 66-year-old male patient presented with epigastric pain, vomiting, and weight loss over a period of several months. Initial ultrasonographic examination of the upper abdomen revealed diffuse intrahepatic and extrahepatic bile duct dilatation with no intra ductal stone (see Fig. 1). The pancreas was enlarged, with heterogeneous texture and no pancreatic duct dilatation. A large hypoechoic mass was identified in the region of pancreatic head (see Fig. 2) with the vessel piercing the lesion. The gall bladder wall was thick and edematous (see Fig. 3).

Subsequent computed tomography (CT) confirmed the pancreatic head mass had extended into porta hepatis causing dilatation of biliary ducts with gall bladder neck invasion (see Figs. 4 and 5).

CT images also demonstrated encasement of the celiac axis and superior mesenteric arteries without occlusion. Diffuse lytic bony lesions were also present (see Fig. 6).
The differential diagnosis at this point would possibly include

1. lymphoma, given the homogeneous nature of the mass and encasement of the mesenteric blood vessels;
2. pancreatic adenocarcinoma;
3. or, less likely, cholangiocarcinoma.

The patient had a CT-guided biopsy of the pancreatic mass, which confirmed to be a plasmocytoma (see Fig. 7).

The patient received chemotherapy followed by autologous bone marrow transplant. Follow-up imaging confirmed initial good response to treatment, but unfortunately, the most recent positron emission tomography scan demonstrated persistent metabolic activity in a lymph node anterior to the pancreas and in the wall of gall bladder (see Figs. 8-10).

2. Discussion

Multiple myeloma is malignant proliferation of single clone of plasma cell—producing monoclonal antibodies. Plasmocytoma is a discrete mass of plasma cells, most often in the bones or occasionally in an extramedullary location [2]. The latter is rare [3], with median age of presentation at 55 years and a slight male predominance. Plasmocytoma can be primary or secondary, with the secondary form more common [2]. Only 5% of plasmocytomas involve extraosseous tissue, and they are typically diagnosed after the diagnosis of multiple myeloma had been established. Most of these involve the upper respiratory tract; only 10% involves gastrointestinal tract, mainly the stomach, the liver, and the spleen. There are only 25 cases of pancreatic
Fig. 4 – Transverse ultrasound (A) and enhanced axial CT (B) images show dilated intrahepatic biliary tree (arrow). TRV RT LIVER = transverse right liver.

Fig. 5 – Enhanced axial CT image through the pancreatic mass at the portal venous phase demonstrated diffuse homogeneous enhancement.

Fig. 6 – Axial CT images in bone window shows widespread lytic bony lesions (arrows). A, at the level of middle thoracic spine. B, at the level of sacrum.

Fig. 7 – CT-guided biopsy of the pancreatic mass using 18-gauge quick core needle biopsy in the prone position.

involvement in the English literature [1]. A pancreatic mass in a patient with an established diagnosis of multiple myeloma should raise the suspicion of pancreatic involvement by the disease [4].

It can involve any part of the pancreas. Pancreatic head involvement is by far the most common [2], resulting in upper abdominal pain and obstructive jaundice.

The radiologic findings of pancreatic plasmocytoma are not very specific. Ultrasonography demonstrates a heterogeneous mass that is hypoechoic to the surrounding tissue. CT shows homogeneous enhancement of a multilobulated mass. Diffuse pancreatic enlargement is often described. Dual-phase CT with pancreatic protocol is considered the modality of choice allowing assessment of vascularity. Magnetic resonance imaging is felt less favored currently [5]. Although CT scan is the investigation of choice, imaging features are not specific and may mimic other entities such as pancreatic carcinoma, lymphoma, islets cell tumor, and metastasis [6].
The treatment of multiple myeloma includes steroid and chemotherapy in addition to radiation therapy for symptomatic lesions. Other methods of treatment are under investigation such as thalidomide, angiogenic agents, and stem cell transplant. To our knowledge, there is no standardized treatment targeting extramedullary plasmocytoma [5].

3. Conclusion

Pancreatic plasmocytoma is a rare entity; it should be considered in the differential diagnosis in patients presenting with a hypoechoic pancreatic head mass and diffuse lytic bony lesions.
