Abstract

The nearby TRAPPIST-1 planetary system is an exciting target for characterizing the atmospheres of terrestrial planets. The planets e, f, and g lie in the circumstellar habitable zone and could sustain liquid water on their surfaces. During the extended pre–main-sequence phase of TRAPPIST-1, however, the planets may have experienced extreme water loss, leading to a desiccated mantle. The presence or absence of an ocean is challenging to determine with current and next-generation telescopes. Therefore, we investigate whether indirect evidence of an ocean and/or a biosphere can be inferred from observations of the planetary atmosphere. We introduce a newly developed photochemical model for planetary atmospheres, coupled to a radiative-convective model, and validate it against modern Earth, Venus, and Mars. The coupled model is applied to the TRAPPIST-1 planets e and f, assuming different surface conditions and varying amounts of CO2 in the atmosphere. As input for the model we use a constructed spectrum of TRAPPIST-1, based on near-simultaneous data from X-ray to optical wavelengths. We compute cloud-free transmission spectra of the planetary atmospheres and determine the detectability of molecular features using the Extremely Large Telescope (ELT) and the James Webb Space Telescope (JWST). We find that under certain conditions the existence or nonexistence of a biosphere and/or an ocean can be inferred by combining 30 transit observations with ELT and JWST within the K band. A nondetection of CO could suggest the existence of an ocean, whereas significant CH4 hints at the presence of a biosphere.

1. Introduction

The nearby TRAPPIST-1 system offers exciting new opportunities for studying the atmospheres of its seven planets with next-generation telescopes such as the James Webb Space Telescope (JWST; Gardner et al. 2006; Beichman et al. 2014) or the European Large Telescope (ELT; Gilmozzi & Spyr- omilio 2007). Due to short orbital periods and large star–planet contrast ratios, planets orbiting such cool host stars are easier to detect and characterize via the transit method than planets orbiting hotter stars and are therefore prime targets to observe the properties of their atmospheres.

On the other hand, the stellar luminosity evolution of M dwarfs is quite different from that of solar-type stars. In particular, the active pre–main-sequence phase of the star can be extended and the stellar UV radiation is high for about a billion years (see, e.g., Baraffe et al. 2015; Luger & Barnes 2015). This could lead to a runaway greenhouse state on an ocean-bearing terrestrial planet and a loss of substantial amounts of planetary water vapor (H2O) before the star enters the main-sequence phase (see, e.g., Wordsworth & Pierrehumbert 2013; Ramirez & Kaltenegger 2014; Luger & Barnes 2015; Tian & Ida 2015; Bolmont et al. 2016; Bourrier et al. 2017). Recently Fleming et al. (2020) have suggested that TRAPPIST-1 has maintained high activity with a saturated XUV luminosity (X-ray and extreme UV emission) for several gigayears. Hence, the planets likely received a persistent and strong XUV flux from the host star for most of their lifetimes.

In such an environment with strong H2O photolysis and subsequent hydrogen escape it has been suggested that the atmosphere could build up thousands of bar molecular oxygen (O2) when assuming, e.g., inefficient atmospheric loss or surface sinks (Wordsworth & Pierrehumbert 2014; Luger & Barnes 2015; Lincowski et al. 2018). This buildup can be prevented if O2 is absorbed into the surface during the early magma ocean phase (see, e.g., Schaefer et al. 2016; Wordsworth et al. 2018) or by extreme UV-driven oxygen escape (Tian 2015; Dong et al. 2018; Guo 2019; Johnstone 2020). Grenfell et al. (2018) suggest that if enough molecular hydrogen (H2) is present it can react with O2 from H2O photolysis to reform water via explosion–combustion reactions.

Bolmont et al. (2016) concluded that the TRAPPIST-1 planets can retain a significant amount of water even for strong far-UV (FUV) photolysis of H2O and large hydrogen escape rates. Three (TRAPPIST-1 e, f, and g) of the seven planets lie in the classical habitable zone (HZ), defined as the region around the star where a planet could maintain liquid water on its surface (Kasting et al. 1993). 3D simulations show that only TRAPPIST-1 e would allow for surface liquid water without the need of greenhouse warming from a gas other than H2O.

Meadows 2017; Catling et al. 2018; Wonderlich et al. 2019; Komacek et al. 2020. Detectable in CO2-rich atmospheres is carbon monoxide

produced by CO2 photolysis (e.g., Schwieterman et al. 2019). Hence, O2 or ozone (O3) cannot be considered as reliable biosignature gases like on Earth (e.g., Selsis et al. 2002; Segura et al. 2007; Harman et al. 2015; Meadows 2017). Due to weak stellar UV emissions at wavelengths longer than 200 nm, planets orbiting M stars show an increase in the abundance of certain bioindicators and biomarkers such as methane (CH4) and nitrous oxide (N2O) compared to Earth around the Sun (see Segura et al. 2005; Rauer et al. 2011; Grenfell et al. 2013; Rugheimer et al. 2015; Wonderlich et al. 2019). Assuming the same surface emissions as on Earth, CH4 would be detectable with the JWST in the atmosphere of an HZ Earth-like planet around TRAPPIST-1 (Wonderlich et al. 2019). Krissansen-Totton et al. (2018b) argued that the simultaneous detection of CH4 and CO2 in the atmosphere of a planet in the HZ is a potential biosignature. However, the buildup of detectable amounts of CH4 is also conceivable by large outgassing from a more reducing mantle than Earth.

The detection of CO2 in cloud-free atmospheres of TRAPPIST-1 planets would be feasible within approximately 10 transits with the JWST (see Morley et al. 2017; Krissansen-Totton et al. 2018a; Fauchez et al. 2019; Lustig-Yaeger et al. 2019; Wonderlich et al. 2019; Komacek et al. 2020). The detection of other species, such as O3, would require many more transits (see, e.g., Fauchez et al. 2019; Lustig-Yaeger et al. 2019; Pidhorodetska et al. 2020). Another species that might be detectable in CO2-rich atmospheres is carbon monoxide (CO), produced by CO2 photolysis (e.g., Schwieterman et al. 2019). Since CO has only a few abiotic sinks and weak biogenic sources, it is often considered as a potential biosignature (Zahnle et al. 2008; Nava-Sedeño et al. 2016; Wang et al. 2016; Meadows 2017; Catling et al. 2018).

Wang et al. (2016) argued that simultaneous observations of O2 and CO would distinguish a true biosignature (O2 without CO) from a photochemically produced false-positive biosignature (O2 with CO). However, Rodler & López-Morales (2014) showed that a detection of Earth-like O2 levels with ELT would only be feasible for a planet around a late M dwarf at a distance below ~5 pc (see also Snellen et al. 2013; Brogi & Line 2019; Serindag & Snellen 2019).

In this study we investigate how the presence of an ocean as an efficient sink for CO would affect the atmospheric concentration of CO and other species. We simulate transmission spectra of TRAPPIST-1 e and TRAPPIST-1 f and determine the detectability of molecular features with the upcoming space-borne telescope JWST and the next-generation ground-based telescope ELT. For the JWST we consider low-resolution spectroscopy (LRS), and for the ELT we use high-resolution spectroscopy (HRS). In particular, we show how much CO2 would be needed to obtain a detectable CO feature in a desiccated atmosphere of TRAPPIST-1 e.

Also the photochemical processes related to the existence of a water reservoir may change the abundances of CO and O2. The recombination of CO and atomic oxygen into CO2 via catalytical cycles was suggested to be slower for dry CO2 atmospheres owing to the lower abundances of hydrogen oxides, HOx (defined as H + OH + HO2; see, e.g., Selsis et al. 2002; Segura et al. 2007; Krissansen-Totton et al. 2018b).

We use a 1D climate–photochemistry model to calculate the composition profiles of CO and other species such as O2 and O3 in CO2-poor and CO2-rich atmospheres. In order to consistently simulate the photochemical processes in CO2-dominated atmospheres, we introduced extensive model updates. The stellar spectral energy distribution (SED) is an input for the model. The UV range of the SED is crucial for the photochemical processes in the atmosphere. To our knowledge we are the first study using an SED of TRAPPIST-1 constructed based on measurements in the UV (Wilson et al. 2020). For comparison we also investigate two other SEDs of TRAPPIST-1 with modeled or estimated UV fluxes as input for our climate–photochemistry model.

In Section 2 we introduce the climate–photochemistry model and validate the new version by calculating the atmospheres of modern Earth, Venus, and Mars. We compare the results with other photochemical models and available observations. We also describe the line-by-line spectral model used to simulate transmission spectra of TRAPPIST-1 e and TRAPPIST-1 f and introduce the calculation of the signal-to-noise ratio (S/N) of atmospheric molecular features. In Section 3 we show the TRAPPIST-1 SEDs used in this study and the considered atmospheric scenarios. Results of the atmospheric modeling, simulated transmission spectra, and S/N calculations are presented in Section 4. In Section 5 we discuss our results, and in Section 6 we present the summary and conclusion.

2. Methodology

2.1. Climate–Chemistry Model

To simulate the potential atmospheric conditions of the HZ planets TRAPPIST-1 e and TRAPPIST-1 f, we use a 1D steady-state, cloud-free, radiative-convective photochemical model, entitled 1D-TERRA. The code is based on the model of Kasting & Ackerman (1986), Pavlov et al. (2000), and Segura et al. (2003) and was further developed by, e.g., von Paris et al. (2008, 2010, 2015), Rauer et al. (2011), and Gebauer et al. (2018b). We have extensively modified both the radiative-convective part of the model and the photochemistry module. The updated version of the model is capable of simulating a wide range of atmospheric temperatures (100–1000 K) and pressures (0.01 Pa–1013 bar). It covers a wide range of atmospheric compositions, including potential habitable terrestrial planets, having N2-, CO2-, H2-, or H2O-dominated atmospheres. The climate module is briefly described in Section 2.2. For a detailed description of the climate module, we refer to the companion paper by Scheucher et al. (2020b). Here we give a detailed description of the updated photochemistry model in Section 2.3.

2.2. Climate Module

The atmospheric temperature for each of the pressure layers is calculated with our climate module. The radiative transfer module REDFOX uses a flexible k-distribution model for opacity calculations based on the random-overlap assumption (see Scheucher et al. 2020b). The radiative transfer is solved using the two-stream approximation (Toon et al. 1989). The module considers 20 absorbers from HITRAN 2016 (Gordon et al. 2017), as well as 81 absorbers in the visible (VIS) and UV with cross sections taken from the MPI Mainz Spectral Atlas.
We calculate the molecular diffusion coefficients for the diffusion-limited escape velocity of H and H2 in N2-, CO2-, or H2-dominated atmospheres from the parameterization shown in Hu et al. (2012). This was derived from the gas kinetic theory, and the coefficients are obtained by fitting to experimental data from Marrero & Mason (1972) and Banks (1973). Following the upper limit of Luger & Barnes (2015), we assume that the oxygen escape flux is one-half the hydrogen escape flux.

The lower model boundary is given by either a fixed volume mixing ratio, f, or a net input or loss at the surface, which depends on the deposition velocity, $v_{dep}$ cm s$^{-1}$, and the surface emission, $\Phi_{BOA}$ in molecules cm$^{-2}$ s$^{-1}$. The volcanic flux, $\Phi_{VOLC}$, is distributed over the lower 10 km of the atmosphere. The boundary conditions used for the simulation of the TRAPPIST-1 planetary atmospheres are given in Section 3.3. Tropospheric lightning emissions of nitrogen oxides, NO, NO$_2$, are also included based on the Earth lightning model of Chameides et al. (1977).

To account for the wet deposition of soluble species, we use the parameterization of Giorgi & Chameides (1985). This parameterization takes as input effective Henry’s law constants, $H'$, of all soluble species. We use the values of $H'$ published in Giorgi & Chameides (1985), as well as the classical Henry’s law constants, $H$, from Sander (2015) and consider available parameterizations of the temperature dependence for the solubility.

In a 1D photochemical model the vertical transport can be approximated by eddy diffusion. In previous model versions the eddy diffusion was fixed to a given profile by Massie & Hunten (1981), which approximates Earth’s vertical mixing. BLACKWOLF uses a parameterization of the eddy diffusion coefficient, similar to Gao et al. (2015), which is based on the equations shown in Gierasch & Conrath (1985). We introduce the parameterization and compare eddy diffusion profiles for Earth, Venus, and Mars in Section 2.3.3.

2.3. Chemical Kinetics

The chemical network used in previous studies such as Grenfell et al. (2007, 2013), Rauer et al. (2011), and Wunderlich et al. (2019) is based on Kasting et al. (1985), Pavlov & Kasting (2002), and Segura et al. (2003) and is able to reproduce Earth’s atmosphere with an N$_2$-O$_2$-dominated composition. This paper introduces an updated and enhanced network also suitable for CO$_2$- and H$_2$-dominated atmospheres. All species included are listed in Table 1, and all reactions can be found in the Table 2. Photochemical reactions are discussed in detail in Section 2.3.2. The chemical network setup is designed to be fully flexible, meaning that subsets of species or reactions can be chosen.

A large number of chemical reactions are taken from the network presented in Hu et al. (2012). Since we focus on the atmosphere of terrestrial planets in the HZ around their host stars, we do not include reactions that are only valid at temperatures above 800 K. From the network of Hu et al. (2012) we do not include reactions with hydrocarbon molecules that have more than two carbon atoms. For higher hydrocarbon chemistry we include the reactions up to C$_5$ shown in Arney et al. (2016). This network has been used and validated in multiple studies focusing on the influence of hydrocarbon haze production on atmospheric composition and climate for a range of different atmospheric conditions (e.g., Arney et al. 2016, 2017, 2018).
We update the chlorine chemistry for Earth-like atmospheres with the reaction coefficients from Burkholder et al. (2015) and add new reactions, taken from the online database of the National Institute of Standards and Technology (NIST\(^\text{11}\); Mallard et al. 1994). In particular, we include reactions that are important for the destruction and buildup of chloromethane (CH\(_3\)Cl) for Earth-like atmospheres. Further, we include chlorine and sulfur chemical reactions known to be relevant in CO\(_2\)-dominated atmospheres such as Mars and Venus from Zhang et al. (2012). Following, e.g., Zahnle et al. (2008), we multiply all termolecular reaction rates by a bath gas factor of 2.5 when CO\(_2\) is the main constituent of the atmosphere and is therefore acting as a third body in the termolecular reactions.

If multiple references are found for the same reaction, we compare the reaction rates assuming a temperature of 288 K and decide case by case which reaction rate is considered. If the reaction rates do not differ by more than a factor of three, we use the reaction rate from the most recent reference. For the rates or multiple rates include a temperature dependence, we use the reference that considers a temperature dependence. If none of the reaction rates do not differ by more than a factor of three, we use the reaction rate from the most recent reference. For cases with a wavelength gap between two data sets we set the cross sections to zero within the gap. We also assume that the cross sections are zero for wavelengths longer or shorter than covered by the available data sets. Quantum yields are interpolated between different data sets. Further, the quantum yields are extrapolated to 100 nm, the lower wavelength limit of the model, and up to the wavelength that corresponds to the bond energy of the reaction stated in Burkholder et al. (2015). Temperature-dependent cross sections and quantum yields are interpolated linearly to the temperature of the atmospheric level.

\(2.3.3\). Eddy Diffusion

The eddy diffusion coefficient, \(K\), in cm\(^2\) s\(^{-1}\) as a function of altitude is assumed analogous to that for heat as derived for free convection by Gierasch & Conrath (1985):

\[
K = \frac{H}{3} \frac{(L/H)^{4/3}}{\rho \sigma T} \left( \frac{R \sigma T_i}{\mu \rho C_p} \right)^{1/3},
\]

where \(H\) is the scale height, \(R\) is the universal gas constant, \(\sigma\) is the Stefan-Boltzmann constant, \(\mu\) is the atmospheric molecular weight, \(\rho\) is the atmospheric density, \(C_p\) is the atmospheric heat capacity, and \(L\) is the mixing length.

Equation (1) was also used by, e.g., Ackerman & Marley (2001) and Gao et al. (2015) to estimate \(K\). To fit the \(K\) profile of Earth, Mars, and Venus, we adapt the formula for \(L\), which was introduced by Ackerman & Marley (2001):

\[
L = \begin{cases} 
H \cdot \max(0.1, \Gamma/\Gamma_{\text{adi}}) & z < \zeta_{\text{ct}} \\
H_{\text{ct}} \left( \frac{20}{p_0} + \left( \frac{1}{p} \right)^{1/4} \right) & z \geq \zeta_{\text{ct}}
\end{cases}
\]

where \(\Gamma\) is the atmospheric lapse rate, \(\Gamma_{\text{adi}}\) is the adiabatic lapse rate, \(\rho\) is the atmospheric pressure, \(p_0\) is the surface pressure, \(\zeta_{\text{ct}}\) is the height of the cold trap, and \(H_{\text{ct}}\) is the scale height at \(\zeta_{\text{ct}}\).

For a planet with an ocean, such as Earth, \(\zeta_{\text{ct}}\) is the atmospheric layer where water condenses out, i.e., at the lowest layer where \(\frac{p}{p_0}\) starts to increase with height. \(p_{\text{sat}}\) is the
Table 2
Reaction Rates of Bimolecular Reactions (R) in cm³ s⁻¹, Termolecular Reactions (M) in cm⁶ s⁻¹, Thermodissociation Reactions (T) in s⁻¹, and Quantum Yields of Photolysis Reactions (P) Used in the Photochemical Module

| No. | Reaction | Reaction Rate or Quantum Yield | Temperature | Reference |

This table is available in its entirety in machine-readable form.

saturation pressure of water. For a planet without an ocean, such as Mars and Venus, the eddy diffusion can be well described by breaking gravity waves alone (see, e.g., Izakov 2001), and the concentration is set to 0 m. The left panel of Figure 1 shows the calculated K profile for Earth compared to the K profile derived from trace gases by Massie & Hunten (1981). The gray shaded region represents a range of observational fits from multiple models (Wofsy et al. 1972; Hunten 1975; Allen et al. 1981). The parameterized values match well the results shown in Massie & Hunten (1981) and lie within the model range except close to the surface, where surface properties can influence transport and toward the upper mesosphere, where, e.g., gravity wave breaking can influence mixing and energy budgets. We do not consider a constant eddy diffusion coefficient profile for Earth in the mesosphere and thermosphere as proposed by, e.g., Allen et al. (1981) in order to enable the calculation of K to be as general as possible without further assumptions. For most planets K is found to increase toward high altitudes (see, e.g., Zhang & Showman 2018). Note that the model also has the possibility to use a fixed, predefined K profile.

The middle panel of Figure 1 shows reasonable agreement for the calculated K profile of Venus with the assumed profiles from Krasnopolsky (2007, 2012) and Zhang et al. (2012). The maximum values of these three studies represent the upper limit of the model range. The lower limit of the model range is taken from Izakov (2001).

The calculated K profile for the Martian atmosphere, compared to the assumed profiles from Krasnopolsky (2010a) and Nair et al. (1994), are shown in the right panel of Figure 1. The lower limit of the model range is from Nair et al. (1994) up to 30 km and from Montmessin et al. (2017) above that. The upper limit is from Krasnopolsky (2010a) and Krasnopolsky (2006). Figure 1 shows that Equation (1) can represent well the K profiles of Earth, Mars, and Venus and hence is suitable to apply to the scenarios we consider for the TRAPPIST-1 planets.

2.4. Model Validation

2.4.1. Earth

We first validate our model by simulating modern Earth around the Sun and comparing the results with observations from measurements of the Michelson Interferometer for Passive Atmospheric Sounding (MIPAS; Fischer et al. 2008) and the Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS; Bernath 2017). Details of the MIPAS

and ACE-FTS data processing can be found in von Clarman et al. (2009) and Boone et al. (2005) respectively. The references of the individual data sets for each species can be found on the MIPAS web page¹² and the ACE-FTS web page.¹³

We select only the data with high quality, determined as follows. For MIPAS data we follow the recommendations that the diagonal element of the averaging kernel needs to be at least 0.03 and the visibility flag must be unity.¹⁴ The ACE-FTS data contain a quality flag indicating physically unrealistic outliers (Sheese et al. 2015). The selected data are averaged for each satellite flyover onto a grid with a resolution of 5° in latitude by 10° in longitude. We repeat this step for each available observation. We take into account 95% of the data and exclude the 5% extremes. The maximum and minimum values for each altitude level represent the measured range shown as gray shading in Figure 2. To calculate the global and annual mean profile of each species, we calculate a monthly mean and from that an annual mean at each grid point. This ensures that each season of the year is equally represented. Finally, we average over the grid with a zonal and weighted meridional mean.

Different from our previous studies, we do not tune the surface fluxes to reproduce the observed surface abundances of CO, NO₂, CH₄, and CH₃Cl (e.g., Grenfell et al. 2013, 2014; Wunderlich et al. 2019). Instead, we use the sum of observed anthropogenic, biogenic, and volcanic surface fluxes (see Table 4) and observed νₜₜₜ (see Table 5). Also included are modern-day tropospheric lightning emissions of NOₓ. We apply an upper boundary condition for H and H₂ with the parameterization from Hu et al. (2012). To simulate modern Earth, we use the solar spectrum from Guemaryard (2004). The temperature profile simulated with the model is shown in the companion paper (Scheucher et al. 2020). To achieve a mean surface temperature of 288.15 K in our cloud-free model, we use a surface albedo of 0.255.

Figure 2 shows that the photochemistry of Earth can be reproduced well with the new chemical network. We also compare well to the results shown by Hu et al. (2012). Tropospheric abundances of all shown species lie within the measurement range. In the upper stratosphere and mesosphere the abundances of HNO₃ are underestimated in both models compared to measurements. This discrepancy could be due to missing NOₓ-related processes, such as energetic particle precipitation, producing NOₓ in the upper mesosphere and subsequent dynamical transport into the stratosphere (see, e.g., Siskind et al. 2000; Kriyolutsy 2001; Funke et al. 2005, 2010, 2014, 2016; López-Puertas et al. 2005; Clilverd et al. 2009).

2.4.2. Mars

As a second validation case we simulate the atmosphere of modern Mars. We use the atmospheric temperature profile from Haberle et al. (2017), representing a scenario with weak dust loading. The data are based on diurnal averages of Mars Climate Sounder (MCS) observations (Kleinböhl et al. 2009). The radiative-convective climate module is not used here to calculate the temperature profile since we want to focus on the validation of the photochemistry model. The climate validation for Mars is presented in Scheucher et al. (2020b). The mean surface pressure of the reference atmosphere is 5.62 hPa (Haberle et al. 2017). We use a bond albedo of 0.25 (Williams 2010). The eddy diffusion coefficients are directly calculated in the model (see Section 2.3.3).

In Table 6 we show the boundary conditions used to model the Martian atmosphere. N₂ serves as a fill gas and is 2.82% over the entire atmosphere, which is similar to the

¹² www.imk-asf.kit.edu/english/308.php
¹³ ace.scis.ca/publications/
¹⁴ share.lsdf.kit.edu/imk/asf/sat/mesospho/data/L3/MIPAS_L3_ReadMe.pdf
measurements of Owen et al. (1977), which suggested a volume mixing ratio of 2.7%.

Figure 3 shows the profile of selected atmospheric species compared to the model results of Krasnopolsky (2010a) and the following measurements. For H₂O we take into account Mars Express Planetary Fourier Spectrometer (PFS) nadir measurements up to 30 km from Montmessin & Ferron (2019) and Spectroscopy for the Investigation of the Characteristics of the Atmosphere of Mars measurements above 20 km from Fedorova et al. (2009). O₃ ranges are taken from nighttime and sunrise/sunset measurements (Lebonnois et al. 2006; Montmessin & Lefèvre 2013). CO observational ranges are taken from retrieval uncertainties around 800 ppm from PFS/Mars Express infrared nadir observations (Bouche et al. 2019). The H₂ range at 80 km is given in Krasnopolsky & Feldman (2001), and the O₂ range at the surface is taken from Trainer et al. (2019). We compute the observational ranges by finding the lowest and highest value in a 2 km grid from measured profiles or observations of the mixing ratio at a given altitude. Note that surface values are located at 1 km for visibility purposes.

The Martian atmosphere simulated with the photochemistry model compares well with the results from Krasnopolsky (2010a) and Nair et al. (1994). The model simulates the visible H₂O abundances close to the lower minimum of measured concentrations. When using an eddy diffusion flux increased by a factor of 10, more water is transported upward and the modeled H₂O abundances fit the measurements (not shown). Since we model an aerosol-free atmosphere, the low H₂O content is consistent with observations of Vandaele et al. (2019) showing increased atmospheric H₂O during dust storms. Note that Krasnopolsky (2010a) and Nair et al. (1994) used a predefined H₂O profile, while we calculate the H₂O profile consistently in the photochemical model. The underestimation of the O₃ content above 60 km may be related to diurnal changes in the solar zenith angle, not included in the model. We obtain a surface O₂ concentration of 1552 ppm, which is consistent with the global mean of 1560 ± 54 ppm inferred by Krasnopolsky (2017) and also in the range of the seasonal variation of O₂ (1300–2200 ppm; Trainer et al. 2019).

In summary, we show that our photochemistry model gives consistent results compared to previous photochemistry models and observations of the Martian atmosphere. Different from many previous models, we also simulate consistently the chemistry of chlorine, sulfur, and methane. The emission fluxes required to reproduce observations of CH₄, HCl, and SO₂ are shown in Figure 6. The Martian CH₄ chemistry will be discussed in detail in a follow-up paper by J. L. Grenfell et al. (2020, in preparation).

2.4.3. Venus

Predicting the atmospheric composition of Venus is challenging since details of the sulfur chemistry are not understood completely (e.g., Mills & Allen 2007; Zhang et al. 2012; Vandaele et al. 2017). The atmospheric chemistry of Venus below and above the cloud deck is usually modeled separately. We validate our model by calculating the atmosphere of Venus only in the photochemical regime above the cloud top at ~58 km, where direct observations of chemical species are available. The temperature profile is taken from the Venus International Reference Atmosphere VIRA-1 (Seiff et al. 1985).

The boundary conditions are presented in Table 7. Following Zhang et al. (2012) and Krasnopolsky (2012), we use fixed volume mixing ratios of H₂O for key species to fit the observed values, and we assume a downward flux of all other species depending on K and H (see also Section 2.3.3). Figure 4 shows the profile of the species with existing observations and profiles taken from Zhang et al. (2012) and Krasnopolsky (2012).

The range of observational values is derived by combining multiple studies. The H₂O range is generated by combining measurements from Bertaux et al. (2007) and measurements shown in Figure 3 of Krasnopolsky (2012). CO measurements are taken from Svedhem et al. (2007) and Figure 2 of Krasnopolsky (2012). HCl measurements are taken from Sandor & Clancy (2012) and Bertaux et al. (2007). For the observational range of SO₂ and SO we use Venus Express solar occultations in the infrared range and SPICAV (Spectroscopy for Investigation of Characteristics of the Atmosphere of Venus) occultations from Belyaev et al. (2012) and submillimeter measurements from Sandor et al. (2010). The OCS observation is taken from Krasnopolsky (2010b), and NO measurements are from Krasnopolsky (2006). As for the Mars
validation, we compute the observational ranges by finding the lowest and highest values in a 2 km grid.

We find that our model is able to reproduce the Venus atmosphere above 58 km and leads to broadly comparable results as for other photochemical models. Our model reproduces the measurements best with an H2O mixing ratio of $4.0 \times 10^{-6}$, which is in between the values shown in Krasnopolsky (2012) and Zhang et al. (2012). The HCl profile of our model is consistent with the decrease between 70 and 100 km found by observations (Sandor & Clancy 2012) and was not reproduced by the models of Krasnopolsky (2012) and Zhang et al. (2012). On using our calculated eddy diffusion coefficients, we underestimates the abundances of SO2 and SO between 90 and 100 km. Using larger eddy diffusion coefficients from Krasnopolsky (2012), we then lie in the observational range of SO2 and SO between 90 and 100 km but slightly overestimate the SO2 abundances around 80 km. This degeneracy may be caused by the missing consideration of sulfur hazes in the upper atmosphere (see, e.g., Gao et al. 2014).

In summary, we find that we can predict the upper atmosphere of Venus similarly well to other models, even without consideration of the effect of hazes above the cloud layer.

### 2.5. Transmission Spectra

The climate–photochemistry model is used to simulate atmospheric temperature and composition profiles of potential atmospheres of TRAPPIST-1 e and TRAPPIST-1 f. With the resulting profiles we produce transmission spectra of the planetary atmospheres using the “Generic Atmospheric Radiation Line-by-line Infrared Code” (GARLIC; Schreier et al. 2014, 2018). GARLIC has been used in recent exoplanet studies such as Scheucher et al. (2018), Katyal et al. (2019), and Wunderlich et al. (2019).

We simulate transmission spectra including 28 atmospheric species15 between 0.4 and 12 μm. Line parameters are taken from the HITRAN 2016 database (Gordon et al. 2017) and the Clough–Kneizys–Davies (CKD) continuum model (Clough et al. 1989). Additionally, Rayleigh extinction is considered (Murphy 1977; Clough et al. 1989; Sneep & Ubachs 2005; Marcq et al. 2011). In the visible we use the cross sections at room temperature (298 K) for O3, NO2, NO3, and HOCI listed in Table 3.

For the 1D climate–photochemistry simulations we do not consider cloud formation. Hence, all the transmission spectra we calculate in this study show cloud-free conditions. However, an Earth-like extinction from uniformly distributed aerosols in the atmosphere can be considered in GARLIC. The aerosol optical depth, $\tau_\lambda$, at wavelength $\lambda$ (μm) is expressed following Angström (1929, 1930):

$$\tau_\lambda = \beta \cdot \lambda^{-\alpha},$$

assuming that the aerosol size distribution follows the Junge distribution (Junge 1952, 1955). For the exponent, $\alpha$, we use 1.3, representing the average measured value on Earth (see, e.g., Angström 1930, 1961). The Angström turbidity coefficient, $\beta$, is expressed using the cross-section data for Earth’s atmosphere taken from Allen (1976):

$$\beta = 1.4 \times 10^{-27} \cdot N_c,$$

where $N_c$ is the column density in molecules cm$^{-2}$ (see also Toon & Pollack 1976; Kaltenegger & Traub 2009; Yan et al. 2015). According to Allen (1976), Equation (4) corresponds to

15 OH, HO2, H2O2, H2CO, H2O, H2, O3, CH4, CO, N2O, NO, NO2, HNO3, ClO, CH3Cl, HOCI, HCl, ClONO2, H2S, SO2, O3, CO2, N2, C2H2, C2H4, C2H6, NH3, and HCN.
Table 4

| Species       | Anthropogenic References | Biogenic References | Volcanic References | Biogenic and Volcanic References |
|---------------|--------------------------|---------------------|---------------------|----------------------------------|
| O₃            | 7.70 x 10¹⁰             | calc.               | ...                 | 1.21 x 10¹²                     |
| CH₄           | 1.16 x 10¹¹             | (1)                 | (1)                 | 1.21 x 10⁸                     |
| CO            | 6.58 x 10⁸              | (3)                 | (3)                 | 3.74 x 10⁸                     |

clear atmospheric conditions with weak scattering by haze or dust.

The transmission spectra from GARLIC are expressed as effective heights:

$$h_z(\lambda) = \int_0^{T_{OA}} (1 - T(\lambda, z)) dz,$$

where $T$ is the transmission along the limb with the tangent altitude, $z$. Here $h_z$ is the integration over all $T$ from the surface to the top of atmosphere (ToA) at each wavelength, $\lambda$. The measured transit depth, $t_{\text{depth}}$, of a planet with an atmosphere is the sum of the planet radius, $R_p$, and $h_z$ with respect to the stellar radius, $R_\ast$. The atmospheric transit depth, $t_{\text{atm}}$, only contains the contribution of the atmosphere to the total transit depth:

$$t_{\text{atm}}(\lambda) = \frac{(R_p + h_z(\lambda))^2}{R_\ast^2} - \frac{R_p^2}{R_\ast^2}.$$  

In order to detect a spectral feature, we make use of the wavelength dependence of $t_{\text{atm}}$. To extract the measurable atmospheric signal, $S_{\text{atm}}$, we subtract the minimum atmospheric transit depth, $t_{\text{min}}$, in the considered wavelength range (baseline) from the $t_{\text{atm}}$ at each wavelength point:

$$t_{\text{min}} = \min(t_{\text{atm}}(\lambda)).$$  

$$S_{\text{atm}}(\lambda) = t_{\text{atm}}(\lambda) - t_{\text{min}}.$$  

The wavelength-dependent $S_{\text{atm}}$, expressed as parts per million (ppm), is used to calculate the $S/N$ of molecular features. Taking into account the $h_z(\lambda)$ instead would overestimate the $S/N$ of the spectral features, because that measure would include the continuum extinction.

2.6. Signal-to-noise Ratio

We determine which atmospheric spectral features of the simulated atmospheres of TRAPPIST-1 e and TRAPPIST-1 f could be detectable with ELT and JWST. Lustig-Yaeger et al. (2019) showed that the $S/N$ for emission spectroscopy of TRAPPIST-1 e and TRAPPIST-1 f is too low to detect spectral features (see also Batelha et al. 2018). Hence, we limit our analysis to transmission spectroscopy.

To calculate the $S/N$ of the planetary atmospheric feature, $S/N_{\text{atm}}$, of a single transit, we first calculate the $S/N$ of the star, $S/N_{\text{star}}$, integrated over one transit and then multiply this value
by $S_{\text{atm}}$:

$$S / S_{\text{atm}} = S_{\text{atm}} \cdot S / N_s.$$  \hspace{1cm} (9)

The factor $1 / \sqrt{2}$ accounts for the fact that the star is observed in transit and out of transit. We calculate the number of transits, $n_{\text{tr}}$, necessary to reach an $S/N$ of 5, assuming that all transits improve $S/N_s$ perfectly. The $S/N_s$ for JWST NIRSpec and MIRI is determined by the method and instrument specifications presented in Wunderlich et al. (2019) (see Table 8 for the wavelength coverage and resolving power, $R = \nu / \Delta \nu$).

The $S/N_s$ of the ELT High Resolution Spectrograph (HIRES; Marconi et al. 2016) is calculated with the ESO Exposure Time Calculator\textsuperscript{16} (ETC) Version 6.4.0 from November 2019 (see updated documentation\textsuperscript{17} from Liske 2008). The ETC uses the background sky model\textsuperscript{18} for the Cerro Paranal and considers photon and detector noises such as readout noise and dark current. The ETC assumes a spectrograph with a throughput of 25%, independent of the resolving power. For HIRES or METIS HRS this value might overestimate the real value. For METIS HRS the expected throughput ranges between 6% and 21% (C. Vázquez 2020, personal communication). Hence, we scale down the $S/N_s$ for both instruments to an average throughput of 10%.

We assume a telescope with a diameter of 39 m at Paranal in Chile (2635 m). The planned location of the ELT at Cerro Armazones (3046 m) is not available in the ETC. The sky conditions are set to a constant air mass of 1.5 and a precipitable water vapor (PWV) of 2.5 (Liske 2008). The ETC does not provide the possibility to choose the individual ELT instrumentations, but we consider the wavelength coverage and $R$ for the instruments planned for the ELT (see Table 8). For each wavelength band we change the radius of the diffraction-limited core of the point-spread function according to the recommendation in the ETC manual. The wavelengths from 2.9 \textmu m to 3.4 \textmu m cannot be calculated by the current version of the ETC.

To simulate an observation of TRAPPIST-1, we scale the stellar spectrum from Wilson et al. (2020) to the J-band magnitude of 11.35 (Gillon et al. 2016) in order to obtain the input flux distribution.

The $S/N_s$ for a 1 hr integration of TRAPPIST-1 for JWST and ELT is shown in Figure 5. The ground-based facility ELT will have a much larger telescope area compared to the spaceborne JWST, but its capability of detecting spectral features with LRS is limited to atmospheric windows with minor telluric contamination. However, high-resolution spectra ($R > 25,000$) resolve individual lines improving their detectability. The Doppler shift of the lines during the transit with respect to the absorption lines of Earth’s atmosphere is measurable for close-in planets (see, e.g., Birkby 2018). Previous theoretical and observational studies have shown that a detection of molecules such as O$_2$, H$_2$O, or CO is feasible via cross-correlation (e.g., Birkby et al. 2013; Snellen et al. 2013; Brogi et al. 2018; López-Morales et al. 2019; Mollière & Snellen 2019; Sánchez-López et al. 2019).

We adopt a simple approach in order to estimate the number of transits that are necessary to detect, e.g., O$_2$, H$_2$O, and CO with the cross-correlation method in our simulated atmospheres. We adapted a formula presented in Snellen et al. (2015) to calculate the $S/N$ of the planet, considering the wavelength dependency of $S_{\text{atm}}$ and $S/N_s$:

$$S / S_{\text{atm}} = \sum_{i=0}^{n_1} S_{\text{atm}}(\lambda_i) \cdot S / N_s(\lambda_i) / n_1 \cdot \sqrt{t_{\text{int}}} \cdot \sqrt{t_i},$$ \hspace{1cm} (10)

where $n_1$ is the number of spectral lines and $t_{\text{int}}$ is the integration time. Parameter $t_{\text{int}}$ is calculated by $t_{\text{int}} = \nu_{\text{eff}} / \Delta \nu$, with the transit duration, $t_{\text{dur}}$, and the number of transits, $n_0$. The $S/N_s$ at the wavelength of the line, $\lambda_i$, used in Equation (10), is the $S/N_s$ shifted by one bandwidth to account for the displacement of the spectral line during transit.

Using Equation (10), we find that a 3\sigma detection of O$_2$ on an Earth twin around an M7 star at a distance of 5 pc might be feasible when co-adding 58 transit observations in the $J$ band with ELT HIRES, assuming a throughput of 20%.

Figure 3. Mars composition profiles for selected species predicted with our photochemistry model shown in blue, compared to the results from Krasnopolsky (2010a) in orange, Nair et al. (1994) in green, and a range of multiple observations in black (see text for details).

### Table 7

**Boundary Conditions of Modern Venus**

| Species | Lower | References |
|---------|-------|------------|
| CO      | \( f = 0.965 \) | Zhang et al. (2012) |
| CO      | \( v_m = 0.1K/H \) | Krasnopolsky (2012) |
| H2O     | \( f = 4.0 \times 10^{-6} \) | tuned |
| OCS     | \( f = 1.2 \times 10^{-8} \) | tuned |
| NO      | \( f = 5.5 \times 10^{-9} \) | Zhang et al. (2012) |
| HCl     | \( f = 1 \times 10^{-6} \) | tuned (calc. edd. diff.) |
| HCl     | \( f = 4 \times 10^{-7} \) | Zhang et al. (2012) (K12 edd. diff.) |
| SO2     | \( f = 3.5 \times 10^{-6} \) | Zhang et al. (2012) |
| other   | \( v_m = K/H \) | Zhang et al. (2012) |

*Note.* For all species not listed here we assume a maximum deposition velocity \( v_m = K/H \) using \( K \) and \( H \) at 58 km to take into account that our BoA is not the surface (see Zhang et al. 2012; Krasnopolsky 2012). \( f_{\text{HCl}} = 1 \times 10^{-6} \) for the run with a calculated \( K \), and \( f_{\text{HCl}} = 4 \times 10^{-7} \) for the run with \( K \) taken from Krasnopolsky (2012). \( N_2 \) serves as a fill gas.

López-Morales (2014) suggested that 26 transits are needed to detect \( O_2 \) when using the same assumptions.

Section 4.5.6 discusses the detectability of the CO spectral feature in the atmosphere of hypothetical planets around other low-mass stars in the solar neighborhood. For stars on the northern sky we calculate the \( S/N \) for the Thirty Meter Telescope (TMT; Nelson & Sanders 2008). This will have a smaller telescope area than the ELT but will be located at a higher altitude of 4064 m, compared to 2635 m at Paranal. Hence, due to the lower PWV and weaker high-altitude turbulence at Maunakea, the TMT is expected to have a similar performance to the ELT. We compare the \( S/N \) of ELT with \( R = 4000 \) at a Vega magnitude of 16 in the \( J \) band to calculation of the \( S/N \) with the same specifications using the Infrared Imaging Spectrograph on TMT by Wright et al. (2014) and find that ELT has a 10% lower \( S/N \) than TMT.

Since the performance of the telescopes during operation is not yet established, we simply assume that the TMT provides the same \( S/N \) as the ELT.

### 3. Stellar Input and Model Scenarios

#### 3.1. TRAPPIST-1 Spectra

The SED in the UV has a large impact on the photochemistry of atmospheres of terrestrial planets (see, e.g., Selsis et al. 2002; Grenfell et al. 2013, 2014; Tian et al. 2014). In this study we use the semiempirical model spectrum of TRAPPIST-1 from Wilson et al. (2020), which we will refer to as W20 SED. The constructed SED uses observational data from XMM-Newton for the X-ray regime and from the Hubble Space Telescope (HST) for the 113–570 nm range with a gap between 208 and 279 nm obtained through the Mega-MUSCLES Treasury survey (Froning et al. 2018). The wavelengths larger than 570 nm are filled by Wilson et al. (2020) with a PHOENIX photospheric model (Baraffe et al. 2015; Allard 2016).

Figure 6 compares the Mega-MUSCLES TRAPPIST-1 SED with spectra, presented in previous studies. Lincowski et al. (2018) estimated the UV radiation of TRAPPIST-1 by scaling the Proxima Centauri’s spectrum to the \( \text{Ly} \alpha \) measurements of TRAPPIST-1 from Bourrier et al. (2017), in the following referred to as L18 SED. Peacock et al. (2019) present a semiempirical non–local thermodynamic equilibrium (non-LTE) model spectrum of TRAPPIST-1, based on the stellar atmosphere code PHOENIX (Hauschildt 1993; Hauschildt & Baron 2006; Baron & Hauschildt 2007), here referred to as P19 SED.
We bin all spectra into 128 bands for the climate model and 133 bands for the photochemistry model. The spectra for TRAPPIST-1, as well as the solar spectrum from Gueymard (2004), are shown in Figure 6. All SEDs are scaled to an integrated total energy of $1361 \text{W m}^{-2}$, which is equal to the energy Earth receives from the Sun.

### 3.2. System Parameters and Habitability

We use the following stellar parameters of TRAPPIST-1: a $T_{\text{eff}}$ of 2516 K (Van Grootel et al. 2018), a radius of 0.124 $R_{\odot}$ (Kane 2018), a mass of 0.089 $M_{\odot}$ (Van Grootel et al. 2018), and a distance of 12.43 pc (Kane 2018). Table 9 provides the planetary parameters for planets e and f used to model the atmosphere and to calculate the $S/N$ of the produced transmission spectra. We do not focus here on TRAPPIST-1 g since initial studies with our model (not shown) suggested cold, nonhabitable conditions, even assuming several tens of bar of surface CO2, although this is a subject for future study (see, e.g., Wolf 2017; Lincowski et al. 2018; Turbet et al. 2018).

Most previous studies used the planetary parameters from Gillon et al. (2017) with an irradiation of 0.662 $S_{\odot}$ for TRAPPIST-1 e and an irradiation of 0.382 $S_{\odot}$ for planet f. In Table 10 we compare the mean surface temperature for different atmospheric compositions and using the irradiation from Gillon et al. (2017) and Delrez et al. (2018b). We also compare the temperatures with results from 3D studies.

The 1D models have difficulties simulating the atmosphere of planets orbiting low-mass stars in synchronous rotation self-consistently (see, e.g., Yang et al. 2013; Leconte et al. 2015; Barnes 2017). However, Table 9 shows that the surface temperatures predicted with our 1D model are in general agreement with the results from 3D studies. Using the stellar irradiation from Gillon et al. (2017), we overestimate the temperatures by $\sim 10$ K for TRAPPIST-1 e. Only for the Titan-like atmosphere with 0.01 bar CH4 and 1 bar N2 do we predict a larger difference of 20 K. For a 10 bar CO2 atmosphere of TRAPPIST-1 f we obtain a 16 K lower surface temperature compared to Fauchez et al. (2019). Note that we only simulate cloud-free conditions. The consideration of clouds in 1D models would likely but not always lead to a lower surface temperature (see, e.g., Kitzmann et al. 2010; Lincowski et al. 2018).

### 3.3. Model Scenarios

As input for the model we use the SEDs shown in Figure 6. The atmosphere in the climate module is divided into 101 pressure levels and the chemistry model into 100 altitude layers. We use the full photochemical network with 1127 reactions for 128 species.

Motivated by the fact that liquid water is a key requirement of life as we know it, we focus here on TRAPPIST-1 e and f, which are found to be favored candidates for habitability (see, e.g., Kitzmann et al. 2010; Lincowski et al. 2018).

We simulate N2- and CO2-dominated atmospheres for TRAPPIST-1 e and CO2-dominated atmospheres for TRAPPIST-1 f. Table 11 shows the assumed surface pressure, $p_s$, and the surface partial pressure of CO2. N2 serves as a fill gas for each simulation. The partial pressures of CO2 are chosen according to the amount necessary to reach a surface temperature of $\sim 273$ K (0.1 bar for planet e and 3.6 bar for planet f) and $\sim 340$ K (1.0 bar for planet e and 10.8 bar for planet f). According to Wordsworth & Pierrehumbert (2013), water loss due to H2O photolysis and hydrogen escape is
expected to be weak for surface temperatures below 340 K (see also Kasting et al. 1993). For TRAPPIST-1 e we additionally use lower CO₂ partial pressures of 10⁻¹⁰ bar and 0.01 bar in order to compare with Hu et al. (2020), who predicted the composition profiles of TRAPPIST-1 e and f with a 1D photochemistry model using the 3D model output from Wolf (2017).

We assume three scenarios regarding the lower boundary condition: a wet and alive atmosphere with an ocean and biogenic and volcanic fluxes as on Earth, a wet and dead atmosphere with an ocean and only volcanic outgassing, and a dry and dead atmosphere without an ocean and with only volcanic outgassing (see Table 11). We use the same surface pressure for all three scenarios having the same partial pressure of CO₂. Hence, depending on the amount of other species in the planetary atmosphere, such as O₂ or CO, the amount of N₂ differs between the scenarios. However, a difference of the surface pressure impedes the comparison between the scenarios owing to effects that are not entirely related to the atmospheric composition, such as the surface temperature, pressure broadening, CIA, the eddy diffusion profile, and the H₂O profile in the lower atmosphere.

Biogenic and volcanic surface emissions are the same as measured for Earth (see Table 4). The \( \nu_{\text{dep}} \) of CO and O₂ are shown in Table 5. For all other species we assume a \( \nu_{\text{dep}} \) as measured for Earth (see Table 5). From Huang et al. (2018) we calculate that the net O₂ emission into the atmosphere is \( 1.29 \times 10^{12} \text{ molecules cm}^{-2} \text{ s}^{-1} \) (11,030 Tg yr⁻¹) without taking into account fossil fuel combustion. To reproduce an O₂ mixing ratio of 0.21 for our Earth validation run (in Section 2.4.1), we need to set a \( \nu_{\text{dep}} \) of 2 \( \times \) \( 10^7 \) cm s⁻¹ (not shown), which is similar to the O₂ \( \nu_{\text{dep}} = 1 \times 10^8 \) cm s⁻¹ used by Arney et al. (2016). Hence, we use the value used by Arney et al. (2016) as a lower limit for the deposition velocity of O₂. The corresponding \( \Phi_{\text{BOA}} \) is \( 1.12 \times 10^{12} \) molecules cm⁻² s⁻¹ to obtain an O₂ mixing ratio of 0.21 with our Earth validation run. The escape rates of H, H₂, and O are calculated according to the parameterizations presented in Section 2.3.

4. Results

4.1. Atmospheric Profiles of TRAPPIST-1 e with 0.1 bar CO₂

In this section we discuss the resulting atmospheric profiles of TRAPPIST-1 e assuming a 0.1 bar surface partial pressure of CO₂ in a 1 bar atmosphere. As model input we use all three TRAPPIST-1 spectra from Figure 6 and compare the resulting atmospheric composition.

4.1.1. Temperature

Figure 7 shows temperature, eddy diffusion coefficient, and composition profiles for selected species for TRAPPIST-1 e with 0.1 bar CO₂. The different scenarios are distinguished by color, and the different stellar input spectra are denoted by different line styles. The temperature profiles are very similar for all runs except near the surface, where the greenhouse effect of H₂O leads to larger temperatures for the wet scenarios compared to the dry and dead runs. The temperature inversion in the middle atmosphere is lacking owing to weak UV absorption by O₃ (see Section 4.1.6). The wet and alive runs show the largest \( T_{\text{surf}} \) owing to warming from biogenic species such as CH₄ (see Table 12). The impact of the different stellar spectra shown in Figure 6 on the planetary \( T_{\text{surf}} \) is generally small.

4.1.2. Eddy Diffusion Coefficients

For the dry scenario the eddy diffusion coefficient, \( K \), near the surface is low and increases continuously toward higher altitudes. This is similar to the \( K \) profiles estimated for Venus and Mars (e.g., Nair et al. 1994; Krasnopolsky 2012). The wet scenarios follow a \( K \) profile that is similar to Earth, with a decrease of \( K \) up to the cold trap and an increase above (Massie & Hunten 1981). This profile is also similar to that calculated.
by Lincowski et al. (2018) for the atmosphere of TRAPPIST-1 e, assuming an Earth-like planet covered by an ocean.

### 4.1.3. H₂O

The water profile in the lower atmosphere depends mainly on the fixed relative humidity and the temperature. For the wet scenarios the relative humidity profile is assumed to be constant at 80% in the lower atmosphere. For the dry runs only the surface H₂O is calculated with the relative humidity; otherwise, the H₂O profile is determined chemically. For pressures below 1 hPa H₂O is mainly destroyed photochemically at wavelengths shorter than 200 nm and reformed via HO₂-driven (HO₂ = H + OH + HO₂) oxidation of CH₄ into H₂O. The scenario that includes biogenic fluxes of Earth as an additional lower boundary condition (wet and alive) leads to significant H₂O production via CH₄ oxidation (see also Segura et al. 2005; Grenfell et al. 2013; Rugheimer et al. 2015; Wunderlich et al. 2019).

![Figure 6](image_url)

**Figure 6.** Input stellar SED of TRAPPIST-1 and the Sun. Red line: TRAPPIST-1 SED with the UV estimated with a semiempirical model using HST observational data provided by the Mega-MUSCLES survey (Wilson et al. 2020), marked W20 SED. Cyan line: TRAPPIST-1 SED with estimated UV flux by scaling the spectrum of Proxima Centauri (Lincowski et al. 2018), marked L18 SED. Violet line: TRAPPIST-1 SED with calculated UV flux using a semiempirical non-LTE model Peacock et al. (2019), marked P19 SED. Black line: solar SED taken from Guemard (2004). For the FUV/NUV ratio the FUV is integrated between 117 and 175 nm and the NUV is integrated over 175–320 nm (see Tian et al. 2014).

### Table 9

| Parameters          | Planet e | Planet f | Reference           |
|---------------------|----------|----------|---------------------|
| Radius (Rₑ)        | 0.94     | 1.08     | Kane (2018)         |
| Mass (Mₑ)          | 0.772    | 0.934    | Grimm et al. (2018) |
| Gravity (m s⁻²)     | 8.56     | 7.85     | ...                |
| Irradiation (Sₑ)   | 0.604    | 0.349    | Delrez et al. (2018b)|
| Transit duration    | 55.92    | 63.14    | Delrez et al. (2018b) |
| Impact parameter b  | 0.24     | 0.337    | Delrez et al. (2018b) |

*Note.* The planetary radii from Delrez et al. (2018b) are corrected according to Kane (2018). The gravity is calculated using given planetary mass and radius. Using the updated stellar parameters from Kane (2018), the planetary radii are ~3 larger and the gravities ~7 lower than the values used by previous studies such as Lincowski et al. (2018).

### 4.1.4. CH₄

The abundances of CH₄ are mainly driven by the surface flux. For the alive scenario we use preindustrial (biogenic and volcanic) flux measured on Earth (6.31 × 10¹⁰ molecules cm⁻² s⁻¹; see Table 4), and for the dead runs we use only geological sources of CH₄ (1.12 × 10¹⁰ molecules cm⁻² s⁻¹; see Table 4). The choice of the SED has no impact on the CH₄ abundances in the lower atmosphere. For pressures below 0.1 hPa, where destruction of CH₄ is dominated by photolysis, the choice of the SED has only a weak impact on the CH₄ concentrations. As found in previous works, the CH₄ abundances are increased for a planet orbiting an M dwarf compared to a few ppm on Earth (e.g., Segura et al. 2005; Grenfell et al. 2013, 2014; Rugheimer et al. 2015; Wunderlich et al. 2019). This is mainly due to reduced sources of OH via, e.g., H₂O + O¹(D) → 2 OH, where O¹(D) comes mainly from O₃ photolysis in the UV. Cool stars, such as TRAPPIST-1, are weak UV emitters, favoring a slowing in the OH source reaction and less destruction of CH₄ by OH (see, e.g., Grenfell et al. 2013).

In Wunderlich et al. (2019) we modeled an Earth-like planet with Earth’s biofluxes around TRAPPIST-1 and found that the atmosphere would accumulate about 3000 ppm of CH₄. The much lower value of around 15 ppm suggested by this study is due to two main reasons. First, for this study we only consider the natural sources of CH₄, whereas in Wunderlich et al. (2019) we also included anthropogenic sources. CH₄ emissions similar to those of modern Earth would correspond to a very short period of Earth’s history, whereas preindustrial emissions of CH₄ persisted for a much longer time. Second, we consider a nonzero CH₄ deposition velocity of 1.55 × 10⁻⁴ cm s⁻¹, reducing the amount of CH₄ accumulated in the atmosphere. We use this measured deposition velocity of CH₄ to validate our model against Earth (see Section 2.4.1). With a zero deposition we would overestimate modern Earth amounts of CH₄, and hence we also consider a deposition of CH₄ for the TRAPPIST-1 planets.
Table 10
Mean Surface Temperature Predicted with Our 1D Climate Model (See Scheucher et al. 2020b) for Different Main Atmospheric Compositions and Stellar Irradiations of TRAPPIST-1 e and TRAPPIST-1 f (Tff)

| Planet | CO₂ (bar) | N₂ (bar) | CH₄ (bar) | Tₐ (S₁₁₈) | Tₐ (S₁₇) | Tₐ (S₁₁₇) | References |
|--------|-----------|----------|-----------|------------|----------|------------|------------|
| e      | 0.01      | 1        | 0         | 253        | 262      | 254        | (1)        |
| e      | 0.1       | 1        | 0         | 269        | 279      | 273        | (1)        |
| e      | 1         | 1        | 0         | 328        | 337      | 331        | (1)        |
| e      | 0         | 1        | 0.01      | 223        | 231      | 211        | (2)        |
| e      | 1         | 0        | 0         | 303        | 312      | 303        | (3)        |
| e      | 10        | 0        | 0         | 392        | 401      | 392        | (3)        |
| f      | 1         | 0        | 0         | 222        | 229      | 230        | (3)        |
| f      | 10        | 0        | 0         | 321        | 334      | 350        | (3)        |

Note. S₁₁₈ corresponds to the irradiation values shown in Delrez et al. (2018b), and S₁₁₇ corresponds to the values taken from Gillon et al. (2017). The surface temperatures predicted with various 3D models are shown for comparison (Tff). The last column shows the reference of the corresponding 3D model study: (1) Wolf (2017), (2) Turbet et al. (2018), (3) Fauchez et al. (2019).

4.1.5. O₂

The alive scenario assumes a constant Earth-like O₂ flux from photosynthesis rather than a constant mixing ratio at the surface. The resulting mixing ratio for TRAPPIST-1 e with 0.1 bar CO₂ is around 35%. The increase of O₂ compared to Earth is consistent with results of Gebauer et al. (2018a), who found that the required flux to reach a certain O₂ concentration is reduced on an Earth-like planet around AD Leo compared to Earth around the Sun. This is due to the lower UV flux of M dwarfs, compared to solar-like stars, resulting in weaker destruction of O₂ in an Earth-like planetary atmosphere. However, for an atmosphere with about 0.35 bar O₂ forest ecosystems would be unlikely because the frequency of wildfires is expected to be increased, preventing the buildup of larger concentrations of O₂ (see, e.g., IPCC 1992; Kump 2008). This effect is not considered in the model.

For the dry and dead runs there is a large spread of O₂ abundances ranging from surface concentrations below 1 ppm using the P19 SED to almost 1% using the L18 SED. This spectrum has the largest stellar FUV/NUV ratio, which was shown to favor the abiotic buildup of O₂ in CO₂-rich atmospheres as follows (see, e.g., Selsis et al. 2002; Segura et al. 2007; Tian et al. 2014; France et al. 2016): CO₂ photolysis below 200 nm leads to CO and atomic oxygen. Then, atomic oxygen either produces O₂ (by, e.g., O + O + M → O₂ + M or O + OH + M → O₂ + H + M) or is recombined with CO via the HOₜ catalyzed reaction sequence, which results overall in CO₂ forming: CO + O → CO₂ (see, e.g., Selsis et al. 2002; Domagal-Goldman et al. 2014; Gao et al. 2015; Meadows 2017). The reduced production of HO₂ by H₂O destruction in the lower atmosphere for the dry and dead cases, compared to the wet and dead runs, leads to more favorable conditions for abiotic O₂ buildup. Additionally, the deposition of O₂ into an unsaturated ocean, as assumed for the wet and dead cases, is stronger than the deposition onto desiccated surfaces for the dry cases (see Kharecha et al. 2005; Domagal-Goldman et al. 2014).

4.1.6. O₃

The production of O₃ in the middle atmosphere depends on the O₂ concentration and the UV radiation in the Schumann–Runge bands and Herzberg continuum (from about 170 to 240 nm). The destruction of O₃ is mainly driven by absorption in the Hartley (200–310 nm), Huggins (310–400 nm), and Chappuis (400–850 nm) bands. HO₂ and NO₂ destroy O₃ via catalytic loss cycles in the middle atmosphere (see, e.g., Brasseur & Solomon 2006; Grenfell et al. 2013). For the scenario with constant O₂ flux of 1.21 × 10⁻¹⁵ molecules cm⁻² s⁻¹, more O₃ is produced than for the dead runs, where O₂ is only produced abiotically. For the L18 SED with lower UV flux between 170 and 240 nm, the O₃ layer is weaker than for the runs using the other stellar spectra. Due to enhanced abundances of O₂ compared to Earth, we find that more O₃ is produced. O’Malley-James & Kaltenegger (2017) suggested a weaker O₃ layer as on Earth, assuming an O₂ surface partial pressure of 0.21 bar.

4.1.7. CO

Photolysis of CO₂ in the UV produces CO and O. The dry scenario builds up more CO than the wet cases. For the alive runs with additional O₂ surface sources, the CO recombines more efficiently to CO₂ (via CO + O → CO₂), resulting in lower CO amounts compared to the dead runs. Additionally, we assume a net deposition of CO from the atmosphere to the soil-vegetation system, reducing the amount of CO accumulated in the atmosphere (e.g., Prather et al. 1995; Sanhueza et al. 1998). As for O₂, the abundances of CO are larger for the dry and dead runs than for the wet and dead runs mainly as a result of the assumed strong uptake of CO by the ocean for the wet scenario.

The CO mixing ratios are comparable to the results of Hu et al. (2020). For an atmosphere consisting of 1 bar N₂ and 0.1 bar CO₂ they suggest a partial pressure of CO of about 0.05 bar using a weak νdep of 1 × 10⁻⁸ cm s⁻¹ and a CO partial pressure of ~1 × 10⁻⁴ bar assuming a direct recombination reaction of O₂ and CO in the ocean. The less effective buildup of CO and abiotic O₂ due to a strong surface sink gives indirect evidence on the presence of a liquid ocean. Hence, under the simulated conditions with strong CO₂ photolysis, CO not only could serve as an "antibiosignature" gas, as discussed in, e.g., Zahle et al. (2008), Wang et al. (2016), Nava-Sedeño et al. (2016), Meadows (2017), Catling et al. (2018), and Schwietzerman et al. (2019), but would also indirectly suggest the absence of a liquid ocean at the surface.

The largest abundances of CO for the dry scenarios are found using the L18 SED. This is due to the lower abundances of HO₂ in particular OH, which reduce the recombination of CO + O into CO₂. In turn, large amounts of HO₂, like for the dry scenario using the P19 SED, lead to low buildup of CO.
The main source of SO2 is volcanic outgassing, which is assumed to be equally distributed over the first 10 km of the atmosphere. For a 1 bar N2 atmosphere with 0.1 bar CO2, this corresponds to pressure levels below ~250 hPa. The large $\nu_{dep}$ of 1 cm s$^{-1}$ (Sehmel 1980) leads to a strong decrease of SO2 toward the surface for all three scenarios. Due to its large solubility in water, SO2 is deposited easily over wet surfaces, such as oceans. However, Nowlan et al. (2014) showed that over desert areas the $\nu_{dep}$ of SO2 is approximately 0.5 cm s$^{-1}$; hence, our value of 1 cm s$^{-1}$, which is applied for dry cases as well, may overestimate the deposition.

For the wet scenarios we assume Earth-like wet deposition following Giorgi & Chameides (1985). Most SO2 dissolves into condensed water and is rained out of the atmosphere as sulfate. This process greatly decreases the mixing ratio of SO2 for the wet cases but not for the dry scenarios.

The remaining SO2 is transported upward and is partly destroyed by photolysis. SO2 photodissociates below 400 nm and is strongest below 250 nm (e.g., Manatt & Lane 1993). Hence, for the scenarios using the P19 SED we find the strongest destruction of SO2 above 100 hPa.

4.1.9. N2O

The main N2O source on Earth are surface biomass emissions. For the alive scenario we find concentrations of N2O comparable to previous studies such as Rugheimer et al. (2015) and Wunderlich et al. (2019). The photodissociation of N2O is closely related to the SED around 180 nm (e.g., Selwyn et al. 1977), leading to lower abundances of N2O using the P19 SED.

4.2. Transmission Spectra of TRAPPIST-1 e with 0.1 bar CO2

Figure 8 shows the simulated transmission spectra of the TRAPPIST-1 e atmosphere scenarios with surface partial pressures of 0.1 bar CO2, binned to a constant resolving power of R = 300. The spectra are simulated by the GARLIC model taking as input the chemical and temperature profiles discussed in Section 4.1. We do not take into account the effect of clouds, but we include weak extinction from aerosols (see Figure 9).

The CO2 absorption features are similarly strong for all runs. The wet and alive runs show strong absorption of O3 in the VIS at around 600 nm and in the IR at 9.6 $\mu$m. The alive run with the P19 SED shows the largest O3 features, due to the more closely related to the SED around 180 nm (closely related to the SED around 180 nm). The CH4 feature at 2.3 $\mu$m could lead to a false-positive detection of O3.

The CH4 feature at 2.3 $\mu$m, which is visible for the alive runs, overlaps in low resolution with the CO feature, which occurs for the dead and dry runs. The dead runs using the W20 and L18 SEDs show much larger absorption of CO at 2.3 $\mu$m than the wet and dry runs. For the dead runs with the P19 SED...

### Table 11

| Scenario          | Planet | CO2 (bar) | $p_\text{O}_2$ (bar) | RH (%) | Surface Flux | $O_2 \nu_{\text{dep}}$ (cm s$^{-1}$) | CO $\nu_{\text{dep}}$ (cm s$^{-1}$) |
|-------------------|--------|-----------|----------------------|--------|--------------|------------------------------------|-------------------------------|
| Wet and alive     | TRAPPIST-1 e | $10^{-3}$ | 1.001                | 80%    | Biogenic and volcanic (see Table 4) | $1 \times 10^{-8}$          | $3 \times 10^{-7}$ (1 $\times 10^{-8}$) |
|                   | TRAPPIST-1 e | 0.01      | 1.01                 |        |              |                                    |                               |
|                   | TRAPPIST-1 e | 0.1       | 1.1                  |        |              |                                    |                               |
|                   | TRAPPIST-1 e | 1.0       | 2.0                  |        |              |                                    |                               |
|                   | TRAPPIST-1 f | 3.6       | 4.0                  |        |              |                                    |                               |
|                   | TRAPPIST-1 f | 10.8      | 12.0                 |        |              |                                    |                               |
| Wet and dead      | TRAPPIST-1 e | $10^{-3}$ | 1.001                | 80%    | Volcanic (see Table 4) | $1.5 \times 10^{-4}$ (1 $\times 10^{-8}$) | $1.2 \times 10^{-4}$ (1 $\times 10^{-8}$) |
|                   | TRAPPIST-1 e | 0.01      | 1.01                 |        |              |                                    |                               |
|                   | TRAPPIST-1 e | 0.1       | 1.1                  |        |              |                                    |                               |
|                   | TRAPPIST-1 e | 1.0       | 2.0                  |        |              |                                    |                               |
|                   | TRAPPIST-1 f | 3.6       | 4.0                  |        |              |                                    |                               |
|                   | TRAPPIST-1 f | 10.8      | 12.0                 |        |              |                                    |                               |
| Dry and dead      | TRAPPIST-1 e | $10^{-3}$ | 1.001                | 1%     | Volcanic (see Table 4) | $1 \times 10^{-8}$          | $1 \times 10^{-8}$          |
|                   | TRAPPIST-1 e | 0.01      | 1.01                 |        |              |                                    |                               |
|                   | TRAPPIST-1 e | 0.1       | 1.1                  |        |              |                                    |                               |
|                   | TRAPPIST-1 e | 1.0       | 2.0                  |        |              |                                    |                               |
|                   | TRAPPIST-1 f | 3.6       | 4.0                  |        |              |                                    |                               |
|                   | TRAPPIST-1 f | 10.8      | 12.0                 |        |              |                                    |                               |

**Note.** The relative humidity (RH) is assumed to be constant up to the cold trap. The surface fluxes are the same as for preindustrial Earth (see Table 4). For wet and alive and wet and dead we assume $\nu_{\text{O}_2}$ for $O_2$ and CO according to the underlying scenario. For all other species the $\nu_{\text{dep}}$ shown in Table 5 are used. For each scenario we assume a range of CO2 surface partial pressures. N2 serves as a solubility in water, SO2 is deposited easily over wet surfaces, and is destroyed by photolysis. SO2 photodissociates below 400 nm into condensed water and is rained out of the atmosphere as sulfate. This process greatly decreases the mixing ratio of SO2 for the wet cases but not for the dry scenarios.

The remaining SO2 is transported upward and is partly destroyed by photolysis. SO2 photodissociates below 400 nm and is strongest below 250 nm (e.g., Manatt & Lane 1993). Hence, for the scenarios using the P19 SED we find the strongest destruction of SO2 above 100 hPa.

wet and dry conditions are not clearly distinguishable owing to the weak buildup of CO in the dry run (see Section 4.1.7). Weak H$_2$O absorption in the lower atmosphere of the dry runs results in more pronounced spectral windows between, e.g., 1.7 and 1.8 $\mu$m. The H$_2$O features between 5.5 and 7 $\mu$m do not show a large difference for the various scenarios since these are dominated by absorption higher up in the atmosphere, where the H$_2$O concentration is predominantly determined by photochemical processes and similar for all cases.

4.3. Atmospheres with Increasing CO$_2$

Figure 10 shows the column amount of H$_2$O, CO, O$_2$, O$_3$, NO$_x$, and HO$_x$ for all three scenarios and with increasing partial pressures of CO$_2$ for TRAPPIST-1 e (left) and TRAPPIST-1 f (right). Semitransparent bars represent column amounts integrated over the entire atmosphere, whereas solid filled bars show upper column amounts integrated at pressures below 10 hPa, dominated by photochemical processes. For simulations shown in Figure 10 we use the W20 SED as input for the climate–chemistry model.

4.3.1. H$_2$O

The H$_2$O amount near the surface mainly depends on the relative humidity and the near surface temperature, leading to an increase of the H$_2$O amount toward larger CO$_2$ partial pressures. Whereas the dry runs show a lower H$_2$O content integrated over the entire atmosphere than the wet runs, at pressures below 10 hPa the three scenarios are comparable (see also Figure 6). The $T_{surf}$ for TRAPPIST-1 e with 1 bar CO$_2$ and TRAPPIST-1 f with 10.8 bar CO$_2$ is $\sim$340 K for the wet runs. While the total H$_2$O amount increases for an increasing $T_{surf}$, the increase in the upper atmospheric column is much less, which suggests that tropospheric climate is difficult to elucidate from observing middle atmosphere H$_2$O. Further, the mixing ratio below $10^{-5}$ (see Figure 7) suggests that H$_2$O loss due to
H$_2$O photolysis and hydrogen escape is expected to be weak for CO$_2$-rich atmospheres according to Wordsworth & Pierrehumbert (2013).

4.3.2. CO

As discussed in Section 4.1, dry and dead conditions favor an increase in atmospheric CO compared to the wet runs. With increasing CO$_2$ this effect is strengthened owing to the enhanced CO$_2$ photolysis for intermediate CO$_2$ amounts. For CO$_2$ partial pressures of 1 bar there is only a weak increase of CO column amounts compared to the atmosphere with 0.1 bar CO$_2$, if the $v_{dep}$ of CO is $1 \times 10^{-8}$ cm s$^{-1}$. For TRAPPIST-1 f runs with 90% CO$_2$ there is only a weak increase of CO compared to the TRAPPIST-1 e run with 50% CO$_2$ (1 bar partial pressure of CO$_2$). This is consistent with the results of Hu et al. (2020). They suggest that in CO$_2$-rich atmospheres of TRAPPIST-1 e a nonzero deposition velocity of $1 \times 10^{-8}$ cm s$^{-1}$ leads to a maximum buildup of CO of around 0.05 bar.

For the wet scenarios we assume a much faster deposition of CO owing to uptake of the ocean and/or vegetation. The fact that the amount of HO$_x$ is approximately the same for dry and wet surface conditions (see Figure 10) suggests that for wet atmospheres with low CO$_2$ the fast deposition of CO accounts for the weak accumulation of CO.

We also simulated the abundances of CO and O$_2$ for the wet scenarios assuming that the deposition of CO and O$_2$ into an ocean is weak (see Figure 11). We find that the concentrations of CO would be equally high for wet & dry conditions. Only for the CO$_2$-dominated atmosphere of TRAPPIST-1 f would more CO be present in the dry run compared to the wet runs.

4.3.3. O$_2$

For the alive scenario the abundance of O$_2$ is mainly driven by the biogenic surface flux, which is equally strong in all alive runs. Due to the high FUV/NUV ratio for TRAPPIST-1, we expect that significant amounts of O$_2$ are produced abiotically from CO$_2$ photolysis. The potentially false-positive detection of O$_2$ in CO$_2$ atmospheres was already discussed by several studies (e.g., Selsis et al. 2002; Segura et al. 2007; Harman...
et al. 2015; Meadows 2017). Figure 7 shows that the abundances of abiotic O₂ increase for dry CO₂-dominated atmospheres but are always lower than expected from a biosphere similar to Earth. On the other hand, for wet conditions without a biosphere much less abiotic O₂ is accumulated in a CO₂-dominated atmosphere. This means that weak biogenic O₂ flux would not be distinguishable from a dry N₂ atmosphere with at least 0.1 bar CO₂.

4.3.4. O₃, NOₓ, and HOₓ

The three scenarios show a different O₃ behavior with increasing CO₂ (see Figure 10). The alive run with the lowest amount of CO₂ accumulates large amounts of NOₓ, destroying most of the O₃. With increasing abundances of CO₂, the temperature increases (see Table 13) and more H₂O evaporates. This leads to more HOₓ near the surface, more removal of NOₓ into reservoirs such as HO₂NO₂, and less catalytic destruction of O₃ by NOₓ (see Figure 12).

For the dead runs the O₃ is produced abiotically and increases for atmospheres with more CO₂. The dry and dead runs have rather low concentrations of NOₓ and HOₓ for CO₂-dominated atmospheres, which suggests a weak gas-phase effect on O₃ for these species. In contrast, the wet and dead conditions lead to a buildup of NOₓ for TRAPPIST-1 f with 90% CO₂ near the surface, resulting in very low O₃ abundances in the lower atmosphere.

Figure 10. Column amounts (molecules cm⁻²) of H₂O, CO, O₂, O₃, HOₓ, and NOₓ for all atmospheric scenarios of TRAPPIST-1 e (left) and TRAPPIST-1 f (right) with increasing partial pressures of CO₂ (see also Table 11). Semitransparent bars show column amounts integrated from BoA to ToA, and solid filled bars show column amounts integrated from 10 hPa to ToA.

Figure 11. Same as Figure 10, but with a νdep = 1 × 10⁻⁸ cm s⁻¹ for O₂ and CO, assuming that the wet runs have an ocean saturated with these gases and the biosphere is not an effective sink for CO. Only O₂ and CO are shown because the other species show similar abundances to Figure 10.

Table 13

| Planet | CO₂ (bar) | Wet and Alive | Wet and Dead | Dry and Dead |
|--------|-----------|---------------|--------------|--------------|
| e      | 10⁻³      | 245.6         | 245.9        | 238.3        |
| e      | 0.01      | 256.7         | 253.3        | 242.7        |
| e      | 0.1       | 273.1         | 269.6        | 251.5        |
| e      | 1         | 335.7         | 331.6        | 281.1        |
| f      | 3.6       | 279.6         | 272.7        | 233.5        |
| f      | 10.8      | 302.2         | 327.0        | 258.9        |

Note. The W20 SED is used as input for the atmospheric model.
4.4. Transmission Spectra for Increasing CO₂

Figure 13 shows the simulated atmospheric appearance of TRAPPIST-1 e during primary transit for the three scenarios and for increasing amounts of CO₂. Several molecular features distinguish the alive run with 10⁻³ bar CO₂ from the dead runs. Features from CH₄, O₂, and N₂O are present owing to the assumed biogenic flux. Strong CH₄ features are especially prevalent in Earth-like atmospheres with low UV environments in the HZ around M dwarfs (e.g., Segura et al. 2005; Rauer et al. 2011; Wunderlich et al. 2019). Additionally, we find a strong NO₂ feature in the VIS, as well as NO₂, NO, and HNO₃ features between 5 and 7 μm, due to the large amounts of these species in cold, CO₂-poor alive runs (see Figure 12). These features are found to be present also for strong flaring conditions with cosmic-ray-induced amounts of NO₂ (see, e.g., Tabataba-Vakili et al. 2016; Scheucher et al. 2018, 2020a). The typical O₃ band around 9.6 μm is absent owing to the large abundances of NO₃ species, which can destroy O₃ catalytically.

The dead runs with low CO₂ abundances show little spectral differences between wet and dry scenarios. Only SO₂ features around 7.5 and 8.5 μm and weak CO bands around 2.3 and 4.7 μm distinguish the dry and dead run from the wet and dead run. With increasing CO₂ the larger abundances of CO for dry and dead conditions lead to stronger CO absorption bands and clearly separate dry from wet runs. The presence of the CO bands for CO₂-rich atmospheres was also shown by, e.g., Meadows (2017) and Schwieterman et al. (2019).

For CO₂ partial pressures of 0.1 bar and above, NO₃ is reduced and its spectral features do not appear in the transmission spectrum. O₃ abundances are increased and molecular bands show up in the VIS and at 9.6 μm. The CH₄ abundances are very similar for all runs, and hence the CH₄ absorption at 2.3 and 3.3 μm for a 1 bar CO₂ should be as strong as for a CO₂-poor atmosphere. However, the increase in CO₂ abundances leads to larger lower atmosphere temperatures and hence more H₂O in this region. Since H₂O absorbs over a wide wavelength range, this results in an increase in the offset of the entire spectrum (see, e.g., Turbet et al. 2019), reducing the CH₄ features relative to the overall absorption. This is also suggested by Table 14, showing the baseline of TRAPPIST-1 e transmission spectra from Figure 13.

The most promising candidates for distinguishing the three scenarios from each other are the CH₄ features, which are just evident in the alive runs and the strong CO bands for the dry runs. Absorption of CH₄ and CO features overlaps at 2.3–2.5 μm, which could inhibit their separation. A simultaneous observation of CH₄ at 3.3 μm is therefore required, as well as measurements of CO at 4.6 μm. Using JWST NIRSpec PRISM covers 0.60–5.30 μm; however, TRAPPIST-1 is close to the saturation limit of NIRSpec PRISM (f < 10.5), resulting in a low duty cycle (see, e.g., Batalha & Line 2017). We do not consider a partial saturation strategy to improve the duty cycle as suggested by Batalha et al. (2018). NIRSpec G235M only covers 1.66–3.12 μm and hence would not be suitable for separating CH₄ and CO. Another possibility to disentangle both features is by observing individual lines with HRS. Figure 14 shows the simulated transmission spectra of the TRAPPIST-1 e runs with 0.1 bar CO₂, binned to the resolution of ELT HIRES (R = 100,000). Since the positions of the lines relative to each other differ between CO and CH₄, one could use the cross-correlation technique to determine which absorber causes the spectral lines or even if both species are present.

The transmission spectra of the TRAPPIST-1 f atmospheres show similar spectral features to those of TRAPPIST-1 e with 1 bar CO₂ (see Figure 15).

4.5. Detectability of Spectral Features

We determine the required number of transits necessary to detect a spectral feature (S/N = 5) with JWST NIRSpec or JWST MIRI. We bin the spectral data until the optimal value is found, leading to the lowest required number of transits. Binning the data decreases the noise contamination, but if the binned wavelength range is too large, molecular absorption bands and atmospheric windows overlap, leading to a cancellation of the spectral feature. Due to the unknown systematic error when binning the synthetic spectral data, we assume only white noise. This gives an optimistic estimation on the detection feasibility of the JWST. Additionally, we estimate the number of transits required to detect spectral absorption lines with ELT HIRES using the cross-correlation technique without binning the spectral data (see Section 2.6).

4.5.1. CO₂

Table 15 shows the number of transits needed to detect selected spectral features for all three atmospheric scenarios of TRAPPIST-1 e with 0.1 bar CO₂. For all the calculations we
Figure 13. Simulated atmospheric features of TRAPPIST-1 e runs, represented by cloud-free transit transmission spectra and binned to a constant resolving power of $R = 300$ (maximum resolving power of NIRSpec PRISM at 5 μm). Individual plots from top to bottom show atmospheres with increasing partial pressures of CO$_2$. Shaded regions represent the 1σ error of 30 co-added transit observations with JWST NIRSpec PRISM and MIRI LRS, binned to $R = 30$ (minimum resolving power of NIRSpec PRISM at 1 μm). Important atmospheric molecular absorption bands are highlighted with horizontal lines in the color of the scenario with the strongest feature or in gray when all scenarios show significant features. Colored triangles indicate minimum atmospheric transit depth of each scenario.
assume cloud-free atmospheric conditions with weak extinction from aerosols (see Equation (3)).

With JWST NIRSpec G395M/F290LP only about five transits are needed to detect the 4.3 μm CO2 feature in a cloud-free atmosphere. About twice as many transits are required to detect CO2 with NIRSpec PRISM. This result is in agreement with other studies, such as Fauchez et al. (2019), who showed that the CO2 at 4.3 μm of a 1 bar CO2 atmosphere of TRAPPIST-1 e would be detectable with JWST NIRSpec PRISM by co-adding nine transits without the existence of clouds. When taking clouds into account, they suggested that 19 transits are required to detect CO2. For a ground-based telescope such as ELT at wavelengths longer than 4 μm, the noise contribution from Earth’s atmosphere leads to very low S/N. The 2.7 μm feature of CO2 is not observable with ELT. Hence, only the CO2 feature around 2.0 μm might be detectable with ELT HIRES in ~30 transits.

The molecular bands for CO2 do not greatly increase when increasing the abundances of CO2 from 10^{-3} bar to 1 bar; hence, the numbers of transits needed to reach the same S/N of 5 are also similar for all runs (see Figure 16). It was shown by Barstow et al. (2016) that even Earth and a 1 bar Venus-like atmosphere would show similar CO2 features, which complicates the determination of the underlying atmospheric main composition by retrieval methods.

4.5.2. H2O

A larger CO2 partial pressure warms the lower atmosphere, leading to more H2O evaporation in the case of a liquid reservoir. This leads to a more opaque lower atmosphere and an increase in the measured planetary radius (see, e.g., von Paris et al. 2011; Madhusudhan & Redfield 2015). In contrast, in the photochemical regime, H2O is not greatly increased for warmer surface conditions (see Figure 10). The effect of the radius increase is much weaker for dry atmospheres, leading to a better detectability of H2O for dry surface conditions. However, the H2O spectral features are too weak in all simulated atmospheres of TRAPPIST-1 e and TRAPPIST-1 f to allow for a detection with JWST NIRSpec. This was also concluded by Fauchez et al. (2019), who found that about 150 transits are required to detect H2O in a cloud-free 1 bar CO2 atmosphere of TRAPPIST-1 e with JWST.

Most H2O bands in the NIR overlap with CH4 absorption features. This could cause a false-positive detection of H2O for large abundances of CH4 (see, e.g., Wunderlich et al. 2019). The cross-correlation technique could disentangle H2O from CH4, but we find that by using the largest ~500 H2O lines, ~1000 transits would be needed to detect H2O with ELT HIRES.

4.5.3. CH4

In low CO2 atmospheres with biogenic surface fluxes the number of CH4 lines that we identify is much larger than the H2O lines, enabling a detection of CH4 with less than 30 transits using ELT HIRES. The detection of the simulated levels of CH4 would be challenging with JWST NIRSpec. In contrast to the alive runs, no CH4 feature is detectable for the dead runs with only geological sources of CH4. However, since the ability to detect CH4 mainly depends on the assumed surface flux, which could be weaker for a potential biosphere on an M-dwarf planet (e.g., Cui et al. 2017) or stronger for enhanced volcanic outgassing of CH4, the detection or nondetection of CH4 alone would not confirm or rule out the existence of a biosphere (see also Krissansen-Totton et al. 2018b).

4.5.4. CO

About 10% of CO2 is needed to produce enough CO photochemically to enable a detection of its molecular absorption feature at 2.35 μm in a cloud-free atmosphere with JWST NIRSpec G235M if surface sinks of CO are inefficient. For the wet scenarios, with significant CO uptake by an ocean or a biosphere, results suggest that CO would not be detectable, even for a CO2-dominated atmosphere (see Figure 17). The CO feature at 4.6 μm overlaps with the CO2 absorption, requiring a retrieval analysis to disentangle both signals. Only about 10 transits are needed to detect the 4.6 μm band with JWST. The G395M filter of JWST would be favorable because the CO2 band at 4.3 μm and the CO feature at 4.6 μm could be observed simultaneously.

The CO feature at 2.3 μm does not overlap with other strong absorption features in the transmission spectrum of the dry scenarios. However, 19 transits are required to detect the CO
feature at 2.3 μm (see Table 15), twice as many as for the detection of the 4.6 μm CO feature.

The detection of CO with the cross-correlation technique has been shown to be feasible for gas giants exoplanets (see, e.g., de Kok et al. 2013; Brogi et al. 2014). We find that the detection of CO would require about 40 transits with ELT HIRES in a dry, CO2-rich, cloud-free atmosphere of TRAPPIST-1 e and f.

4.5.5. Other Molecules

Results suggest that no other molecular absorption features would be observable with JWST or ELT for the atmospheres considered here. Even a detection of the strong NO2 feature around 6.2 μm in an alive CO2-poor atmosphere (see green line in top panel of Figure 13) would require around 50 transits with JWST MIRI (not shown). The O3, SO2, and N2O features lie in a spectral region where the stellar flux is too low to allow high S/N. The O2 feature is not strong enough for a detection with JWST NIRSpec. As also suggested by Rodler & López-Morales (2014), we find that the 1.27 μm band is more favorable than the 0.76 μm band for detecting O2 in a planetary atmosphere around a very late M dwarf. We find that with ELT over 900 transits are required to detect O2 by cross-correlating the lines between 1.24 and 1.3 μm, assuming an average throughput of 10% for ELT HIRES. This is consistent with the results of Rodler & López-Morales (2014), who suggested that hundreds of transits are needed to detect O2 in the atmosphere of Earth around an M7 star at a distance similar to TRAPPIST-1 with ELT using a high-resolution spectrograph with a throughput of ~20% (see Origlia et al. 2010).

4.5.6. SPECULOOS Targets

With a distance of only 12.4 pc from the Sun, TRAPPIST-1 is one of the closest late-type M dwarfs. However, we show that for the simulated atmospheres only CO2 would be potentially detectable within ~10 transits. To further characterize the atmosphere of the planets, observing the K band with HRS might allow us to determine whether a spectral feature around 2.3 μm can be attributed to absorption from CH4 or CO. Our results suggest that for a dry and dead atmosphere of TRAPPIST-1 e about 40 transits are required to detect CO with ELT HIRES. To detect an Earth-like O2 feature with the same number of transits, a host star similar to TRAPPIST-1 is required at ~7 pc or less (see Rodler & López-Morales 2014; Serindag & Snellen 2019).

The Search for habitable Planets EClipsing ULtracOOl Stars (SPECULOOS; Delrez et al. 2018a) is a ground-based transit survey that is looking for Earth-sized exoplanets around the nearest late M dwarfs to brown dwarfs. Figure 18 shows the number of transits required to detect CO with the cross-correlation technique using TMT (Northern Sky) or ELT (Southern sky), assuming a hypothetical planet with the same properties as TRAPPIST-1 e around each member of the target list of SPECULOOS with a Teff of at least 2000 K (see Gillon et al. 2020). The assumed atmospheric spectral feature is the same as in the dry scenario with 0.1 bar CO2.

There are only 13 stars within a distance of 7 pc (Teff > 2000 K), where the atmospheric O2 feature of a hypothetical terrestrial planet would be detectable within 40 transits according to Rodler & López-Morales (2014). However, non-LTE effects in the O2 1.27 μm band may prevent a detection (López-Puertas et al. 2018). Figure 18 suggests that more targets exist for which the CO feature could be detected. For
late M dwarfs (2400 K < \text{\textit{T}}_{\text{eff}} < 2800 K) CO could be detected up to \sim12 \text{pc} using ELT or TMT by co-adding 30 transits. Early L dwarfs (\text{\textit{T}}_{\text{eff}} < 2400 K) only have slightly smaller stellar radius than late M dwarfs but are much fainter, resulting in a low S/N, and more transits are required to detect atmospheric molecular features with transmission spectroscopy.

### 5. Discussion

With our climate–photochemistry model, 1D-TERRA, we simulated potential atmospheres of TRAPPIST-1 e and TRAPPIST-1 f. We determined the composition of the planetary atmospheres, assuming N2- and CO2-dominated atmospheres with wet and dry surface conditions. We did not consider O2-rich atmospheres, accumulated from H2O photolysis during the pre–main-sequence phase of TRAPPIST-1 (see, e.g., Wordsworth & Pierrehumbert 2014; Luger & Barnes 2015; Bolmont et al. 2016). However, an Earth-like biogenic flux of O2 is considered, and O3 can also build up abiotically via CO2 photolysis. For detailed discussion of the potential composition and transmission spectra of O2-dominated atmospheres from H2O photolysis we refer to Lincowski et al. (2018).

The main goal of our study was to investigate which spectral features of wet or dry planets in the HZ could be detectable

---

**Table 15**

| Telescope | Species (\textit{\lambda}) | Wet and Alive | Wet and Dead | Dry and Dead |
|-----------|-----------------------------|---------------|--------------|--------------|
| JWST      | CO2 (4.3 \text{\mu}m)      | 5 (11)        | 4 (9)        | 4 (8)        |
| ELT       | CO2 (1.8–2.3 \text{\mu}m)  | 33            | 28           | 26           |

**Figure 16.** Number of transits required to reach an S/N of 5 for the corresponding spectral features of CO2 at 4.3 \text{\mu}m, O3 at 9.6 \text{\mu}m, CO at 2.35 \text{\mu}m, and H2O at 1.4 \text{\mu}m with JWST NIRSpec (top and middle panels) and CH4 from 2.1 to 2.5 \text{\mu}m and O2 from 1.24 to 1.3 \text{\mu}m with ELT HIRES (bottom panel) in a cloud-free atmosphere of TRAPPIST-1 e. The x-axes correspond to the increasing partial pressures of CO2. Solid filled bars: required number of transits is below or equal to 30. Semitransparent bars: required number of transits is larger than 30.

**Figure 17.** Number of transits required to reach an S/N of 5 for the corresponding spectral features of CO2 at 4.3 \text{\mu}m and CO at 2.35 \text{\mu}m with JWST NIRSpec (left and middle) and CH4 from 2.1 to 2.5 \text{\mu}m with ELT HIRES (right) in a cloud-free atmosphere of TRAPPIST-1 f. The x-axes correspond to the increasing partial pressures of CO2. Solid filled bars: required number of transits is below or equal to 30. Semitransparent bars: required number of transits is larger than 30.
with the upcoming JWST and ELT. We identify three species that could be detectable in a cloud-free atmosphere of TRAPPIST-1 e or f by co-adding less than 30 transits: CO₂, CH₄, and CO. Under the assumed boundary conditions, CO₂ would be detectable with JWST and ELT with about 10 transits. This is also consistent with several other studies investigating the detectability of the atmospheric features of the TRAPPIST-1 planets (Morley et al. 2017; Batalha et al. 2018; Krissansen-Totton et al. 2018a; Fauchez et al. 2019; Lustig-Yaeger et al. 2019; Wunderlich et al. 2019). However, for N₂-dominated atmospheres the uncertainties of the retrieved CO₂ abundances are up to 2 orders of magnitude when co-adding 10 transits (see Batalha et al. 2018; Krissansen-Totton et al. 2018a).

The effect of clouds and hazes is not considered in the model, and we only consider weak extinction by aerosols for the simulation of the transmission spectra. We do not expect a large impact on the chemical composition when considering thin cloud or haze layers (see Venus validation, Figure 4). However, the presence of clouds can significantly reduce the detectability of molecular spectral features (see, e.g., Kitzmann et al. 2011a, 2011b; Benneke & Seager 2013; Vasquez et al. 2013; Bétrémieux & Kaltenegger 2014; Bétrémieux & Swain 2017; Moran et al. 2018; Fauchez et al. 2019; Lustig-Yaeger et al. 2019; Komacek et al. 2020; Suissa et al. 2020). We use a similar expression to simulate the effect of aerosol absorption to Kaltenegger & Traub (2009). They conclude that the apparent radius of an atmosphere like on Earth is mainly determined by Rayleigh scattering and aerosol, H₂O, and CO₂ absorption. For Earth, the inclusion of realistic cloud coverage has only a small effect on the apparent radius and hence the detectability of spectral features.

For the wet scenarios with low CO₂ abundances and Earth-like biomass surface emissions we find that CH₄ would be detectable on TRAPPIST-1 e using the cross-correlation technique with less than 30 transits. Increasing the amount of CO₂ leads to additional greenhouse warming and more H₂O evaporated into the atmosphere. More H₂O in the lower atmosphere leads to an increase of the minimum transit depth in the transit spectrum, i.e., the observational baseline (see also Turbet et al. 2019). The strongest CH₄ feature at 3.3 μm is about 40 ppm above the baseline, when very little H₂O is present in the atmosphere. For a lower atmosphere with a relative humidity of 80% and a Tsurf of ~335 K the baseline increases by 20 ppm compared to a cold atmosphere with a Tsurf of ~245 K. Due to this effect, for CO₂-dominated atmospheres of TRAPPIST-1 e and TRAPPIST-1 f CH₄ would not be detectable for a preindustrial Earth-like emission flux of CH₄ since this feature would be partially swamped by the baseline. For these cases the spectral appearance would not suggest the existence of a biosphere within the detection limits, i.e., it would be a false negative detection of CH₄.

Enhanced outgassing when assuming, e.g., a more reducing mantle than modern Earth would need to be 2–3 orders of magnitudes larger than for modern Earth to build up as much CH₄ as for the alive scenarios (see also Ryan et al. 2006; Krissansen-Totton et al. 2018b). Since also the outgassing of CO is expected to be large for a highly reduced mantle, simultaneous detection of CO could distinguish an atmosphere with large amounts of outgassed abiogenic CH₄ from an atmosphere with mainly biogenic CH₄ (see also Krissansen-Totton et al. 2018b).

The presence of large amounts of CO has been suggested to indicate the absence of life on an exoplanet (Zahnle et al. 2008; Nava-Sedeño et al. 2016; Wang et al. 2016; Meadows 2017; Catling et al. 2018). We find that the CO feature at 2.3 μm would be detectable with JWST NIRSpec for a dry atmosphere with at least 0.1 bar CO₂ by co-adding ~20 transits (Figure 16). In contrast to CH₄, CO would be detectable also for CO₂-dominated atmospheres owing to the enhanced CO buildup from CO₂ photolysis.

The detection of CO with ELT HIRES requires twice as many transits than with JWST when assuming an average throughput of 10%. Previous studies such as Snellen et al. (2013) or Serindag & Snellen (2019) assume a mean throughput of 20% for ELT. However, to achieve this large efficiency, further development of the instrument design might be necessary (see, e.g., Ben-Ami et al. 2018).

For dry surface conditions, without a liquid ocean, we expect that very little CO would be deposited onto the surface. In contrast, the existence of an ocean may inhibit the buildup of substantial amounts of CO in a CO₂-rich atmosphere through catalytic cycles and an effective CO surface sink. This would lead to a nondetection of CO for wet surface conditions. However, the detection of CO in a CO₂-rich atmosphere of an M-dwarf planet could also be compatible with the presence of an ocean and a biosphere with ineffective surface sinks of CO or increased CO surface flux (Krissansen-Totton et al. 2018b; Schwieterman et al. 2019). Hence, the detection of CO does not ultimately discriminate between wet and dry surface conditions, but a nondetection of CO and a simultaneous detection of CO₂ in the atmosphere of a potential habitable TRAPPIST-1 planet can hint at an effective surface sink for CO, suggesting the existence of an ocean.

As for CO, we find that abundances of SO₂ are much larger for dry surface conditions than for wet conditions. For the wet scenarios, most of the SO₂ is oxidized into highly soluble sulfate and hence efficiently removed from the atmosphere by wet and dry deposition. For the dry scenarios we do not consider any wet deposition. Loftus et al. (2019) suggest that...
the detection of an H$_2$SO$_4$–H$_2$O haze layer together with SO$_2$ indicates that the planet does not host significant surface liquid water. The large amounts of SO$_2$ we find for the dry surface conditions are consistent with their study. However, the detection of SO$_2$ would not be feasible for any of the dry runs of TRAPPIST-1 e and TRAPPIST-1f with JWST or ELT. Furthermore, the SO$_2$ may form a haze layer.

For the simulated N$_2$- and CO$_2$-dominated atmospheres, one would require large observational times to detect spectral features in the atmospheres of the TRAPPIST-1 planets with JWST or ELT (see also Morley et al. 2017; Batalha et al. 2018; Krissansen-Totton et al. 2018a; Lustig-Yaeger et al. 2019; Wunderlich et al. 2019; Gillon et al. 2020).

In this study we assume white noise only when co-adding multiple transits or binning spectral data to a lower resolution than observed. This assumption may underestimate the required number of transits significantly, especially for weak spectral features (see, e.g., Fauchez et al. 2019). Imaging spectroscopy concepts such as the Large UV/Optical/Infrared Surveyor (LUVOIR; The LUVOIR Team 2019) and the Habitable Exoplanet Observatory (HabEx; Mennesson et al. 2016) may provide new opportunities to observe the atmosphere of terrestrial planets (see, e.g., Pidhorodetska et al. 2020). The angular separation between TRAPPIST-1 and TRAPPIST-1 e is only 2.4 mas, much smaller than for Proxima Centauri b (37 mas; O’Malley-James & Kaltenegger 2019). This might be too small to separate the star and the planets with LUVOIR or HabEx (see also Stark et al. 2015). Hence, transmission spectroscopy is the most promising way to constrain the atmospheric characteristics of the habitable TRAPPIST-1 planets in the next few decades.

The recent detection of H$_2$O absorption in the atmosphere of the HZ planet K2-18b is one example of how the existence of an H$_2$ envelope could enable the characterization of the atmosphere of potentially rocky planets (Benneke et al. 2019; Tsiaras et al. 2019). Initial observations of the TRAPPIST-1 planets showed no hint of cloud-free H$_2$- or helium-dominated atmospheres, suggesting that atmospheres are dominated by heavier elements (de Wit et al. 2016, 2018; Wakeford et al. 2018; Burdanov et al. 2019). However, hydrogen-rich atmospheres with high-altitude clouds or hazes are also consistent with the observations of the TRAPPIST-1 planets (Moran et al. 2018). Such hydrogen-rich atmospheres of the planets would increase the scale height, leading to improved detectability of spectral features.

6. Summary and Conclusion

We introduced and validated our new chemical network, part of our updated 1D coupled climate–photochemistry model (1D-TERRA). The model is capable of simulating the atmosphere of terrestrial planets over a wide range of temperatures and pressures. Our chemical network is based on those presented by Hu et al. (2012) and Arney et al. (2016). Additionally, we added chlorine chemistry and extended the sulfur chemistry with chemical reactions listed in Zhang et al. (2012), in order to simulate Venus-like atmospheres. We showed that the model is able to reproduce modern Earth, as well as CO$_2$-dominated atmospheres such as present on modern Mars and Venus. The resulting composition profiles are consistent with observations and other photochemical models, dedicated to modeling the atmospheres of Mars (Nair et al. 1994; Krasnopolsky 2010a) and Venus (Krasnopolsky 2012; Zhang et al. 2012).

In this paper we simulated the potential atmospheres of the TRAPPIST-1 e and TRAPPIST-1 f planets assuming N$_2$- and CO$_2$-dominated atmospheres for three main scenarios regarding the lower boundary condition: (1) a wet and alive atmosphere with an ocean and biogenic and volcanic fluxes as on Earth, (2) a wet and dead atmosphere with an ocean and only volcanic outgassing, and (3) a dry and dead atmosphere without an ocean and with only volcanic outgassing (see Table 11). We showed the simulated atmospheric composition and spectral appearance of TRAPPIST-1 e with 0.1 bar CO$_2$ using three different SEDs as input for the climate–chemistry model. To our knowledge ours is the first study that uses an SED of TRAPPIST-1 that was constructed based on measurements in the UV (Wilson et al. 2020).

Starting from an N$_2$-dominated atmosphere, we increased the surface partial pressures of CO$_2$ from $10^{-3}$ bar for TRAPPIST-1 e up to 10.8 bar for TRAPPIST-1 f. The main results regarding the composition of the simulated atmospheres are listed below.

1. The alive runs with Earth-like biogenic flux accumulate about 50% more O$_3$ as on modern Earth owing to Earth’s weaker UV environment and hence weaker O$_2$ sinks.
2. For dry CO$_2$-rich atmospheres, the abiotic production of O$_2$ and O$_3$ is significant (see also Selsis et al. 2002; Segura et al. 2007; Harman et al. 2015; Meadows 2017), as expected owing to the low FUV/NUV ratio of TRAPPIST-1 (Tian et al. 2014). However, the abundances of abiotic O$_2$ and O$_3$ are one order of magnitude lower than those runs with biogenic emissions. In contrast, the wet and dead scenario without biogenic emissions shows little abiotic O$_2$ and O$_3$ owing to effective O$_2$ uptake by the ocean.
3. CO can be an indirect marker of an ocean, being 100 times larger on an ocean-less world with a CO$_2$-rich atmosphere (see also Zahnle et al. 2008; Gao et al. 2015; Nava-Sedeño et al. 2016; Wang et al. 2016; Meadows 2017; Schwieterman et al. 2019; Hu et al. 2020).
4. For dry scenarios the mixing ratio of O$_2$ and O$_3$ can differ by over two orders of magnitude depending on the choice of the SED. For the wet scenarios the concentrations of O$_3$ in the middle atmosphere depend on the choice of the SED by a factor of ~5.
5. For dry scenarios the outgassed SO$_2$ leads to larger atmospheric concentrations than for the wet cases that include wet deposition.

We used the simulated atmospheric composition to calculate cloud-free transmission spectra of TRAPPIST-1 e for all three scenarios. Important spectral features found for the individual scenarios are listed in Table 16.

We used the transmission spectra and the TRAPPIST-1 SED from Wilson et al. (2020) to calculate the number of transits required to detect molecular features of TRAPPIST-1 e and TRAPPIST-1 f. The results are listed below.

1. The detection of CO$_2$ at 4.3 μm with JWST NIRSpec PRISM requires ~10 transits assuming cloud-free conditions (similar to findings by Morley et al. 2017; Batalha et al. 2018; Krissansen-Totton et al. 2018a; Fauchez et al. 2019; Lustig-Yaeger et al. 2019; Wunderlich et al. 2019). With the cross-correlation technique using ELT HIRES
Important Molecular Absorption Features and Corresponding Wavelength in $\mu$m of the Simulated Transmission Spectra of TRAPPIST-1 e for All Three Scenarios and with CO$_2$-poor (10$^{-3}$, 0.01 bar) and CO$_2$-rich (0.1, 1 bar) Atmospheres

| Scenario          | CO$_2$-poor (10$^{-3}$, 0.01 bar) | CO$_2$-rich (0.1, 1 bar) |
|-------------------|---------------------------------|-------------------------|
| Wet and alive     |                                  |                         |
| O$_3$ (9.6)       |                                | O$_3$ (9.6)              |
| NO$_2$ (below 0.7, 3.45, 6.2) |                         |                         |
| HNO$_3$ (5.85)    |                         |                         |
| N$_2$O (8.5)      |                         |                         |
| Wet and dead      |                                  |                         |
| CH$_4$            |                                | CH$_4$ (2.3, 3.3, 7.7)  |
| NO$_2$ (below 0.7, 3.45, 6.2) |                         |                         |
| N$_2$O (8.5)      |                         |                         |
| Dry and dead      |                                  |                         |
| CO (2.35, 4.6)    |                                | CO (2.35, 4.6)          |
| SO$_2$ (7.35, 8.7)|                         | SO$_2$ (7.35, 8.7)      |

the CO$_2$ feature around 2.0 $\mu$m might be detectable by co-adding ~30 transits. CO$_2$ will be easier to detect for the dry and dead scenario owing to weak absorption of H$_2$O and CH$_4$.

2. For the wet and alive runs CH$_4$ might be detectable with ELT HIRES for the simulated cloud-free atmospheres of TRAPPIST-1 e with a surface temperature below 330 K. CH$_4$ is not detectable for any simulated case without biomass flux.

3. O$_3$ is not detectable for the simulated atmospheres of TRAPPIST-1 e or TRAPPIST-1 f using the cross-correlation technique with ELT HIRES (see also Rodler & López-Morales 2014; Serindag & Snellern 2019).

4. SO$_2$ indicates that a planet might not host significant surface liquid water. However, SO$_2$ is not detectable for any of the dry runs of TRAPPIST-1 e and TRAPPIST-1 f with JWST or ELT.

5. CO at 2.35 $\mu$m might be detectable with JWST NIRSpec G235M for dry scenarios with weak surface deposition of CO and a CO$_2$ partial pressure above 0.01 bar. The detection of CO requires about 60 transits with JWST NIRSpec PRISM and about 40 transits with ELT HIRES. The CO feature at 4.6 $\mu$m would be detectable with JWST but partially overlaps with CO$_2$ absorption. Accurate retrieval may be able to disentangle CO and CO$_2$ with JWST.

We conclude that the three scenarios considered for TRAPPIST-1 e might be distinguishable for cloud-free conditions by combining ~30 transit observations with JWST NIRSpec and ELT HIRES in the K band (2.0–2.4 $\mu$m), if the CO$_2$ partial pressures on top of a 1 bar N$_2$-dominated atmosphere are above 0.01 bar and below 1 bar. The alive scenario, assuming Earth-like emission of CH$_4$, could be identified by the detection of CH$_4$. The nondetection of CO suggests the existence of a surface ocean. In turn, the detection of CO suggests dry surface conditions. A detection of CO$_2$ and a nondetection of CO and CH$_4$ suggest that liquid water on the surface reduces the amount of CO in the atmosphere and that biogenic emissions of CH$_4$ are weak.

This research was supported by DFG projects RA-714/7-1, GO 2610/1-1, SCHR 1125/3-1, and RA 714/9-1. We acknowledge the support of the DFG priority program SPP 1992 “Exploring the Diversity of Extrasolar Planets (GO 2610/2-1).” M.-P. acknowledges financial support from the State Agency for Research of the Spanish MCIU through project ESP2017-87143-R, the “Center of Excellence Severo Ochoa” award to the IAA-CSIC (SEV-2017-0709), and EC FEDER funds. P.C.S. gratefully acknowledges support by the German Aerospace Center under DLR 50 OR 1901. We thank Michaël Gillon for providing the SPECULOOS target list, Franklin Mills for sending cross-section data of several sulfur species, and Vladimir Krasnopolsky for providing chemical profiles of Mars. The SED used in this study is based on observations made with the NASA/ESA Hubble Space Telescope, obtained from the Data Archive at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. These observations are associated with program No. 15071. Support for program No. 15071 was provided by NASA through a grant from the Space Telescope Science Institute. We thank the anonymous referee for the helpful and constructive comments.
